The objective of this study was to evaluate and compare the effects of live yeast (ADY) and inactivated yeast (IDY) on ruminal physicochemical parameters in dairy cows subject to a high-carbohydrate (HC) challenge. The trial was conducted from September to December 2023 at Schothorst Research Center (The Netherlands) using a 3×3 Latin square design involving 3 dairy cows with cannulated rumen, 3 treatments (Ctrl, ADY, IDY), and 3 consecutive 28-day periods (including 4 phases adaptation, transition, HC challenge and post challenge). The challenge was to raise the diet's starch content from 16.4% to 26.3% of dry matter within 2 days. Ruminal conditions were continuously monitored using measurement system (DASCOR), recording pH and redox potential (Eh) every minute (1 440 datapoints/day). Data of pH and Eh were analyzed using linear mixed models (REML) with treatment and day as fixed factors, cow as a random factor, and hour as a repeated measure. Post hoc comparisons were performed with Tukey's test ($p < 0.05$). Results showed that the increase of rapidly fermentable carbohydrates significantly altered rumen pH and Eh during challenge phase. Yeast supplementations limited the drop in ruminal pH compared with the control group during the last day of challenge phase (Ctrl: 5.86_a; ADY: 5.97_c; IDY: 5.91_b, $p<0.05$). Regarding redox potential, the HC challenge increased Eh by +8.1 mV in control cows during the last day. This result indicating a shift toward a less reductive rumen environment, while IDY mitigated significantly these fluctuations (Ctrl: -292_b mV; ADY: -291_b mV; IDY: -295_a mV, $p<0.05$). In conclusion, inactivated yeasts helped stabilize ruminal environment during a HC challenge. These effects were particularly pronounced in the hours following feeding, suggesting improved resilience of rumen function under high-carbohydrate challenge.

Live yeast supplementation modulates recovery of rumen function and performance following subclinical ruminal acidosis in dairy cows

M. Terré[1], A. M. Hanzek[2], M. Gindri[2], E. Chevaux[2], C. Villot[2]
[1] IRTA, Ruminant Production, Torre Marimon, 08140 Caldes de Montbui, Spain, [2] Lallemand SAS, rue Briquettiers, 31702 Blagnac, France

Although the impacts of subclinical ruminal acidosis on rumen function and animal performance are well studied, the temporal dynamics of recovery after a challenge and the potential for nutritional strategies to accelerate restoration remain insufficiently characterized. In this study, thirty Holstein lactating dairy cows (≥45 DIM) without any supplement (CTRL) or supplemented with Saccharomyces cerevisiae CNCM I-1077 (LSC) were challenged with a high-starch diet (15.6% CP, 31.0% starch) for 4 weeks. Their recovery trajectories on a conventional diet (15.6% CP, 24.6% starch) were evaluated during the following 4 weeks. Reticulo-rumen parameters and feeding behaviour were continuously monitored using sensors and automated feeding systems, combined with daily milk recordings. A ruminal disorder index (RDi; a validated composite indicator integrating multiple reticulo-rumen pH metrics) was used to reflect ruminal pH disturbances. Recovery dynamics were analysed using mixed-effects models including treatment (CTRL and LSC), days from challenge (linear and quadratic terms), and their interactions. Results showed that RDi, rumination time, and activity exhibited a more dynamic and faster recovery pattern in LSC compared with CTRL cows, characterized by earlier stabilization of ruminal conditions by live yeast. Specifically, LSC cows showed a faster quadratic recovery in RDi following challenge, meaning the reduction rate decreases over time. In contrast, CTRL group followed the opposite pattern with a slower recovery and an increasing reduction rate as days progressed (trt×day: $P<0.05$; trt×day^2: $P<0.05$). Rumination time in LSC cows was associated with a stronger positive day effect combined with more pronounced deceleration ($P<0.05$), whereas CTRL animals recovered more gradually with only mild curvature. Activity displayed a sharper initial decline in LSC cows with stronger negative day effect, followed by a pronounced positive quadratic component ($P<0.05$) in both groups of animals, consistent with the patterns observed for rumination. Although variables related to feeding behaviour and milk composition were impacted during the recovery phase, they did not exhibit biologically strong treatment-specific temporal changes except for total meal duration. Meal duration in CTRL cows showed a steeper initial rise and stronger deceleration and a more negative quadratic term ($P<0.05$), indicating a sharper early increase in CTRL that slowed more quickly compared with the smoother pattern in LSC. Overall, live yeast supplementation significantly modified recovery trajectories of key rumen and behavioural indicators based on reticulo-rumen sensors. These findings highlight the importance of modelling temporal responses when evaluating nutritional strategies and indicate that S. cerevisiae CNCM I-1077 may accelerate functional recovery following subclinical ruminal acidosis.

Synergistic Co-fermentation of Palm Kernel Cake Enhances Nutrient Digestibility and Modulates Rumen Microbiota in Beef Cattle

H. Mi[1], Z. Wang[1], C. Zhou[2], D. Xiao[1]
[1] Hunan Agricultural University, No. 1, Nongda Road, 410128 Changsha, China, [2] Institute of Subtropical Agriculture, Chinese Academy of Sciences, No. 644, Yueda 2nd Road, 410125 Changsha, China

This study posits that co-fermenting palm kernel cake (PKC) may enhance its nutritional value, and that the partial substitution of conventional feed with this fermented product could improve nutrient digestion in beef cattle by positively influencing the rumen microbiota. To test this, PKC was subjected to a synergistic co-fermentation process employing Aspergillus niger and mannanase. Thirty beef cattle were randomly assigned to two groups (n=15): a control group (CON) receiving a standard basal diet, and a treatment group (FP) where fermented PKC (FPKC) partially replaced soybean meal and corn. Throughout a 90-day feeding trial, body weight, rumen fluid, and fecal samples were collected on days 30, 60, and 90 to evaluate growth performance, rumen fermentation parameters, and nutrient digestibility. Furthermore, rumen fluid samples collected on day 90 underwent 16S rRNA gene sequencing to analyze the microbial community structure. The results indicated that the synergistic co-fermentation involving fungi and enzymes effectively enhanced the nutritional profile of PKC, indicated by a significant reduction in mannan and acid detergent fiber (ADF) contents, coupled with a notable increase in crude protein (CP) content ($P < 0.05$). In a feeding trial, no significant differences in growth performance were observed between the FP and CON groups ($P > 0.05$). However, after 90 days, the FP group showed significantly better digestibility of dry matter (DM), CP, and neutral detergent fiber (NDF) compared to the CON group ($P < 0.05$). Rumen fermentation analysis revealed that the FP group had lower levels of butyrate and NH_3-N compared to the CON group ($P < 0.05$). Microbial 16S rRNA sequencing revealed a significant alteration in the rumen microbiota composition. The FP group exhibited a higher relative abundance of Bacteroidetes, while the CON group was predominantly composed of Firmicutes. The Rikenellaceae RC9 gut group, a genus renowned for its ability to degrade complex structural carbohydrates and enhance fiber fermentation efficiency, emerged as a key marker for the FP group. In contrast, the CON group was characterized by a predominance of Ruminococcus, Christensenellaceae R-7 group, and Butyrivibrio. Collectively, these findings demonstrate that the synergistic co-fermentation process efficiently degrades complex antinutritional carbohydrates such as mannan while simultaneously enhancing the protein content of PKC. Administering FPKC to beef cattle enhanced nutrient digestibility and positively altered the rumen microbiome to support fiber-degrading bacteria. This highlights the potential of fermented palm kernel cake as an effective feed ingredient for improving rumen health and nutrient use in beef cattle.

Exploratory investigation of maternal care and early postnatal calf behavior related to milk intake in a dam-bound rearing system in the first 24 hours after birth

J. Kurek[1], A. Neuser[1], T. Nutto[1], A. Kurek[1], J. Steinhoff-Wagner[1,2]
[1] Professorship of Animal Nutrition and Metabolism, TUM School of Life Sciences, Liesel-Beckmann-Str. 2, 85354 Freising-Weihenstephan, Germany, [2] HEF World Agricultural Systems Center, TUM School of Life Sciences, Liesel-Beckmann-Str. 2, 85354 Freising-Weihenstephan, Germany

Maternal behavior, including intensive licking and encouraging the calf to suckle immediately after birth, might be essential for activating the newborn's physiological processes and aiding thermoregulation by reducing potential evaporative heat loss. Although suckling at the udder within the first 24 hours is a critical component of neonatal development in cow-bound rearing systems, this behavior and influencing factors remains insufficiently described in detail. The aim of this exploratory study was to quantify key maternal and calf behavioral patterns occurring after birth, with a particular focus on behaviors associated with early colostrum intake. In addition, the study aimed to evaluate how maternal behavior, cow- and calf-related factors, and environmental conditions influenced the calf's colostrum intake during the first 24 hours of life. The study was conducted at the Veitshof research farm of the Technical University of Munich using data from cows (n = 13) and their calves during the first 24 hours after birth. Cow-related data included parity, gestation length, calving duration, and udder morphology, the latter assessed according to breed value estimation scores for Brown Swiss cows. In addition, maternal behavior was video recorded and evaluated, including the duration and intensity of licking as well as the location of licking events on the calf's body, which was divided into five anatomical regions. Calf-related measurements comprised body weight, body temperature at birth and after 24 hours, and a detailed description of behavioral aspects such as activity, inactivity, udder-searching duration (reflected the time from birth until the calf successfully located the udder), drinking duration (colostrum intake time), and drinking frequency. Furthermore, climate conditions were recorded, and the temperature-humidity index was calculated. Statistical analyses included descriptive statistics and Spearman rank correlations. The results showed that cows licked the calves on 122 ± 11 (mean ± SE) events with a total duration of 122.28 ± 9.24 minutes in the first 24 hours after birth. Ten out of 13 calves suckled colostrum from the udder within the first 6 hours postpartum, with an average drinking duration of 6.43 ± 1.87 minutes in this period. Three calves required human assistance (teat finding) to obtain colostrum from the udder. Over the first 24 hours, calves spent on average 30.36 ± 7.32 minutes searching for the udder and 40.12 ± 4.98 minutes drinking. The mean number of drinking events during the first 24 hours was 19 ± 3. Correlation analysis indicated that calves spending more time searching for the udder were generally more active ($r = 0.52$, $p \leq 0.05$) and experienced a higher number of maternal licking events ($r = 0.36$, $p \leq 0.05$). Udder height over ground showed a weaker association with udder-search duration ($r = 0.24$, $p \leq 0.05$). Total drinking duration was positively linked to calf activity ($r = 0.37$, $p \leq 0.05$), while higher parity of the dam ($r = –0.29$, $p \leq 0.05$) and longer teats ($r = –0.23$, $p \leq 0.05$) were associated with reduced drinking duration. Overall, the findings highlight the importance of integrated management strategies such as continuous observation to support successful colostrum intake in cow–bound rearing systems.

The effect of 3-sialyllactose in combination with Bacteroides thetaiotaomicron isolated from Ningxiang pigs on the intestinal development of piglets

B. Tan[1,2], L. Zhang[1,2], J. Wang[1,2]
[1] Hunan Agricultural University, No.1 Nongda Road, Furong District, 410128 Changsha, China, [2] Yuelushan Laboratory, No. 246 Hongqi Road, Donghu Sub-district, 410128 Changsha, China

Intestinal development is a core process in the rapid growth of piglets, and optimizing gut microbiota homeostasis during the early-life window is critical for improving growth performance. Milk oligosaccharides are key bioactive components in maternal milk, playing important roles in promoting probiotic colonization, maintaining microbial balance, and regulating host immunity. Our previous results revealed significant differences in milk oligosaccharide profiles and gut microbiota structures between Chinese indigenous Ningxiang (NX) and Large White sows. A high SL content in NX colostrum was significantly positively correlated with the abundance of Bacteroides thetaiotaomicron (BT) in piglets. The BT2 strain isolated from Ningxiang pigs efficiently metabolized sialyllactose (SL), particularly 3-SL, through GH enzymes, producing sialic acid and SCFAs. Therefore, this study further explored the effects of this key bacterial strains utilizing specific oligosaccharides (3-SL) on piglets intestinal development and function. Six litters of cross-bred (Duroc × Landrace× Yorkshire) piglets with similar genetics and parity were selected. For each litter, three healthy newborn piglets with similar body weight were orally administered saline, 3-SL, or 3-SL+BT2 from day 1 until weaning at day 21, followed by sampling on day 24. The results showed that, compared to the control group: (1) The 3-SL and 3-SL+BT2 groups had significantly reduced diarrhea rates ($P < 0.05$). (2) Villus height (VH) and villus height to crypt depth ratio (V/C) in the small intestine were significantly increased, while crypt depth (CD) in the small intestine was significantly decreased, and CD in the colon was significantly increased in both 3-SL and 3-SL+BT2 groups ($P < 0.05$). (3) Serum D-lactic acid (D-LA) levels were significantly reduced in the 3-SL and 3-SL+BT2 groups ($P < 0.05$). Intestinal development- and barrier-related gene and protein expression in the ileum and colon were significantly up-regulated, and the levels of sialic acid, acetate, propionate, and total short-chain fatty acids (SCFAs) in the colonic contents were significantly elevated ($P < 0.05$). (4) In the 3-SL+BT2 group, butyrate and valerate levels in the colonic contents were significantly increased compared to the control group($P < 0.05$). Compared to the 3-SL group: (1) The diarrhea rate was even lower in the 3-SL+BT2 group. (2) Crypt depth in the duodenum was significantly lower, V/C was significantly higher, and the number of AB-PAS-positive cells was significantly increased with more intense staining in the 3-SL+BT2 group ($P < 0.05$). (3) The contents of sIgA were significantly increased, and the expression of gut development and barrier-related genes or proteins such as β-catenin, TGF-β, IGF1, Lgr5, and ZO-1 was significantly up-regulated ($P < 0.05$). The results indicate that the combination of 3-SL and BT2 effectively promotes intestinal development and barrier function in piglets, thereby improving gut health. These findings provide a theoretical basis for the development and application of synbiotics and offer a reference for nutritional interventions aimed at improving piglet intestinal health.

Investigating the optimal histidine to lysine ratio in piglets: impact on performance, blood parameters and carnosine content in the skeletal muscle

D. Siebert[1], K. Schuh-Von Graevenitz[2], G. Dusel[2]
[1] CJ Europe GmbH, Unterschweinstiege 2-14, 60549 Frankfurt am Main, Germany, [2] Technische Hochschule Bingen, Fachbereich Agrarwirtschaft, Berlinstraße 109, 55411 Bingen, Germany

Histidine (His) is an essential amino acid in pigs; therefore, an inadequate supply of His may impair growth performance. However, research on His requirement of pigs is scarce. In addition to being involved in protein synthesis, His has broad functions and is incorporated into specific body proteins, which may should be considered when estimating its requirement. Histidine is an important component of haemoglobin (Hb), and His deficiency may influence Hb synthesis. Furthermore, His can be metabolized together with ß-alanine to form the dipeptide carnosine, which is an important antioxidant. The aim of this study was to determine the optimal standardized ileal digestible (SID) His-to-Lys ratio in nursery piglets for growth, carnosine concentration in muscle, and selected blood parameters. 192 piglets (Topigs TN70; starting weight: 7.2 kg) were placed in 8 pens/treatment (4 pigs/pen; 50/50 castrated/female piglets). A diet based on cereals and soybean meal was formulated to be deficient in His. Supplementary L-His was used to achieve six graded levels of SID His-to-Lys ratios (0.20, 0.24, 0.27, 0.31, 0.35 and 0.38, respectively). Body weight (BW) and feed intake (FI) were measured at start and end of trial. Feed conversion ratio (FCR) was calculated. At the end of trial (day 41), 72 animals were euthanized and sampled to measure carnosine in the M. longissimus dorsi. Additionally, blood plasma was collected from 72 animals for the analysis of Urea-nitrogen (PUN) and the small blood count parameters (haematocrit, haemoglobin, leucocytes and thrombocytes, respectively). A one-way ANOVA with the fixed effects of treatment and sex was applied to the data. Starting BW was used as a covariate. Means were compared using Tukey test ($P<0.05$). A quadratic regression model was applied to determine SID His-to-Lys ratio needed to achieve maximum performance to be considered the recommended His-to-Lys ratio. The recommended SID His-to-Lys ratios (0.33, 0.34 and 0.34) were estimated for BW, FI and FCR. Haematocrit, Hb and PUN showed a quadratic response with a recommended SID His-to-Lys ratio of 0.32, 0.33 and 0.33, respectively. With a dietary SID His-to-Lys ratio of 0.20 and 0.24, the measured Hb values (9.8 g/dL and 10.1 g/dL, respectively) were below the laboratory reference range (10.8 g/dL to 14.8 g/dL). The lowest carnosine content (70.0 mg/100g of meat) was observed at SID His to Lys ratio of 0.20 and increased linearly to a maximum of 383.4 mg/100 g of meat at SID His to Lys of 0.38. The SID His-to-Lys ratio of 0.34 could be suggested for a maximum performance in piglets, with 0.34 being also recommended by NRC. The muscular carnosine concentration increased linearly with increasing dietary His without reaching a plateau. Animals fed with the two lowest SID His-to-Lys ratios (0.20 and 0.24) had the lowest Hb levels, which may indicate anaemia in the animals. Although it is well described that piglets may develop anaemia with a reduced Hb value due to iron deficiency, the finding that a dietary His deficiency can also lead to anaemia is new and requires further research.

Effects of dietary carob pulp as a source of non-starch polysaccharides on carcass traits and fatty acid composition in intensively reared Iberian crossbred pigs

J. Álvarez-Rodríguez[1], C. M. Muñoz-Sastre[1], J. Santana-Sánchez[2], M. Á. Latorre[1]
[1] University of Zaragoza-IA2, C/ Miguel Servet 177, 50013 Zaragoza, Spain, [2] La Cherneca SL, C/ Convento, 17, 06290 Usagre, Badajoz, Spain

A total of 60 Duroc x Iberian pigs (109±2.1 kg of body-weight, BW; 8.5 months of age), half surgically castrated males (SCM) and half immunocastrated females (ICF), were selected from six split-sex large pens (2 m2/pig). The aim of the study was to evaluate the impact of dietary carob pulp (CPULP) inclusion (0, 10 and 20%), as a source of non-starch polysaccharides (NSP), during the last 50 days of the finishing phase on growth, carcass quality and fat composition. Each pen received ad libitum one of the three experimental diets differing in CPULP level. The three diets were formulated to provide similar nutrients; 2,500 kcal net energy/kg, 110 g crude protein/kg and 5.2 g total Lysine/kg. However, increasing CPULP inclusion raised NSP content (211, 228 and 271 g/kg of feed, respectively). This was compensated with adding lard, thereby increasing per kg of feed the supply of saturated fatty acids (16, 21 and 26 g SFA/kg) and monounsaturated fatty acids (17, 23 and 30 g MUFA/kg) with minimal changes in polyunsaturated fatty acids (15, 15 and 16 g PUFA/kg). The BW was recorded the first day of the trial and the day before the slaughter to calculate average daily gain (ADG). Pigs were slaughtered in a commercial abattoir (30 km away) with a 20-h lairage period. Carcass weight (including head) was registered to calculate killing-out proportion. The weight of trimmed hams and shoulders was recorded 24 h post-mortem, and yields were expressed as a proportion of carcass weight. The loin pH (pH45) was measured 45 min post-mortem (last thoracic rib) and the subcutaneous lumbar fat thickness was also measured. Finally, fatty acid composition of subcutaneous fat was analyzed. The data were statistically analyzed with standard using least square means models with diet, sex and their interaction as fixed effects. Dietary CPULP inclusion did not affect (P>0.10), final BW (152.2, 151.7 and 152.4±2.8 kg), ADG (799, 801 and 760±26.6 g/day), carcass weight (120.9, 121.6, 122.3±2.3 kg), or killing-out proportion (79.5, 80.1 and 80.2±0.44%). However, pigs fed 0% and 10% CPULP showed thinner fat thickness than those fed 20% CPULP (5.3, 5.4 vs. 6.0±0.17 cm, P<0.01). The CPULP inclusion did not affect (P>0.10) ham yield (10.4, 10.3 and 10.2±0.23%) or shoulder yield (6.6, 6.3 and 6.6±0.14%). However, CPULP decreased pH45 (6.56 vs. 6.38 and 6.44±0.038, P<0.05). The contents in SFA (38.7, 37.8 and 38.1±0.31%) and MUFA (52.8, 53.0 and 52.8±0.30%) of fat did not differ among diets (P>0.10) but, unexpectedly, PUFA content increased with CPULP inclusion (8.4 vs. 9.2 and 9.1±0.12%, P<0.001). Sex did not affect ADG (765 vs. 808±21.8 g/day, for SCF and ICF; P>0.10). However, SCM were lighter at slaughter than ICF (147.6 vs. 156.6±2.3 kg; P<0.01), and it was also detected in carcass weight (117.6vs. 125.5±1.9 kg, P<0.01). However, killing-out proportion did not differ between sexes (79.7 vs. 80.1±0.36%, P>0.10) nor fat thickness (5.6 vs. 5.6±0.14 cm for SCM and ICF, P>0.10). Although sex did not influence ham yield (10.1 vs. 10.5±0.20%, in SCM and ICF, P>0.10), shoulder yield was greater in SCM than in ICF (6.7 vs. 6.3±0.12%, P<0.05). Loin pH45 was similar between sexes (6.44 and 6.48±0.031, in SCM and ICF, P>0.10) and fatty acid composition was likewise unaffected by sex. In conclusion, dietary inclusion of 20% CPULP increased carcass fatness and PUFA content without impairing growth rate in intensively Iberian crossbred pigs, regardless of sex. A moderate inclusion level of 10% CPULP increased PUFA content but had minimal effects on carcass fatness.

Integrating growth performance and tissue functional transcriptomics to elucidate the effects of a xylanase and β-glucanase combination in post-weaning pigs

P. Aymerich[1], E. Ball[2], L. F. Romero[3], D. E. Velayudhan[1], M. A. Ton Nu[1], R. Muns[2], Y. Dersjant-Li[1], E. Vinyeta[1]
[1] Danisco Animal Nutrition & Health (IFF), Willem Einthovenstraat 4, 2342 BH Oegstgeest, Netherlands, [2] Agri-Food & Biosciences Institute (AFBI), Large Park, BT26 6DR Hillsborough, United Kingdom, [3] Biofractal, Sitio Picota, 8100-317 Loule, Portugal

The aim of the study was to investigate the impact of xylanase and β-glucanase (XB) dietary supplementation on piglet performance and tissue specific functional transcriptomic responses when fed diets differing in NSP content. Our hypothesis was that supplementation with XB to diets fed during the first two weeks post-weaning improves piglet performance and metabolic efficiency, and attenuates the physiological challenge caused by high dietary NSP content. Eighty entire male weaned pigs across five batches ((LR × LW) × Duroc; 8.6 ± 0.42 kg BW; 28 days of age) were assigned to four dietary treatments in a 2 × 2 factorial arrangement with two NSP level (LNSP vs. HNSP) and with or without XB supplementation as main factors. Diets were formulated to be isoenergetic and balanced for digestible amino acids. The LNSP diet was a corn -soya based diet, whereas the HNSP diet included barley, wheat, wheat bran, and rapeseed meal (analyzed total NSP: 7.8 vs. 12.0%, respectively). Piglets were fed diets in mash form the first 14 days post-weaning. Body weight, feed intake, and feed conversion ratio (FCR) were individually recorded. On day 14 all pigs were euthanized and stomach, ileum, and liver tissues were collected for RNA extraction. The mRNA was sequenced (Illumina, 150 PE, poly-A enriched, 20M reads per sample) and gene abundance calculated using Kallisto. Differential gene expression (DGE) was tested among treatments (Deseq2), followed by a topology-based Quantitative Pathway Activation method (QPA, Biofractal, Portugal) using an adjP<0.05 threshold. High NSP increased FCR (+13%; $P < 0.05$). In contrast, XB supplementation increased average daily feed intake (+14%; $P < 0.05$) and average daily gain (+29%; $P < 0.01$) and tended to reduce FCR (-9%; $P < 0.1$), independent of NSP level ($P > 0.1$). Transcriptomic analysis revealed that NSP level was the primary driver of hepatic DGE changes, whereas XB supplementation on HNSP diets predominantly affected gastric and ileum responses. Pathway level analysis showed that increasing NSP induced adaptive responses in the stomach and ileum, characterized by more active tissue remodeling, barrier function, and immune sensing, and promoted coordinated nutrient metabolism activation in the liver. These responses indicate a developmental stimulus that increased physiological demand and a mechanistic link to the increased FCR observed in pigs fed HNSP diets without XB. Conversely, XB supplementation attenuated NSP-induced adaptive response in the stomach and ileum under HNSP conditions, reducing immune recognition and innate activation while preserving tissue integrity, and markedly inhibited hepatic cellular stress and inflammatory responses. Under LNSP conditions, XB promoted a metabolically efficient phenotype across all three tissues, activating digestive, absorptive, and antioxidant pathways in the ileum, supporting hepatic and gastric mucosal development, without inducing compensatory stress responses. Notably, BPIFA1 expression was downregulated in pigs fed LNSP diets supplemented with XB (Padj < 0.01), consistent with reduced epithelial stress and microbial signaling at the intestinal mucosa. These findings demonstrate that while dietary NSP primarily elicits compensatory physiological responses that may limit efficiency, XB supplementation improves feed intake and performance by promoting more efficient tissue specific functional states across both low and high NSP diets.

Effects of dietary γ-aminobutyric acid supplementation on growth performance and novel object test responses in nursery piglets

E. Huenul[1], J. F. Pérez[1], D. Saavedra[1], K. Rochina[1], S. M. Martin-Orúe[1]
[1] Universitat Autònoma de Barcelona, Animal Nutrition and Welfare Service (SNiBA), 08193 Barcelona, Spain

Weaning is a critical developmental stage in pigs, and implementing effective nutritional strategies during the nursery period can enhance growth performance in the subsequent fattening phase. Recent studies have explored the use of dietary supplementation γ-aminobutyric acid (GABA), an inhibitory neurotransmitter in the central nervous system, which may influence the GABAergic system and the gut–brain axis, reducing the adverse effects of stress and improving gastrointestinal function. This study aimed to investigate the effects of GABA supplementation on performance and behavioral responses to fear in weaned piglets, as assessed through a novel object test. A total of 128 piglets (Duroc x Landrace) at 28 d-old were allocated into 16 pens (8 pigs/pen) at the UAB experimental farm. At arrival, pens were assigned to a control diet (CTR; 6.9 ± 0.96 kg) or supplemented with 100 mg GABA /kg of feed (GABA; 6.9 ± 0.75 kg), balanced by weight between treatments. At days 21, 32 and 35 a back test was conducted to identify piglets' coping style as high resistance (HR) or low resistance (LR). Body weight (BW), average daily gain (ADG) and average daily feed intake (ADFI) per pen was measured weekly. At 47 d-old, a total of 20 piglets (10 HR and 10 LR), balanced across treatments, were individually subjected to a novel object test (NOT) in their familiar pen, including 1 minute of habituation followed by 3 min with the exposition to the novel object (NO). Latency to touch the NO, as well as the duration and frequency of contact with the NO, were measured. GABA-supplemented piglets tended to exhibit higher ADFI compared to CTR piglets during the first (136 vs. 113 g/day; P = 0.069) and third weeks (447 vs. 417 g/day; P = 0.076) post-weaning. ADG was higher in GABA group than CTR during the first week post-weaning (72 vs. 32 g/day; P = 0.041), with a tendency to a higher ADG in the second week (176 vs. 127 g/day; P = 0.079), and from 35 d-old onward, GABA-supplemented piglets had higher BW compared with CTR (Δ = 600g; P < 0.05). Regarding the NOT, no differences were observed in the interaction between treatment and coping style, and no difference were observed in the habituation phase. GABA-supplemented piglets touched the novel object more quickly (23.6 vs. 140.4 s; P < 0.001), more frequently (9.9 vs. 5.8 n; P = 0.007), and for longer durations (31.7 vs. 13.5 s; P = 0.025) than the CTR group. HR-piglets showed a higher time touching the NO (32.2 vs. 12.9 s; P = 0.022) than the LR-piglets. The potential of GABA to reduce stress and enhance intestinal health could be observed in piglets, as it may have enabled them to better cope with weaning stress and, consequently, prevent the marked reduction in feed intake and performance observed in CTR pigs. Moreover, the stress- and anxiety-reducing potential of GABA is reflected more clearly in the results of the NOT, were pigs reacted with less fear to the NOT as reflected by their faster contact to the NO and the longer time spent interacting with it. However, the treatment did not appear to alter the inherent responses associated with each pig's coping style. In conclusion, GABA supplementation enhanced performance during the early post-weaning period and reduced fear responses in the NOT, without altering inherent coping styles, suggesting improved emotional state and welfare in nursery pigs.

Magnesium-protected zinc as an alternative to zinc oxide on growth of weaned piglets

R. Aureli[1], Z. Garlatti[2], E. Bacou[2], J. Le Cour Grandmaison[2]
[1] dsm-firmenich, 1 bd d'Alsace, 68128 Village-Neuf, France, [2] Terresis Agriculture, 27 av Franklin Roosevelt, 35400 Saint-Malo, France

Zinc is an essential trace element in piglet nutrition, playing a key role in growth, immune function, gut and overall health. However, the amount of zinc naturally present in standard feed is insufficient to meet the animals' requirements, making supplementation critical, particularly during the post-weaning period when piglets are most vulnerable. Conventional zinc sources, such as zinc oxide (ZnO), are widely used but can have limited bioavailability, which may reduce their effectiveness in supporting optimal growth and health. This limitation has driven the design of innovative zinc sources, including magnesium-protected zinc. By enhancing zinc bioavailability and absorption thanks to a patented magnesian protection, this novel source helps ensure that piglets receive the levels needed to support their development, ultimately leading to better zootechnical performance and supported gut health. A 42 day study was carried out to evaluate the growth performance of post-weaning piglets in a controlled feeding trial. Twenty-four castrated male piglets, weaned at 28 days of age (initial body weight 4.7 ± 0.45 kg), were randomly allocated to two experimental treatments, with four pens of three animals per treatment. The trial consisted of a 14-day starter phase followed by a 28-day grower phase. Two diets were formulated to provide a total zinc level of 150 mg/kg feed, differing only in the zinc source: conventional 125 ppm zinc from zinc oxide (CON) or 125 ppm zinc from magnesium-protected zinc (CAPMAG® Zn; CAP). Diets were based on wheat, barley, and soybean meal and were distributed as crumble during the starter phase and as pellets during the grower phase, with ad libitum access. Body weight, average daily weight gain (ADG), average daily feed intake (ADFI), and feed conversion ratio (FCR) were recorded to evaluate growth performance. Data were analyzed using a linear model (R software) using weaning weight as a co-variable and with the pen as the unit. This analyze was followed by Tukey test. During the starter phase, ADG for the CAP group was 144 g/day compared with 125 g/day for CON (+15.3%; $P>0.05$). ADFI was also higher but non-significant in CAP (226 vs. 179 g/day; +26.1%; $P>0.05$), leading to a non-significant increase in FCR (1.651 vs. 1.441; $P>0.05$). In the grower phase (D14–42), ADG was significantly improved by +24.3% for CAP compared to CON (389 vs. 313 g/day; $P<0.05$). Feed intake tended to be higher (645 vs. 559 g/day; +15.3%; $P>0.05$) and FCR showed numerical reduction for CAP versus CON (1.658 vs. 1.568; $P>0.05$). Over the entire post-weaning period, CAP piglets showed a significant higher ADG by +22.8% compared to CON (307 vs. 250 g/day; $P<0.05$) and an improved final body weight by +2.34 kg (17.62 vs. 15.27 kg; +15.4%; $P>0.05$). ADFI was slightly increased (505 vs. 433 g/day; +16.8%; $P>0.05$), and overall FCR improved numerically (1.645 vs. 1.727; −4.8%; $P>0.05$). These results demonstrate that magnesium-protected zinc enhances growth performance and feed efficiency under challenging post-weaning conditions, even with few replicates and animals per pen. The most pronounced effects occurred during the grower phase and over the whole post-weaning period, highlighting the improved bioavailability of this novel form of zinc. Further studies are needed to clarify its mode of action. In conclusion, supplementing post-weaning piglets with magnesium-protected zinc improves growth compared with conventional ZnO at the same inclusion level, offering a practical approach to optimize zinc nutrition during this critical period.

Microalgal Chlorella sorokiniana as a functional feed ingredient improves post-weaning piglet performance

S. K. Kar[1], A. Van Enckevort[2], E. Houtzager[3], S. J. Koopmans[1]
[1] Wageningen Livestock research, Animal Nutrition, De Elst 1, 6708 WD Wageningen, Netherlands, [2] Denkavit Nederland BV, Tolnegenweg 65, 3781 PV Voorthuizen, Netherlands, [3] Phycom, Koningsschot 11, 3905 PP Veenendaal, Netherlands

The post-weaning phase in swine production is marked by pronounced metabolic and immunological challenges that can impair growth and increase vulnerability to enteric disturbances. This study combined cellular bioactivity screening with controlled in vivo trials to assess the potential of Chlorella microalgae as a functional dietary component to support piglet performance during this critical period. In vitro characterization was performed using receptor-activity profiling in HEK293 cells and transcriptomic analysis in IPEC-J2 porcine intestinal epithelial cells to compare Chlorella sorokiniana and Chlorella vulgaris. Across both platforms, C. sorokiniana exhibited a stronger and broader bioactive profile than C. vulgaris. The carbohydrate-enriched "rest fraction" of C. sorokiniana particularly modulated pathways associated with innate immunity, antiviral defense, and metabolic regulation, including mTOR-related signaling. Based on these results, two in vivo trials were conducted to determine the optimal inclusion level and processing method for C. sorokiniana in weaned piglets. In the first phase (day 1–8 post-weaning), dietary inclusion of 0.8% drum-dried C. sorokiniana significantly improved growth performance compared to the control group. Specifically, piglets receiving 0.8% microalgae achieved a higher body weight at day 8 ($P < 0.05$) and an increased average daily gain (ADG) during the first week ($P < 0.05$). Feed efficiency was also significantly enhanced ($P < 0.05$) in the 0.8% inclusion group. Further investigations into processing methods showed that while mechanical cell wall rupture (bead-milling) resulted in a numerical improvement in feed conversion ratio (FCR) compared to intact cells, the difference did not reach statistical significance ($P > 0.05$). Increasing the inclusion level from 0.8% to 1.6% did not yield further significant improvements in ADG or FCR ($P > 0.05$), indicating a plateau in biological response at the 0.8% level. Regarding intestinal health, no significant differences were observed in faecal consistency scores between the control and algae-supplemented groups throughout the study ($P > 0.05$). Additionally, the performance benefits observed in the first week did not persist into the late rearing phase (day 14–35), where growth parameters were statistically similar across all treatments ($P > 0.05$). In conclusion, C. sorokiniana is a bioactive functional ingredient that effectively mitigates the immediate post-weaning performance dip. The study demonstrates that a dietary inclusion of 0.8% drum-dried C. sorokiniana significantly boosts growth and feed efficiency during the first week post-weaning, supported by strong in vitro evidence of immune-metabolic pathway activation. These findings suggest that microalgae supplementation is most effective when targeted at the critical transition window immediately following weaning.

Tiny but mighty: small dose of standardized dry grape extract potentiates antioxidant defenses in broiler chickens

P. Engler[1], D. Bień[2], S. Cissé[1], M. E. A. Benarbia[1], S. Jaworski[2], A. Lange[2], P. Ciborowska[3], A. Zalewska[3], J. Urban[3], M. Michalczuk[3], A. Matuszewski[2,3]

[1] Nor-Feed, 3 Rue Amedeo Avogadro, 49070 Beaucouzé, France, [2] Warsaw University of Life Sciences, Institute of Animal Sciences, Ciszewskiego 8, 02-786 Warsaw, Poland, [3] Warsaw University of Life Sciences, Institute of Biology, Ciszewskiego 8, 02-786 Warsaw, Poland

Antioxidant defenses are crucial for livestock resilience against many stressors. Over the last few decades, a strong emphasis has been put on potential complementary antioxidant from natural sources. They are however often studied in vitro, or at high concentrations. Thus, the aim of the present study was to evaluate the effect of a dietary supplementation of broiler chickens with a commercial standardized dry grape extract (NG) on zootechnical performances and physiological antioxidant parameters. 756 day-old all-male Ross 308 broiler chickens were randomly divided into two groups and raised for 35 days. Control birds (CTL, n=392) received a classic feeding program. The rest of the chickens (NG, n=364) were fed the same dietary program with the addition of 30ppm of NG (Nor-Grape®, Nor-Feed, France) from D1 to D35. Body weight, feed intake and FCR were measured for each replicate per period. Blood samples were collected on 30 chickens per group on D11 and D35 to measure global antioxidant protection (TEAC) and oxidative damages (MDA). Endogenous antioxidant levels were also monitored to assess the potential modulatory effect of the supplementation on CAT, SOD and GSH-Px. On D35, mean liveweight of NG chickens was greater than the CON (+3.1%, $p<0.001$). No differences ($p>0.05$) were found in terms of feed intake or mortality between groups, apart from a lower FCR in the finisher phase for NG broilers ($p<0.05$). On D11, antioxidant defenses were positively modulated by the supplementation as evidenced by a higher TEAC (+28.4%, $p<0.001$), CAT and SOD activities (+27.9% and +8.3% respectively $p<0.05$) compared to CTL birds. On D35, NG birds showed global and significant increase in all antioxidant defenses monitored (+3.3% TEAC, +15.9% CAT, +16.7% GSH-Px and +9.0% SOD, $p<0.01$) parallel to a significant reduction in oxidative damages (-14.9%, $p<0.05$). Overall, these results confirm previous findings showing that a dietary addition of 30ppm of NG potentiates the antioxidant defense system, improving the chickens' resilience. This translates into improved performances as illustrated in this work.

Protective antioxidant effects of a dietary polyphenol combination in broilers under heat stress

J. Estévez[1], P. Martín-Atance[1], S. Haldar[2], A. K. Dhara[2], S. Sihi[2], S. Sawant[1], S. Carné[1]
[1] Industrial Técnica Pecuaria, S.A. (ITPSA), Av. de Roma 157, 7th floor, 08011 Barcelona, Spain, [2] Agrivet Research & Advisory P Ltd, 714 Lake Town, Block A,, 700089 Kolkata, India

In livestock, heat stress impairs nutrient digestibility, growth, and muscle development, increasing maintenance energy requirements and reducing feed efficiency and performance while increasing meat quality defects. Citrus flavonoids and curcuminoids mitigate cellular oxidative stress mainly through the upregulation of endogenous antioxidant enzymes via Nrf2–Keap1, inhibition of ROS-producing enzymes, and direct radical scavenging. This study aimed to assess the antioxidant protective effects of a dietary combination of citrus flavonoids and curcuminoids in broiler chickens under heat stress, focusing on performance, oxidative status, carcass traits, and meat oxidative quality. A 42-day trial was conducted with 600 male Ross 308 AP95 broilers assigned to five dietary treatments (10 pens/treatment; 12 birds/pen): negative control (NC), positive control (PC; +100 IU/kg vitamin E), and the NC diet supplemented with a combination of citrus flavonoids and curcuminoids (TNP; HEBOX®) at 300, 600, or 900 mg/kg. Birds were reared in floor pens and exposed to heat stress from days 28 to 42 (mean temperature–humidity index >29). At day 42, growth performance, carcass traits, and oxidative status were evaluated by measuring malondialdehyde (MDA), paraoxonase-1 (PON1), and total antioxidant capacity (TAOC) in plasma, and malondialdehyde (MDA) in thigh meat, using 4 birds/pen (n=40). Results are expressed as mean ± SEM and analysed by one-way ANOVA by SAS. TNP supplementation tended to increase body weight ($P<0.05$ ANOVA trend test), by 3% at 900 mg/kg (2811±38 g) vs. NC (2728±55 g). Mortality, average daily feed intake and feed conversion ratio numerically improved with increasing TNP inclusion. TNP tended to increase yield (761.7±1.9 g/kg TNP900 vs. 755.5±2.7 g/kg NC) and breast relative weight (272.0±2.0 g/kg TNP900 vs. 269.1±2.5 g/kg NC) in a concentration-dependent manner ($P<0.05$ ANOVA trend test), and the relative weight of drumsticks were significantly increased in TNP600 ($P<0.05$; 90.0±0.6 g/kg) vs. NC (87.5±0.6 g/kg) and PC (87.4±0.6 g/kg). At 600 and 900 mg/kg, TNP decreased MDA in plasma by 14% ($P<0.05$; 10.20±0.34 nmol/mL and 10.31±0.41 nmol/mL, respectively) vs. NC (12.05±0.22 nmol/mL), with no effect of PC. TAOC of plasma increased by 8.7% ($P<0.05$) in TNP600 (0.841±0.023 mM) vs. NC (0.774±0.009 mM), and tended to be higher in TNP900, vs. NC and PC. PON1 showed the lowest level in NC (16.20±0.41 ng/mL) and raised significantly in PC (20.62±0.39 ng/mL) and with TNP, with the highest value at 300 mg/kg (24.63±0.55 ng/mL). PC did not reduce meat MDA (9.22±0.26 µg/g) vs. NC, whereas TNP at 600 mg/kg reduced MDA by a 10.5% and 15.7% vs. NC (9.59±0.39 µg/g) and TNP300 (10.18±0.41 µg/g), respectively ($P<0.05$). This study indicates that dietary supplementation with TNP enhances the capacity of broilers to cope with heat challenge by improving oxidative balance and associated metabolic responses. Improvements in plasma MDA, PON1, TAOC demonstrate the in vivo antioxidant effects of TNP under heat stress and its support of endogenous antioxidant defenses. This antioxidant protection improved meat oxidative stability, as evidenced by reduced MDA levels in thigh meat, performance, mortality, and carcass traits, suggesting a more efficient metabolic adaptation to thermal challenge. In conclusion, dietary combination of citrus flavonoids and curcuminoids represents an effective nutritional strategy to mitigate oxidative imbalance and support performance, carcass quality, and meat oxidative stability in broiler production systems exposed to heat stress.

From agricultural residue to high-value prebiotics: Upcycling sorghum lignocellulosic biomass into cello-oligosaccharides

N. Mahna[1], S. Kumar[1], A. K. Samanta[1], S. Arora[1]
[1] ICAR - National Dairy Research Institute, Animal Nutrition, Karnal, Haryana, 132001 Karnal, India

The development of functional feed ingredients that selectively modulate gut microbiota is central to next-generation animal nutrition strategies aimed at improving animal health and productivity. Cello-oligosaccharides (COS) are emerging prebiotics; however, sustainable production of structurally and functionally defined COS remains limited. This study developed structurally defined COS from sorghum crop residue and evaluated their prebiotic functionality. Sorghum crop residue was subjected to alkaline fractionation using sodium hydroxide (2.0–3.5 M) to obtain a cellulose-enriched substrate for enzymatic bioconversion in COS. Pretreatment with 2.0 M sodium hydroxide achieved the highest cellulose recovery (35.6% yield; 94.5% recovery). FTIR confirmed effective delignification and hemicellulose removal. Scanning electron microscopy (SEM) revealed substantial disruption of the compact lignocellulosic matrix and increased surface porosity following alkali treatment, facilitating enzyme accessibility. X-ray diffraction (XRD) analysis indicated enhanced cellulose crystallinity, with the crystallinity index increasing from 73.58% in untreated residue to 81.38% following 2.0 M NaOH treatment. Based on recovery efficiency, structural integrity and reduced chemical severity, 2.0 M NaOH was selected as the optimal pretreatment condition. The recovered cellulose was subsequently subjected to controlled enzymatic depolymerisation using Aspergillus niger cellulase to selectively produce COS. A central composite design was employed to assess the effects of pH (4.5–5.5), temperature (30–50 °C), enzyme loading (20–30 IU g^{-1}) and incubation time (8–24 h). Optimised reaction conditions (pH 4.5, 30 °C, 30 IU g^{-1} enzyme loading and 8 h incubation) resulted in the production of COS. HPLC analysis revealed 40.33% COS (DP2–DP5) and 29.28% glucose from 2% (w/v) cellulose. Notably, cellohexaose (DP6) was additionally detected, increasing the total COS fraction to 58.41 % with 30.76 % glucose. COS production followed a quadratic model, while glucose formation was primarily influenced by enzyme loading and incubation time. Prebiotic functionality was assessed based on selective microbial growth, using Ligilactobacillus salivarius RBL22 and Escherichia coli ATCC 25922. COS exhibited a higher prebiotic activity score (1.25) and prebiotic index (1.80) compared with standard inulin (PAS-1.13; PI 1.59) and native cellulose (PAS 0.52; PI 0.31), indicating superior selectivity towards beneficial bacteria. Overall, this study demonstrates that alkali-assisted structural modification of sorghum lignocellulose, validated through FTIR, XRD and SEM analyses, enables the production of functionally superior COS as a sustainable prebiotic in animal feed application.

EntoBoost: a multi-model screening platform to identify and study insect fractions with health-promoting effects in animal feeds

N. A. Sibinga[1], E. Fako[1,2], M. Kraft[2], J. Nerinckx[3], V. Vermeylen[3], J. De Smet[1], A. Declercq[3], N. Everaert[2]
[1] KU Leuven, Department of Microbial and Molecular Systems, Kleinhoefstraat 4, 2440 Geel, Belgium, [2] KU Leuven, Department of Biosystems, Kasteelpark Arenberg 30, 3001 Heverlee, Belgium, [3] Ghent University, Department of Animal Science and Aquatic Ecology, Coupure Links 653, 9000 Gent, Belgium

Inclusion of insect-derived ingredients in livestock diets has been associated with health benefits across diverse production systems. However, as with many other promising functional feed ingredients, these effects have proven difficult to reliably reproduce and the underlying mechanisms remain poorly understood. Screens for bioactivity in natural products typically measure antimicrobial and/or antioxidant activity but moving directly from these readouts to in vivo trials with production animals is risky and the success rate is low. To streamline the development of functional feed ingredients, there is a need for intermediate screening platforms that model additional biological complexity while remaining simple enough to evaluate multiple candidates. As part of the EntoBoost project, we aim to address this knowledge and methodology gap using complementary fractionation protocols and bioactivity assays designed to disentangle the effects of complex insect-derived feed ingredients through systematic evaluation of black soldier fly (BSF; Hermetia illucens) larval fractions. BSF larvae are processed via a combination of wet mode fractionation (press cake, pellet, aqueous fraction, cream, and lipid) and chemical purification (proteins, lipids, and chitin) to produce a library of potentially bioactive insect fractions. These fractions are then screened using complementary infection models: (1) for broilers: an in vitro ileal fermentation model challenged with NetB-producing Clostridium perfringens; (2) for pigs: an analogous model using enterotoxigenic Escherichia coli (ETEC); and (3) for shrimp: an in vivo Artemia franciscana model challenged with Vibrio spp. to assess pathogen inhibition and survival. The broiler model has been established and validated. Grower feed was subjected to in vitro digestion using a broiler-adapted INFOGEST protocol with gastric and intestinal phases at 41 °C. The resulting digest served as substrate for ileal fermentation, inoculated with contents from two-week-old broilers and spiked with C. perfringens strain CP56 at approximately 3 log CFU/mL. A qPCR assay targeting the netB toxin gene confirmed stable colonization throughout 24-hour fermentation. Infected fermentations exhibited elevated gas production and reduced acetate levels relative to non-infected controls, indicating measurable shifts in microbial metabolic activity under pathogen challenge. Acetate was the sole detectable short-chain fatty acid, consistent with the ileal origin of the inoculum. This validated platform now serves as the basis for systematic screening of BSF fractions for anti-infective activity. Screening of chitin-derived fractions is currently underway across all three platforms, and initial results from the broiler, pig, and Artemia models will be presented. The combination of systematic fractionation with species-specific infection models creates a pipeline to link specific bioactive components to measurable anti-infective outcomes. While developed here for insect-derived fractions, the screening platforms are applicable to other ingredient types. Fractions identified through these screens will subsequently be evaluated for host-modulating effects, building toward a mechanistic understanding of how bioactive feed ingredients interact with gut health.

Antioxidant Supplementation in Maternal Diet Modulates the Effects of Season on Swine Progeny

A. Magro[1,2], P. Vázquez[3], G. Gómez[4], J. García-Casco[3], F. Sánchez[5], C. López-Bote[2], C. Óvilo[3], M. Muñoz[3], A. Heras-Molina[2]
[1] UEM, C. Tajo, s/n, 28670 Villaviciosa de Odón, Spain, [2] UCM, Avda. Complutense s/n, 28040 Madrid, Spain, [3] INIA-CSIC, Ctra. de La Coruña, km 7,5, 28040 Madrid, Spain, [4] IRIAF, N-310, 19, 13700 Tomelloso, Spain, [5] SRC, Ctra. de San Juan del Puerto, s/n, 21290 Jabugo, Spain

The prenatal environment plays a vital role in shaping postnatal development. Maternal heat stress can impair foetal growth and result in intrauterine growth restriction (IUGR), particularly under production conditions that pose thermoregulatory challenges, such as the outdoor farming of Iberian pig sows. Dietary strategies aimed to alleviate the detrimental effects of heat stress (e.g. antioxidant supplementation) could benefit traditional outdoor Iberian pig rearing. This study intended to evaluate the effects on growth and the development of head and brain, as sign of IUGR, of two maternal antioxidant strategies and their interaction with gestational season. Two trials were carried out: one under thermoneutral conditions (TN; gestation from November to March) and other under heat stress conditions (HS, gestation from May to September). Seventy-two Iberian sows per season were allocated to three dietary groups (n = 24) from day 50 of gestation until weaning: a) C (control), 100 IU vit E/kg and inorganic sources of minerals (Mn, Zn, Cu, Se) according to FEDNA 2013; b) VE, supplemented with 200 IU vit E/kg; and c) OM, including 45%–100% organic trace minerals to enhance bioavailability. Piglets were weighted at 0, 15 and 21 days (d). At birth, piglets (n=699) were classified as small (S), medium (M) or large (L) according to birthweight (BiW). At 21 d, 108 male piglets (48 born under HS and 60 under TN, half S and half L in each season) were measured and weighted. Then, they were euthanised to obtain brain and head weights and measures. Data were analysed using a linear model including the diet, BiW and season and their interaction and a Tukey post hoc test performed in R 4.5.1. Significance was considered with $p < 0.05$. At birth there were no significant differences between diets nor seasons. However, at 15 and 21 d, piglets born under HS were lighter and smaller than those born under TN. At 21 d, a season*BiW interaction was observed: L and M piglets were heavier in winter than summer, but S piglets had the same weight regardless of season. At this age, OM piglets were heavier than C, whereas no differences were found between VE with OM or C. S piglets had heavier brains and heads and higher brain/body weight ratio than L offspring. Neurodevelopmental traits appeared more sensitive to maternal antioxidant supplementation under HS conditions. Thus, OM offspring born under HS showed heavier heads and brains than C or VE piglets, while no significant differences were observed in TN conditions. However, the brain-to-head weight ratio was higher in VE offspring under HS compared to TN conditions, with no season variations in C nor OM groups. Relative head size showed a diet×season interaction: it was larger in C and VE litters born under HS than TN conditions, whereas OM offspring showed similar values across seasons. Results show that effects on the progeny of the maternal antioxidant supplementation were modulated by external conditions. Under heat stress, OM diet was associated with improved body development, reducing signals of IUGR related to head and brain size. In conclusion, these findings highlight the importance of season-specific nutritional strategies to optimize offspring development in Iberian pig production systems This work was financially supported by PID2022-139367OB-C22 and PREP2022-000441 funded by MICIU/AEI/10.13039/501100011033 (FEDER/UE, FSE+).

Immunomodulatory effects of nucleotide-based formulations enriched with seaweed and olive bioactive compounds in mammals: evidence from an LPS-induced rat model

S. Segarra[2], J. Teichenne[1], R. Mariné-Casadó[1], A. Mas-Capdevila[1], J. M. Alcaide-Hidalgo[1], A. Antolín[1], D. Martínez-Puig[2], J. Velasco-Alvarez[2], A. Caimari[3]

[1] Eurecat, Technology Centre of Catalunya, Av. de la Universitat, 1, 43204 Reus, Spain, [2] R&D Bioiberica SAU, Av. dels Països Catalans, 34, 08950 Esplugues de Llobregat, Spain, [3] 3Centre Tecnològic de Catalunya, Av. de la Universitat, 1, 43204 Reus, Spain

Background and objective: Nutritional immunomodulation is a One Health-aligned strategy to enhance host resilience and reduce reliance on antimicrobials, thereby contributing to antimicrobial resistance mitigation. Bioactive compounds derived from seaweed, olive tree, and nucleotide-rich yeast extracts have demonstrated immunomodulatory properties and synergistic activity in previous invertebrate models, supporting their potential as feed-based immunomodulatory alternatives. This study aimed to evaluate these compounds in a preclinical lipopolysaccharide (LPS)-induced inflammatory/infectious-like rat model to assess their potential health benefits for livestock and companion animals. Methods: Fifty 8-week-old male Wistar rats were allocated to five groups (n = 10) and orally supplemented for 42 days with either nucleotides (NU; Nucleoforce® HF), nucleotide formulations enriched with seaweed meal (NUS; Nucleoforce® Immunity), or olive extract (NUO; Nucleoforce® Performance) at 107 mg/kg, or with vehicle alone (1 mL/kg condensed milk diluted 1:4 with water; positive and negative control groups). All products were supplied by Bioiberica SAU (Spain). Rats received an intraperitoneal challenge of 500 mg/kg LPS on day 36, followed by 300 mg/kg LPS daily from day 37 to day 42, except for the negative control group, which received saline injections from day 36 to day 42. Morphometric parameters, hematological profiles, gene expression in spleen and peripheral blood mononuclear cells (PBMCs), biochemical parameters in blood and small intestine, and histological analyses of ileum and colon were evaluated. Results: All supplemented groups demonstrated significant immunomodulatory effects by mitigating LPS-induced damage. The nucleotide-based formulations showed specific effects on the expression of genes associated with inflammation and Th1/Th17 immune responses in PBMCs (including Rorc, IL-10, Tnf, and Tbx21) as well as in spleen tissue (including Cd4, Cd14, Cd19, and S100a9). Furthermore, the NUS and NUO formulations significantly reduced circulating IL-10 levels and improved hematological parameters, including red blood cell count, hematocrit, and hemoglobin concentration. No significant effects on tissue histology were observed. Discussion & conclusion: The nucleotide-based formulations evaluated in this study demonstrated clear immunomodulatory potential and may represent effective nutritional tools to enhance health and performance in livestock and companion animals, particularly under conditions associated with anemia or immunosuppression. The previously described synergistic interactions among these bioactive compounds of diverse origin were reflected in the coordinated regulation of hematological, transcriptional, and inflammatory markers in the study herein. Overall, supplementation positively influenced immune balance across Th1, Th2, Th17, and Treg axes, as well as B cell-related signaling, together with hematological status and systemic resilience. These findings support the use of such formulations as sustainable nutritional strategies to reduce dependence on antimicrobials and growth promoters in different animal species.

Anti-inflammatory effect of Cyanidin-3-O-lathyroside from Eleutherococcus sessiliflorus in LPS-induced in vitro model

A. J. E. Cabuloy[1], C. H. Lee[1], M. S. Kim[1], S. H. Kim[1]
[1] Chonnam National University, Animal Science, 77, Yongbong-ro, Buk-gu, 61186 Gwangju, South Korea

Natural bioactive compounds derived from plants have attracted increasing attention as potential feed additives for improving immune health in livestock. Cyanidin-3-O-lathyroside, an anthocyanin compound found in various plant sources, has been suggested to possess anti-inflammatory properties; however, its immunomodulatory mechanisms remain poorly understood. This study investigated the anti-inflammatory effects of cyanidin-3-O-lathyroside in lipopolysaccharide (LPS)-stimulated RAW 264.7 macrophages, a widely used model for studying innate immune responses. Macrophage activation was assessed by examining cell morphology and quantifying pro-inflammatory cytokine expression using quantitative PCR (qPCR). Extracellular cytokine levels and inflammatory mediator activity were measured using ELISA and nitric oxide (NO) assays. The underlying molecular mechanism was further examined through immunoblot analysis of nuclear factor-kappa B (NF-κB) signaling pathway targets and immunofluorescent staining of p65 nuclear translocation. Treatment with cyanidin-3-O-lathyroside significantly attenuated macrophage activation and reduced both mRNA and protein expression levels of pro-inflammatory cytokines, including tumor necrosis factor alpha (TNF-α), interleukin-1 beta (IL-1β), and interleukin-6 (IL-6). In addition, the expression of inflammatory mediators such as inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) was markedly decreased. Mechanistically, cyanidin-3-O-lathyroside inhibited the phosphorylation of IκB-α and suppressed the nuclear translocation of NF-κB p65 in a dose-dependent manner. These findings demonstrate that cyanidin-3-O-lathyroside effectively suppresses LPS-induced inflammatory responses through modulation of the NF-κB signaling pathway. The results suggest that this compound may have potential as a natural anti-inflammatory bioactive compound for regulating immune responses in livestock, supporting its possible application as a functional feed additive to improve animal health and resilience.

Effects of a phytogenic blend of capsicum, clove and garlic in starter feed on the growth performance of Holstein dairy calves.

R. E. Crossley[1], S. Torrey[1], S. Van Kuijk[2]
[1] Trouw Nutrition, 7504 McLean Road East, N0B 2J0 Puslinch, ON, Canada, [2] Trouw Nutrition R&D, Stationsstraat 77, 3800 AG Amersfoort, Netherlands

A phytogenic blend of capsicum oleoresin, clove essential oil and garlic essential oil (Fytera™ Advance) has demonstrated a positive impact on growth performance metrics in livestock species yet has not been examined in dairy calves. The objective was to investigate the effects of this phytogenic blend, supplemented in calf starter, on the growth performance of Holstein dairy calves from birth to 15 weeks of age. The study took place at a commercial calf-rearing facility in Ontario, Canada from October 2024 to June 2025. A total of 283 Holstein dairy calves (136 heifers, 147 bulls) were enrolled in one of two dietary treatments: 1) a negative control of textured starter feed (CON) and 2) the same starter feed with 375 g/MT of the phytogenic blend (FA). Calves were individually housed from birth to weaning and bottle-fed 9 L/d of milk replacer (3 feeds × 3 L), until a two-step weaning process between weeks 8 and 11. Starter feed was offered ad libitum from the start of trial, with individual intakes recorded until the end of the weaning phase at 11 weeks. Calves were then transferred to group-housing, maintaining groups of the same dietary treatments, yet intakes were no longer recorded. Individual BW were recorded at birth, 7, 11 and 15 weeks. Visual health scoring of eye and nasal discharge, ear position and faecal consistency on a 4-point scale (from 0-3, least to most severe) were recorded and treatment records were collected. Calculated measures included ADG, and feed efficiency (FCR and F:G). Analyses were completed in SAS Studio. Cumulative intakes and scour score frequency and severity were analyzed in PROC MIXED, with fixed effects of treatment. PROC GLIMMIX was utilized for BW, ADG, FCR and F:G with fixed effects of treatment, week, and their interaction. Sex and birthweight category (≤ 36 kg = Low, 37- 46 kg = Mid, and > 46 kg = High) were included as covariates in all models. Calf within treatment was a random effect, with the repeated measure of week. Body weight, FCR and F:G utilized a lognormal distribution and identity link, with reported values back-transformed to the data scale. A Gaussian distribution with identity link was utilized for ADG. Calves on FA had a tendency for greater mean BW compared with CON (P=0.066), with FA calves having a 4.4 kg greater mean BW at 15 weeks. No significant difference was detected in the ADG of FA calves compared to the CON (P = 0.427). There were no significant differences in cumulative intakes between treatments (P = 0.771). However, there was a tendency for greater starter intakes among the FA calves compared to the CON calves during the pre-weaning phase from birth to week 7 (CON = 7.8 kg ± 0.44 SE, FA = 8.8 kg ± 0.46 SE; P = 0.088). No significant differences in feed efficiency (FCR, P = 0.946; F:G, P = 0.639) were detected. Less than 1% of eye, ear and nasal scores, and 6% of faecal scores were ≥1. There tended to be a higher proportion of CON calves receiving at least one treatment for scours (CON = 70%, FA = 59%; P = 0.053). However, a low median age of 10-12 d at first treatment when calves had consumed < 200 g of starter on average suggests this difference may be due to a proactive farm treatment protocol for scours. These findings suggest this phytogenic blend may be a promising calf starter additive and further investigation of the health impacts of FA under a variety of commercial farm conditions is warranted.

Natural bioactives preserve gut resistome stability in broilers compared with antibiotic growth promoters

R. Andreaki[1], P. Kyriakaki[1], S. Koulocheri[1], A. Pappas[1], A. Mavrommatis[1], E. Tsiplakou[1]
[1] Agricultural University of Athens, Department of Animal Science, Iera Odos 75, GR-11855 Athens, Greece

The increasing concern over antimicrobial resistance in livestock production highlights the need for sustainable alternatives to antibiotic growth promoters with nutribiotic potential. Two hundred broiler chickens were allocated to four dietary treatments with five replicates each: Control [CON; 100% of the recommended synthetic vitamin E (80 IU VitE/kg)], ANTIB (100% VitE plus 55 mg/kg zinc bacitracin), CW10, and CW0. CW10 and CW0 diets contained 10 and 0 IU VitE/kg feed, respectively, and were supplemented with 100 mg gallic acid equivalents of polyphenols from grape pomace, 150 mg β-glucans from wine lees, and 25 mg canthaxanthin equivalents from mandarin cold-pressed essential oil per kg feed. Cecal digesta collected at 35 days were analyzed using shotgun metagenomics and metatranscriptomics to characterize the gut resistome and transcriptional activity of antibiotic resistance genes (ARGs). Resistome richness and total ARG abundance did not differ among treatments. Antibiotic supplementation produced selective shifts in resistance-related functional categories and increased signals linked to microbial stress adaptation and communication. In contrast, bioactive diets showed resistome profiles comparable to the control and did not enrich resistance-associated genes. Metatranscriptomic analysis showed that antibiotic supplementation activated ARG classes associated with macrolide–lincosamide–streptogramin, tetracycline, fluoroquinolone, nitroimidazole, and phenicol resistance. This was accompanied by increased expression of DevR, capsular polysaccharide synthesis protein Cap8G, rhamnan synthesis proteins, glycosyltransferase WbuB, and polysaccharide biosynthesis tyrosine autokinase, along with higher expression of polyphosphate kinase and β-lactamase induction pathways. In contrast, CW10 and CW0 maintained ARG expression comparable to or lower than the control, with the only notable shift being increased expression of the exopolysaccharide biosynthesis glycosyltransferase VpsI. Overall, the bioactive mixtures did not promote resistome expansion or ARG activation, supporting their potential as nutribiotic alternatives to growth promoters in broiler production.

Evaluation of thinned apple by-products in ETEC F4-challenged weaned piglets

M. Tretola[1], P. Lin[1,2], F. Bertolin[1], L. Pinotti[2], P. Silacci[1], N. Pradervard[1], G. Bee[1], M. Girard[1]
[1] Agroscope, Swine Research Group, La Tioleyre 4, 1725 Posieux, Switzerland, [2] University of Milan, Department of Veterinary Medicine and Animal Sciences, Via dell'Università 6, 26900 Lodi, Italy

Post-weaning diarrhea induced by enterotoxigenic Escherichia coli (ETEC) F4 represents a major cause of economic losses and antimicrobial use in pig production. Thinned apples (TA), an underutilized by-product of apple orchards rich in polyphenols and other fermentable substrates, may offer a nutritional approach to support gut health during this critical period. This study evaluated the effects of dietary TA supplementation on growth performance, fecal consistency and selected blood parameters in ETEC F4-challenged piglets. At weaning (d-4), 90 ETEC F4-susceptible piglets (25 ± 3 d of age) were allocated to three post-weaning diets (10 pens/treatment; 3 piglets/pen): a standard starter diet (CON), or isonitrogenous and isoenergetic diets supplemented with 3% (TA3) or 6% (TA6) TA . Four days after weaning (d0), piglets were orally challenged with 2 mL of ETEC F4 (10^{1}□ CFU/mL). Body weight (BW) was recorded at d−4, d0, and on days 3 and 9 post-infection. Average daily gain (ADG) and feed intake were calculated for defined intervals. Fecal score was recorded daily, and days with diarrhea (score ≥ 3) were determined. Data were analyzed using linear mixed models with diet as fixed effect and run and pen as random effects. At weaning, piglets had similar BW (7.60 ± 0.85 kg; P > 0.10), and no dietary effects on BW were detected at any subsequent time point (P > 0.10), reaching a simiar (P > 0.10) final BW of 8.95 ± 0.563 kg at the end of the trial. The ADG and feed intake were not affected by TA inclusion (P > 0.05). However, a tendency (P = 0.05) for differences in ADG was observed in the 0–3 day period, where the lowest value was observed in TA3 pigs (0.011 ± 0.005 kg/d) compared to TA6 (0.024 ± 0.012 kg/d) and CON (0.039 ± 0.019 kg/d). Regardless of the treatment, the fecal score significantly changed over time (P < 0.001), with most of the piglets developed diarrhea with the maximum occurrence being between 2 (fecal score 3.06 ± 0.25) and 4 (fecal score = 3.07 ± 0.21) days post-infection. No severe diarrhea (fecal score = 4) were observed. Fecal score and the percentage of piglets with diarrhea were comparable (P > 0.10) between the groups along all the different time points investigated. The days in diarrhea in CON (4.73 ± 2.49 days), TA3 (4.63 ± 2.78 days) and TA6 (4.83 ± 2.93 days) were also similar (P > 0.10) between the groups. Serum biochemical parameters (creatinine, urea, non-esterified fatty acids and glucose) were not influenced (P > 0.10) by the treatment. In conclusion, inclusion of 3% or 6% TA did not improve growth performance or affect clinical signs to ETEC F4 challenge.

Supplementation of a porcine-derived bioactive complex in the diet reduces post-weaning diarrhea and modulates gut microbiota in ETEC-challenged piglets

I. Bez[1], M. Blanc[1], C. Cintra[1], R. Nunes[1], G. Stofella[1], S. Weber[1], L. Costa[1]
[1] MonoHub – Research Group for Monogastric Animals, Graduate Program in Animal Science, Pontifícia Universidade Católica do Paraná (PUCPR), School of Medicine and Life Science, Imaculada Conceição, 1155, Prado Velho, 80215-901 Curitiba, Brazil

Post-weaning enteric dysfunction impairs pig health and performance. This study evaluated the effects of increasing dietary levels of a porcine-derived bioactive complex (CBS) containing mucosal-associated components (mucin, secretory IgA, phospholipids, sphingolipids, lysozyme and intestinal alkaline phosphatase), as an alternative to antibiotic growth promoters, on the growth performance, diarrhea incidence (DI), and gut microbiota in piglets weaned at 21 or 25 days of age (WA) and challenged with Escherichia coli (ETEC) F4+ K88. A total of 144 piglets were randomly assigned to a 5 × 2 factorial design, with 5 treatments and 2 WA (21 and 25 d). Tested treatments consisted of: T1 (basal diet; negative control), T2 (basal diet + 120 mg/kg chlorohydroxyquinoline), and T3-T5 (basal diet + CBS at 830, 2,000, or 4,100 U/kg, respectively). Piglets were orally challenged with ETEC F4 on day 14, and the trial lasted 35 days. Additionally, a non-challenged group fed the basal diet (T6) was included at 21 and 25 d of age. Average daily gain (ADG), average daily feed intake (ADFI), feed conversion ratio (FCR), and DI were analyzed separately for the pre-challenge (d 1–14) and post-challenge (d 15–35) periods using ANCOVA models including treatment, WA, and their interaction as fixed effects, with initial body weight as a covariate. Treatment dose-response was also evaluated by modeling treatment level as a quantitative variable. When appropriate, multiple comparisons were performed using Dunnett's test with T1 or T2 as control groups. An additional model including all treatments was used to compare challenged groups (T1–T5) with the non-challenged group (T6). On d 35, 48 piglets were euthanized for microbiota composition and characterized by gene sequencing. Alpha and Beta diversity, and differential taxonomic abundance (LEfSe) were subsequently evaluated. During d 1-14, ADG, ADFI, and FCR did not differ among treatments ($P > 0.05$), whereas piglets weaned at 25 d showed greater ADG than those weaned at 21 d ($P < 0.001$). After the challenge, WA affected final body weight ($P = 0.0038$) and ADG ($P = 0.0120$), but treatments did not influence ADG, ADFI, or FCR ($P > 0.05$). A dose-dependent tendency for reduced diarrhea incidence was observed with increasing CBS levels in both periods (pre: $P = 0.083$; post: $P = 0.0949$). In multiple comparisons, T5 showed lower diarrhea incidence than T2 (pre: $P = 0.046$; post: $P = 0.0499$). No differences were detected between challenged treatments (T1–T5) and the non-challenged (T6) for any variable ($P > 0.05$). Microbiome analysis revealed high Escherichia abundance across challenged groups, consistent with the ETEC F4+ infection. Alpha diversity did not differ ($P > 0.05$), but Beta diversity showed greater dispersion in T1, whereas T4 clustered more tightly, indicating greater homogeneity in microbiota response within that treatment. LEfSe identified Streptococcus enriched in T1 and reduced in higher CBS groups, especially T4/T5 ($P < 0.05$). Overall, dietary supplementation with the CBS did not alter growth performance of ETEC-challenged piglets, while WA remained an important determinant of post-weaning growth. Nonetheless, increasing CBS levels mitigated diarrhea incidence and stabilized gut microbial composition, as evidenced by lower Streptococcus abundance and improved microbiota homogeneity. These findings suggest that CBS could serve as a viable alternative to antibiotic growth promoters during post-weaning enteric challenges.

Improving Zootechnical Performance of Broilers with Polyphenol Blend

M. Osredkar Mergole[1], V. A. Rios De Castilho Heiss[2], S. Molino[1], O. Desrues[1], E. Santin[1]
[1] Silvateam S.p.A., BU Feed, Via Torre 7, 12080 San Michele Mondovi, Italy, [2] Federal University of Grande Dourados, Faculty of Agricultural Sciences, Dourados, 79840 Mato Grosso do Sul, Brazil

The poultry industry prioritizes rapid growth, feed efficiency, and breast yield through intensive breeding and management. While these improvements have advanced production, they have also led to challenges with meat quality and raised concerns about animal welfare and performance. This study investigated how a polyphenol blend (PB) with strong antioxidant properties influences broiler performance, carcass traits, and incidence of myopathies. A total of 760 male Ross chicken was distributed in two groups (control and 300g/ton of PB) in a randomized experimental design, with ten replicates of 38 birds each. The parameters evaluated: weekly zootechnical performance, carcass yield and scores of myopathies (at 42 days). By day 42 PB group had significantly higher body weight (BW) (3668.5 g) and cumulative weight gain (WG) (3623.4 g) compared to control BW (3565.4 g) and WG (3520.4 g) ($p \leq 0,05$). Feed conversion ratio (FCR) was significantly improved in PB group (1.506 versus 1.556 ($p \leq 0,05$)), while feed intake (FI) remained consistent across both groups, indicating that performance improvements resulted from better efficiency. The final weight of the birds selected for carcass yield and cuts with a variation of ±5% from the group averages was significantly higher for PB group (3.480 kg vs. 3.400 kg; $p \leq 0,05$), with significantly higher weight of legs (0.832 g) compared to control group with weight of legs (0.799g). Wings, breast, boneless breast, back and feet are not significant. Carcass and cuts yield (%) did not differ significantly. PB group showed numerical, though non-significant, reduction in severe wooden breast incidence with 54% lower risk of having more severe WB (10,3% of severe WB score vs 27,6% of severe WB score in control group). A slight reduction in incidence of white striping was observed at 42 days for PB group compared to control (1.45 vs 1.47). In summary, these findings indicate that polyphenol blend with high antioxidant activity can improve performance and carcass yield of broilers under intensive breeding system.

Assessing accuracy and on-farm applicability of dairy cow feed intake prediction equations

M. Gierus[1], S. Steiner[1], L. Dardabou[1], G. Terler[2]
[1] Institute of Animal Nutrition, Livestock Products and Nutrition Physiology, BOKU University, Muthgasse 11, 1190 Vienna, Austria, [2] Institute of Livestock Research, Agricultural Research and Education Centre Raumberg-Gumpenstein (HBLFA Raumberg-Gumpenstein), Altirdning 11, 8952 Irdning-Donnersbachtal, Austria

Precise dry matter intake (DMI) estimation is essential for performance-adapted ration formulation in dairy cows. This study evaluated the accuracy and applicability of 15 established DMI equations using data from Austrian research trials. The dataset comprised 76 dairy cows (Holstein-Friesian, Fleckvieh) across lactation (DIM 20–300 d), parities (1–4), body weights (550–750 kg), milk yields (20–55 kg/d), and concentrate intakes (4–10 kg DM/d). Diets reflected regional practice: grass silage (35–45% NDF DM), maize silage, and concentrates, resulting in total DMI of 15–28 kg/d. Actual DMI was calculated as offered minus refused feed (<5% refusals). Fifteen models were tested: simple (2–3 variables: Vadiveloo & Holmes 1979; Yungblut et al. 1980; Rayburn & Fox 1993), moderate (4–6: NRC 2001; Lee et al. 2021; Tylutki et al. 2008; Freitas et al. 2006; Santos et al. 2009; Souza et al. 2014; Fuentes Pila et al. 2003; Jeroch et al. 2008), and complex (≥7: Allen et al. 2019; Gruber et al. 2004, formulas 1 and 6; Chase & Sniffen 1985). Inputs included BW^0.75, milk yield (MY), fat yield (FY), DIM, forage and ration NDF (FNDF, RNDF), and energy density (MJ NEL/kg DM). Outliers (>2.5 SD) were removed, <5% missing values imputed, redundancies eliminated, and data aggregated to daily means. Accuracy metrics were sum of squared errors of prediction (SSEP; primary), mean bias (predicted–observed), R^2, and ANOVA ($p<0.05$). Bland–Altman plots assessed bias; applicability was rated by variable count (easy ≤5; moderate 6–7; complex >7). Gruber et al. (2004) Formula 1 showed lowest SSEP (R^2=0.92, bias −0.12 kg/d), followed by Formula 6 (bias +0.08 kg/d) and Tylutki et al. (2008) (R^2=0.89, bias −0.21 kg/d). NRC (2001) ranked mid-tier; Allen et al. (2019) underperformed, likely due to unmodeled parity and DIM effects. Seven models (e.g., Tylutki, NRC, Vadiveloo) were easily applicable using routine BW, MY, and FY data. Bland–Altman plots indicated minimal bias at 18–22 kg/d DMI, with overprediction in early lactation and underprediction at peaks (>25 kg/d). Predictions were tighter for Fleckvieh than Holstein-Friesian. ANOVA revealed significant differences ($p<0.01$), with the top three models outperforming others by 15–25% SSEP. Tylutki et al. (2008) offered the best balance of accuracy and practicality for Central European farms, while Gruber models suit research with full datasets. These equations support precise feeding, reducing energy deficits (ketosis risk), excesses (overconditioning, fertility loss), feed costs, and N/P excretion. Regional validation highlights the need for models tailored to silage-based, moderate-yield systems. Integration into management software could increase milk yield by 2–5% and reduce feed waste by 5–10%, advancing sustainable dairy nutrition. Literature Allen et al., J Dairy Sci 2019;102:2682–2696 Chase & Sniffen, J Dairy Sci 1985;68:871–879 Freitas et al., J Dairy Sci 2006;89:3102–3112 Fuentes Pila et al., J Dairy Sci 2003;86:111–118 Gruber et al., J Anim Physiol Anim Nutr 2004;88:251–263 Jeroch et al., Tierernährung 2008;36:45–67 Lee et al., J Dairy Sci 2021;104:8285–8298 NRC, J Anim Sci 2001;79:249–263 Rayburn & Fox, J Dairy Sci 1993;76:1411–1418 Santos et al., J Dairy Sci 2009;92:3437–3446 Souza et al., J Dairy Sci 2014;97:7499–7509 Tylutki et al., J Dairy Sci 2008;91:1945–1954 Vadiveloo & Holmes, J Dairy Sci 1979;62:1425–1429 Yungblut et al., Can J Anim Sci 1980;60:601–609

Accuracy of five dry matter intake prediction models in lactating dairy cows across energy-corrected milk yield classes: a meta-analysis

U. Serbester[1], A. G. Aydoner[1], P. Y. Bozkaya[1], Z. Cebeci[1]
[1] Cukurova University, Animal Science, Balcali, 01330 Adana, Turkey

Accurate prediction of dry matter intake (DMI) is fundamental to ration formulation and precision feeding in dairy production. Five mechanistic models are applied to estimate DMI in lactating dairy cows: NRC (2001), NASEM (2021), the Cornell Net Carbohydrate and Protein System (CNCPS), GfE (2023), and Agroscope; however, their comparative accuracy across different production levels has not been systematically evaluated in a large meta-analytic framework. We hypothesised that predictive performance would differ significantly among models and would be modulated by the cow's energy-corrected milk (ECM) yield class. A database of 429 treatment means was assembled from 132 peer-reviewed studies published between 1984 and 2025, comprising 6,827 Holstein cows housed exclusively in freestall systems and fed total mixed (TMR) or partial mixed (PMR) rations. Only studies using completely randomised (CRD) or randomised block (RBD) designs were included; Latin square and crossover experiments were excluded. Treatment means were classified into three ECM yield classes: Class 1 (<30 kg/d; n=113; mean=24.7 kg/d), Class 2 (30–40 kg/d; n=174; mean=35.1 kg/d), and Class 3 (>40 kg/d; n=142; mean=46.1 kg/d). Prediction accuracy was assessed using mean prediction bias, root mean square error (RMSE), and Lin's concordance correlation coefficient (CCC). Overall, NASEM (2021) yielded the lowest RMSE (2.41 kg/d; bias=+0.11 kg/d; CCC=0.735) and NRC (2001) achieved the highest CCC (0.781; bias=−0.48 kg/d; RMSE=2.68 kg/d). Agroscope showed moderate accuracy (bias=−0.66 kg/d; RMSE=2.60 kg/d; CCC=0.690), while GfE (2023) showed the greatest systematic underprediction (bias=−1.96 kg/d; RMSE=2.87 kg/d; CCC=0.683) and CNCPS underpredicted consistently across all classes (bias=−1.60 kg/d; RMSE=2.71 kg/d; CCC=0.729). In Class 1 cows, NRC (2001) showed the lowest RMSE (2.45 kg/d) and highest CCC (0.588), while NASEM (2021) had the smallest bias (+0.27 kg/d) but the lowest CCC observed across all classes (0.475). GfE (2023) performed worst in this class (bias=−2.45 kg/d; RMSE=3.35 kg/d; CCC=0.355), followed by CNCPS (bias=−1.91 kg/d) and Agroscope (bias=−1.06 kg/d). In Class 2, NASEM (2021) yielded the lowest RMSE (2.23 kg/d; bias=−0.03 kg/d) and NRC (2001) the highest CCC (0.744; bias=−0.29 kg/d), whereas Agroscope (bias=−1.04 kg/d), CNCPS (bias=−1.84 kg/d), and GfE (bias=−1.92 kg/d) continued to underpredict. In Class 3 cows, CNCPS showed the lowest RMSE (2.46 kg/d; CCC=0.747) despite persistent underprediction (bias=−1.05 kg/d), and NRC (2001) achieved the highest CCC (0.753) but the highest RMSE (3.19 kg/d; bias=−0.72 kg/d). NASEM (2021) offered the most balanced performance in this class (bias=+0.14 kg/d; RMSE=2.57 kg/d; CCC=0.688), while Agroscope showed near-zero bias (+0.12 kg/d) but poor agreement (CCC=0.533; RMSE=2.78 kg/d). No current model provided adequate DMI predictions across all ECM classes. NASEM (2021) is recommended as the most balanced model overall, given its consistently low RMSE and near-zero bias. GfE (2023) requires revision across all production levels; CNCPS (2015) requires improvement particularly in Classes 1 and 2, although its low RMSE in Class 3 suggests some sensitivity to high-production conditions. Development of ECM class-specific equations would strengthen precision feeding tools and support resource efficiency in circular dairy systems.

Use of real-time forage-harvester NIRS to reduce whole-plant maize silage nutrient variability through dynamic cutting-height control

J. L. Monge[1]
[1] *Universidad Nacional de Villa María, I.A.P.Cs.Bs.&As., A. Jauretche 1555, 5900 Villa María, Argentina*

Cutting height is a tool to modify whole-plant maize silage composition, but it typically involves a trade-off between fibre concentration and DM yield. Increasing cutting height reduces DM yield while decreasing NDF (Diepersloot et al., 2026; Aiello et al., 2008). However, fixed cutting-height settings do not account for within-field variability, which can increase silage heterogeneity and limit precision feeding. We hypothesised that a NIRS–guided dynamic cutting-height approach can increase the proportion of harvested material within a target NDF range and reduce within-field variability, while limiting DM yield losses compared with fixed settings. The aim was to regulate the level and variability of nutritional components during whole-plant maize silage harvest by dynamically adjusting cutting height using on-board NIRS. An on-farm trial was conducted on whole-plant maize (Don Mario 2789) at a dairy farm in Villa María, Córdoba, Argentina, in collaboration with John Deere Argentina. Harvest was performed using a John Deere 8500i self-propelled forage harvester equipped with HarvestLab 3000 NIRS sensors. Treatments were fixed cutting height 15 cm (H15), fixed 45 cm (H45), and variable cutting height (HVar; switching among 15, 25 or 45 cm). In HVar, header height was adjusted to maintain 33–38% NDF based on real-time readings (if NDF >38% for ≥5s, raise header; if NDF <33% for ≥5s, lower header). The design was a randomised complete block with five strip-plot replicates per treatment (7.5 m×~200 m), yielding ~520 observations per replicate. Treatment effects were tested by ANOVA (Fisher's LSD, $p<0.05$). Dispersion was assessed with Levene's test, SD and CV. For a practical interpretation, useful DM (tDM/ha) within the target range was calculated as yield × in-range fraction, and the land requirement to supply 3.1 tDM/cow/year was estimated as ha/cow/year= 3.1/useful DM. DM yield differed among treatments ($p<0.05$): H15= 15.36±3.42 tDM/ha; HVar= 13.82±3.40 tDM/ha; H45= 12.32±3.79 tDM/ha. NDF also differed ($p<0.05$): H15= 37.22±1.90%; HVar= 35.23±1.67%; H45= 34.37±1.91%. NDF variability (CV) was lowest in HVar (4.73%) vs H15 (5.11%) and H45 (5.56%), with differences in dispersion ($p<0.01$). The proportion of readings within 33–38% NDF was 65.0%, 73.3% and 86.6% for H15, H45 and HVar, respectively. The mean DM yield associated with this in-range dataset was 14.9, 12.3 and 13.8 tDM/ha for H15, H45 and HVar, respectively. Consequently, the estimated land requirement to supply target-quality DM was 0.32, 0.34 and 0.26 ha/cow/year for H15, H45 and HVar, respectively. Consistent with published evidence, increasing cutting height resulted in relative decreases in DM yield and NDF. DM yield showed a relative decrease of 6.60% per 10 cm increase (from 15 to 45 cm), which is larger than the relative decreases reported by Diepersloot et al.(2026) (~3.80% per 10 cm) and Aiello et al.(2008) (~3.70% per 10 cm). Likewise, NDF showed a relative decrease of 2.55% per 10 cm in this study, compared with ~2.40% in Diepersloot et al.(2026) and 2.2-3.5% in Aiello et al.(2008). In this context, the dynamic strategy reduced within-field variability (lower CV) and increased the fraction of harvested forage within the nutritionally defined NDF window (33–38%), thereby improving maize silage uniformity while avoiding the larger DM yield losses associated with a high fixed cutting height. Overall, these findings support the hypothesis that real-time NIRS–guided cutting-height control can help deliver more uniform maize silage and provide a practical pathway to tighter diet formulation in precision feeding systems.

Artificial intelligence applied to feed delivery in dairy farms

A. J. De Paula Nunes Cassimiro[1], E. Da Silva Ramos[2], C. D. De Sousa Bezerra[2], R. A. Pereira Franco[1], A. Assis Cardoso[1], E. Noronha De Andrade Freitas[2]

[1] Federal University of Goiás, Electrical, Mechanical and Computer Engineering School, Av. Universitária, n.º 1488 - quadra 86 - Setor Leste Universitário, 74605-010 Goiânia, Brazil, [2] Federal Institute of Goiás, Department of Informatic, Rua 75, nº46. Centro, 74055-110 Goiânia, Brazil

Feeding management represents one of the major cost components and a key factor influencing productivity in dairy production systems. Despite the increasing adoption of precision livestock farming technologies, daily feed allocation adjustments in dairy herds are still commonly based on heuristic rules and manual observations, which limits the ability to adapt to dynamic variations in animal intake and environmental conditions. In this context, this study proposes an automatic recommendation model for daily feed allocation in dairy herds based on machine learning techniques. The study was conducted on a commercial Brazilian dairy farm with 294 lactating cows, integrating multiple sources of zootechnical, nutritional, climatic, and herd management data. Three supervised regression models — Linear Regression, Random Forest, and XGBoost — were evaluated to predict next-day total mixed ration intake for different groups of cows. The dataset comprised 1,087 days of data collection and 5,404 feed preparation records, including variables such as milk production, herd size, amount of feed offered, feed refusals, days in milk, and climatic conditions. The models were trained using three-fold cross-validation and evaluated using the coefficient of determination (R2) and Mean Absolute Error (MAE). The results showed that the Linear Regression model achieved the best predictive performance, reaching R2 = 0.88 and MAE = 96.4 kg, demonstrating a strong ability to capture variations in feed intake across different cow groups. Furthermore, the application of the model enabled a reduction in feed waste during the test period, highlighting its potential as a decision-support tool for feed management and for improving the economic efficiency of dairy operations. Overall, the results indicate that the integration of heterogeneous data sources combined with machine learning models represents a promising approach for advancing precision livestock farming and developing intelligent decision-support systems for dairy farms.

A pilot study integrating jaw accelerometry and surface electromyography for automated monitoring of chewing dynamics in cattle

R. Zsoldos[1,2], S. Meale[2], O. Guzhva[1]
[1] Swedish University of Agricultural Sciences, 1Department of Biosystems and Technology, Box 190, 234 22 Lomma, Sweden, [2] The University of Queensland, 2School of Agriculture & Food Sustainability, 5391 Warrego Highway, 4343 Gatton, Australia

Precision livestock farming increasingly relies on sensor-based monitoring systems to quantify feeding behaviour and support more efficient and sustainable feed management. Mastication dynamics play a key role in feed particle breakdown, saliva production, rumen buffering, and ultimately feed utilization efficiency. However, objective quantification of chewing mechanics and associated muscular effort remains challenging under practical conditions, particularly when attempting to synchronise heterogeneous sensor data streams and capture both jaw kinematics and muscle activity simultaneously. This pilot study investigated whether integrating multimodal sensors combining jaw-mounted accelerometers with surface electromyography (sEMG) could enable automated detection of chewing cycles and provide quantitative indicators of mastication dynamics in cattle. Jaw movements were recorded using upper and lower jaw triaxial accelerometers (AX3, Axivity Ltd., Newcastle upon Tyne, UK; sampling frequency 100 Hz), while bilateral masseter muscle activity was measured using wireless sEMG sensors with integrated inertial channels (Trigno™, Delsys Inc., Natick, MA, USA; EMG sampling frequency 2000 Hz). Two heifers were monitored repeatedly across thirteen feeding sessions in a cross-over design including hay and pellet diets. Chewing bouts were detected from lower-jaw acceleration signals and individual chewing cycles were identified using peak-detection algorithms. sEMG envelopes were synchronised with accelerometer signals using cross-correlation–based lag estimation to compensate for asynchronous sensor start times. For each bout, chewing frequency, a grinding amplitude proxy derived from the median absolute deviation (MAD) of the chew-band filtered difference between lower and upper jaw accelerometers, and cycle-level muscular effort (median integrated sEMG area per cycle) were calculated. Delsys inertial channels (masseter and forehead) were explored as an internal reference to support robustness against jaw-sensor disturbances. A total of 25 chewing bouts were successfully aligned between accelerometer and sEMG recordings. Chewing frequency ranged from 1.31 to 1.73 Hz across feeding conditions. Median chewing frequency was 1.49 Hz (IQR 1.47–1.56) for hay and 1.46 Hz (IQR 1.41–1.58) for pellet feeding. Grinding amplitude (MAD) tended to be higher during hay feeding than pellet feeding, indicating greater jaw excursion during fibrous feed processing. When considered jointly with chewing frequency, hay bouts generally occupied a region characterised by higher grinding amplitude, suggesting increased mechanical processing during fibrous feed consumption. These results demonstrate the feasibility of combining accelerometry and sEMG for automated quantification of chewing behaviour and muscular effort in cattle. Such multimodal sensor approaches provide a methodological framework for characterising mastication dynamics and may support future precision feeding research by linking chewing patterns with feed physical properties, intake behaviour, and digestive efficiency. In future applications, data derived from this approach could contribute to predictive models relating mastication dynamics to feed processing and utilization across diets, breeds, and age groups, supporting the development of sensor-based indicators of feed processing and rumination efficiency.

Comparative assessment of 3-dimensional camera and GreenFeed systems for on-farm feed efficiency evaluation

A. Guinguina[1], J. Nousiainen[2], P. Huhtanen[1]
[1] Natural Resources Institute Finland, Production Systems, Tietotie, 31600 Jokioinen, Finland, [2] Valio Ltd., Farm Services, Meijeritie 6, 00370 Helsinki, Finland

Improving feed efficiency (FE) in dairy cattle can reduce greenhouse gas emissions per unit of milk and enhance profitability. Routine genetic improvement, however, is hindered by the high cost of measuring dry matter intake (DMI). Technologies such as the GreenFeed system (C-Lock Inc.), which quantifies gas exchange, and 3D camera–based system for estimating DMI may offer practical solutions for large-scale on-farm phenotyping. This study aimed to: 1) compare cow rankings for 3D camera-derived DMI (3D_DMI) with rankings for GreenFeed-derived gas exchange and efficiency traits, and 2) evaluate the relationship between 3D_DMI and DMI predicted from energy-corrected milk (ECM) and gas exchange using published equations. Data were collected from October 2024 to October 2025 on a 250-cow commercial dairy farm (Maitoaho, Kiuruvesi, Finland) equipped with both technologies. A subset of 112 cows was monitored while receiving a grass silage–based total mixed ration (forage-to-concentrate ratio 51:49, DM basis). The 3D camera provided individual DMI estimates, while the GreenFeed system recorded daily methane (CH_4), carbon dioxide (CO_2), and oxygen (O_2) exchange, from which heat production (HP) was calculated. Cow-level least-squares means for 3D_DMI, ECM, and GreenFeed-derived traits (CH_4, CO_2, O_2, HP, ECM/HP, and CH_4/ECM) were estimated by parity using PROC MIXED in SAS, with a cow × parity fixed effect and cow within parity as a repeated measure. Based on these means, cows were ranked separately for each trait (rank 1 = optimal for the respective trait). Agreement between ranking methods was evaluated using Spearman rank correlations (ρ), reranking magnitude, and ranking consistency within the top 25% of cows. Dry matter intake predicted from ECM and gas-based equations were regressed on 3D_DMI using PROC MIXED (random cow within parity effect). Model performance was assessed by coefficient of determination (R^2), root mean square prediction error (RMSPE), concordance correlation coefficient (CCC), and mean square error decomposition. The ECM followed a typical lactation pattern, peaking at about 39 kg/d around week 7 in lactation before gradually declining to about 30 kg/d by late lactation. The camera-derived DMI increased from 19 kg/d in early lactation to about 25 kg/d in late lactation. Rank correlations between 3D_DMI and GreenFeed-derived traits were weak to moderate (−0.23 to 0.34). The strongest associations were observed for O_2 ($\rho = 0.34$), HP ($\rho = 0.32$), and CH_4 ($\rho = 0.30$), followed by CH_4/ECM and ECM/HP ($|\rho| = 0.23$), and CO_2 ($\rho = 0.21$). Energy corrected milk showed essentially no association with 3D_DMI ranking ($\rho = -0.04$). Substantial reranking occurred across traits, with mean shifts of 28–41 positions and only 21–50% ranking consistency among the top 25%-ranked animals. Regression analyses showed weak relationships between 3D_DMI and DMI predicted from ECM and gas-based equations. Across models, R^2 ranged from 0.03 to 0.20 and CCC from 0.05 to 0.12, with RMSPE between 2.94 and 4.68 kg DMI/d. Most prediction error was due to slope (29-87%) and mean (1-67%) biases. The results show considerable reranking between 3D_DMI and GreenFeed-derived traits, suggesting these technologies capture different aspects of cow metabolism and efficiency. The weak predictive relationship and limited concordance between 3D_DMI and equation-based DMI indicate poor agreement between the two approaches under commercial production conditions. Further work is needed to clarify how these technologies may complement each other for large-scale phenotyping and selection of feed-efficient dairy cattle.

SipControl: High-resolution pressure sensing to characterize granular sucking behavior in automated calf feeders

E. Johannhardt[1], A. Deininger[2], M. Gültas[1]
[1] South Westphalia University of Applied Sciences, Agriculture, Lübecker Ring 2, 59494 Soest, Germany, [2] Urban GmbH & Co. KG, Product Management, Auf der Striepe 9, 27798 Wüsting, Germany

Current data acquisition in automated calf feeders provides limited insights into the specific drinking behavior of calves. While parameters such as milk intake, visit frequency, and average drinking speed are recorded, the direct biomechanical interaction at the teat remains unmonitored. This granular sucking behavior enables advanced evaluations of individual animal health, ethology, and behavioral traits. SipControl utilizes high-frequency pressure sensors to capture individual sucking events, closing the gap between cumulative intake data and real-time behavioral monitoring. The objective of this technical approach is to demonstrate the seamless integration of SipControl into automated feeding systems and to visualize high-resolution sucking patterns at the teat. By transforming raw pressure signals into interpretable data streams, this method establishes a novel digital framework for future research in calf health, behavior, and precision livestock farming. The prototype of SipControl is integrated into a commercial calf-rearing facility in Lower Saxony. The farm manages an average of 300 calves. Since September 2025, the system has been continuously recording drinking visits in real-time for approximately 50 calves per batch. The animals, predominantly male Holstein-Friesian calves, enter the facility at four weeks of age. The nursing phase lasts 52 days. To date, the system has successfully captured over 5,000 individual feeding station visits per batch, providing a comprehensive dataset of sucking dynamics under practical farming conditions. The data acquisition is based on a high-frequency pressure sensor integrated directly into the milk line. The captured pressure fluctuations allow for the characterization of the calf's biomechanical sucking work, specifically the alternating phases of sub-atmospheric pressure generation and release, represented as a quasi-sinusoidal waveform. Data processing is handled on-site by a Raspberry Pi, which receives the raw sensor signals and transmits them into a time-series database. Simultaneously, log data from the automated feeder is captured in real-time and synchronized within the same database. Post-acquisition, the data is cleaned and pre-processed for subsequent feature extraction and behavioral analysis. Initial visualizations of the pressure data confirm the system's ability to capture fine-grained drinking dynamics. The sensor data allows the direct calculation of sucking frequency and the precise determination of individual sucking pauses based on inter-pulse intervals. By integrating data from the automated feeder, it is further possible to calculate the milk volume per swallow. Preliminary analysis suggests that amplitude height, when adjusted for teat material and wear, provides proxies for individual sucking strength. Furthermore, restless drinking behavior can be identified through metrics based on the mean, standard deviation, and coefficient of variation of the pressure signals. The data also reveals significant post-feeding activity at the teat after the milk allowance is exhausted, as well as activity during visits without milk entitlement. This technical approach demonstrates that pressure sensing is a viable and robust method for monitoring calf behavior. By making individual sucking acts quantifiable and synchronizing them with feeder logs, SipControl provides a novel data foundation that surpasses current industry standards. These findings offer significant potential for developing early warning systems for disease detection and addressing complex ethological questions regarding feeding management in automated systems.

Evaluation of non-invasive sensors for monitoring vital signs in dairy cows using pulse oximetry and infrared thermometry

M. González-Cabrera[1], V. Hernández[1], J. Muñoz-Quirós[1], A. Morales-Delanuez[1], A. Argüello[1], N. Castro[1], L. E. Hernández-Castellano[1]
[1] IUSA-ONEHEALTH 4 Animal Production and Biotechnology Group, Institute of Animal Health and Food Safety, Universidad de Las Palmas de Gran Canaria, Trasmontaña s/n, 35413 Arucas, Spain

Continuous monitoring of physiological parameters in dairy cows is key to improving animal health, welfare, and farm productivity. However, traditional methods used to measure heart rate, respiratory rate, and body temperature require animal restraint and manual assessment, which can increase stress and limit their applicability for frequent monitoring under commercial farming conditions. Therefore, the development of non-invasive sensor-based technologies is gaining increasing interest within precision livestock farming systems. The aim of this study was to evaluate the feasibility of using low-cost, non-invasive sensors (i.e., a pulse oximeter and an infrared thermometer) to measure vital variables (i.e., heart and respiratory rates and temperature) in dairy cows under field conditions. The study was conducted on 40 multiparous Holstein dairy cows at different stages of lactation on a commercial dairy farm. Heart rate and respiratory rate were measured using a stethoscope and compared with measurements obtained using a pulse oximeter placed on both front and rear teats. Rectal temperature was recorded with a digital thermometer and compared with teat surface temperature measured using an infrared thermometer. The Pearson correlation coefficient was calculated using PROC CORR in SAS 9.4, and statistical significance was set at $P \leq 0.05$. The pulse oximeter measured heart rate at the teat level and showed a high correlation with stethoscope measurements, particularly in rear teats ($r = 0.79$ and $r = 0.85$, respectively; $P < 0.001$). However, the device was unable to obtain reliable measurements in pigmented teats, likely due to interference caused by melanin absorption affecting the photoplethysmographic signal. Respiratory rate measured with the pulse oximeter did not correlate with values obtained using the stethoscope ($P \geq 0.104$). Likewise, infrared teat temperature measurements were not correlated with rectal temperature ($P \geq 0.576$), suggesting that environmental factors and local physiological changes associated with milking may influence surface temperature readings. These findings suggest that pulse oximetry applied at the teat level may represent a promising approach for non-invasive heart rate monitoring in dairy cows within automated milking environments, although further technological adaptations are required to overcome limitations related to pigmentation and respiratory signal detection. Project carried out with a 2025 Leonardo Grant for Scientific Research and Cultural Creation from the BBVA Foundation.

Use of computed tomography to predict commercial lamb cut weights

Y. Huo[1], H. Calnan[1], G. Gardner[1], F. Anderson[1], L. Pannier[1], D. Gutzke[2]
[1] Murdoch University, 90 South Street, Murdoch, 6150 Melville, Australia, [2] Meat & Livestock Australia, 45 King Street, Bowen Hills, 4006 Brisbane, Australia

Accurate prediction of commercial cut weights underpins value-based trading in lamb supply chains. While hot standard carcass weight (HSCW) and GR tissue depth (110mm from the spine over the 12th rib) are widely used in Australia, their ability to discriminate variation in individual cut weights is limited. This study evaluated whether computed tomography (CT)-derived carcass composition traits improve prediction of commercial cut weights relative to GR tissue depth. 100 lambs from Meat & Livestock Australia's (MLA) Information Nucleus Flock, representing terminal, maternal, and Merino sire types, were slaughtered under commercial conditions. HSCW and GR tissue depth were recorded. Chilled carcasses were CT-scanned and dissected into commercial cuts following AUS-MEAT specifications. CT lean%, fat%, and bone% were quantified at whole-carcass and sectional levels. Log-transformed cut weights were modelled using linear mixed-effects models including HSCW and one of five fatness indicators (GR, carcass CT lean%, sectional CT lean%, carcass CT fat%, sectional CT fat%), with boner included as a random effect. Model performance was assessed via five-fold cross-validation using R^2 and RMSE as indicators of precision, and bias and slope deviation as indicators of accuracy. HSCW was the dominant predictor across all models. However, inclusion of CT traits, particularly sectional CT lean%, improved predictive precision for most cuts. For precision, the value of RMSE was as low as 0.03 to 0.05 (< 0.1% of cut weight for most cuts), however, the value of R^2 varied markedly among cuts (0.23–0.80), with larger, anatomically distinct cuts predicted most accurately. The CT lean component model provided the highest precision for the majority of fore, hind, and saddle cuts, and broadened predictive range of cut weights compared to GR model. Cross-validation confirmed stable performance in precision with minimal reduction in R^2 and minimal increase in RMSEP. For accuracy, although bias was low (bias < 3%), greater slope deviations were observed for smaller and anatomically complex cuts. These results demonstrate that CT-derived traits provide statistically robust and commercially meaningful improvements in predicting lamb cut weights, supporting more precise value-based marketing and carcass assessment systems.

What does outdoor access cost? A mechanistic analysis of energy expenditure in free-range slow-growing chickens

G. Dukhta[1], Y. Guyot[2], S. Chaumont[1], S. V. Mignon[1], E. Pampouille[2], B. Méda[1]
[1] INRAE, Université de Tours, BOA, 37380 Nouzilly, France, [2] Institut Technique de l'Aviculture, L'Orfrasière, 37380 Nouzily, France

Mechanistic nutrition models for broilers are mainly calibrated for fast-growing strains reared indoors under thermoneutral conditions, limiting their use for slow-growing genotypes reared in free-range systems. The aim of this study was to re-parameterize the daily time-step mechanistic growth model MsChick (Dukhta, 2023; DOI: 10.54598/002640) for slow-growing chickens with outdoor access. MsChick is a mechanistic "white-box" framework that predicts daily body weight (BW) based on feed characteristics and daily feed intake (DFI). It represents the daily partitioning of ingested energy and amino acids between maintenance, protein deposition and lipid deposition, thereby providing physiologically interpretable parameters. In the current study, we used individual daily performance data (BW and DFI) measured with high-throughput electronic feeders. These data were collected over two summer flocks (2022–2023) in males and females of the slow-growing S77N strain, reared either indoors or with outdoor access from day 28 (approximately 300 birds per sex × year × housing condition; Chaumont et al., 2025; DOI: 10.1093/jas/skaf157). Observed DFI values were used as model input to estimate, for each bird, three interpretable parameters controlling growth potential and basal maintenance cost: mean feather-free body protein deposition (meanBPD in g/d), protein maturity rate (precocity in d^{-1}), and fasting heat production (FHPinit in kJ/kg $BW_{0.70}$/d). The adjustment procedure minimised the difference between observed and predicted BW. In this first step, the additional cost of activity and thermoregulation (αAT) was fixed to the MsChick indoor default (αAT,IN = 33% of FHPinit). As expected, males exhibited lower precocity than females (0.031 vs 0.036 d^{-1}) but higher meanBPD (6.2 vs 4.1 g/d) and higher FHPinit (340 vs 294 kJ/kg $BW_{0.70}$/d), consistent with their higher BW and protein turnover. While indoor birds were reared under thermoneutral conditions, birds reared with outdoor access were exposed to more variable climatic conditions and could be more physically active. To capture this extra energy cost (i.e. activity + thermoregulation), we re-estimated an outdoor coefficient αAT using a two-step approach. First, total maintenance-related expenditure was derived from the energy balance (energy intake minus retained energy in proteins and lipids, and heat increment of feeding). Second, basal maintenance cost was computed by applying the indoor mean FHPinit value for each sex × year group to each bird according to its $BW_{0.70}$. The difference between total maintenance-related expenditure and basal maintenance cost was thus attributed to activity + thermoregulation and expressed as αAT,out as a percentage of FHPinit. With this approach, αAT,out was estimated to be higher than the indoor default value. It averaged about 39% and 45% of basal maintenance cost in males and females, respectively, exceeding the indoor default value. Moreover, in outdoor-access birds, combining total maintenance cost (calculated as FHPinit × [1 + αAT,out]) with abdominal fat percentage explained a large fraction of feed conversion ratio variability ($R^2 = 0.84$), whereas each predictor alone explained only a limited proportion of the variability ($R^2 < 0.40$). This work provides a first parameter set for slow-growing birds and a transferable calibration framework for representing outdoor-related energetic costs in mechanistic models while preserving interpretability and providing a basis for future scenario analyses (e.g. differing outdoor activity levels or environmental conditions).

Early prediction of growth dynamics and feed conversion ratio using random forest regression models in growing pigs

V. Ács[1], G. Kövér[2], G. Bee[3], V. Halas[1]
[1] Hungarian University of Agricultural and Life Sciences, Department of Farm Animal Nutrition, Guba Sándor Street 40, 7400 Kaposvár, Hungary, [2] Hungarian University of Agricultural and Life Sciences, Department of Animal Breeding, Guba Sándor Street 40, 7400 Kaposvár, Hungary, [3] Agroscope, Pig Research Unit, Rte de la Tioleyre 4, 1725 Posieux, Switzerland

In precision pig nutrition, high-frequency behavioural data generated by automated feeder systems create opportunities for growth-modelling as a dynamic, state-dependent process rather than as a static endpoint. The objective of this study was to develop and evaluate a trajectory-based autoregressive modelling framework capable of predicting week-to-week body weight transitions and estimating feed conversion ratio (FCR) from behaviour-derived proxy variables. The emphasis was on methodological robustness and transferability across independently collected datasets. Behavioural descriptors were calculated from raw automatic feeder records collected across multiple European datasets, including meal size, visit size, feeding frequency, total visits, total meals, meal duration, feeding rate, and the irregularity index of feed intake (IIFI; Salgado et al., 2021). Pigs visited the feeder on average 15–20 times per day, resulting in approximately 1,200–1,700 feeder events per animal during a 12-week fattening period. This generated a high-dimensional, longitudinal dataset characterised by repeated measures, behavioural heterogeneity, temporal dependency, and nonlinear interactions. To integrate behavioural organisation with physiological performance, individual body weight was recorded weekly. To model growth as a transition process, a trajectory dataset was constructed by pairing each observed body weight at week t (BW(t)) with the subsequent measurement at week t+1 (BW(t+1)). This formulation represented an explicit autoregressive structure in which the future state depends on current physiological status and behavioural descriptors. Subsequently, random forest regression (500 trees, bootstrap aggregation) was applied to predict BW(t+1) using BW(t), relative production week (time covariate), and selected behavioural predictors with low missingness. Predictors exceeding predefined missingness thresholds were excluded, remaining gaps were median-imputed, and models were fitted only when a sufficient number of week-to-week transitions was available. Model performance was quantified using R^2 and RMSE across consecutive weekly transitions. In parallel, FCR was calculated as total feed intake (kg) divided by body weight gain (kg). A separate random forest model was trained exclusively on behavioural descriptors to predict FCR with moderate but consistent accuracy across datasets. The results demonstrate that short-term growth progression can be robustly described using a structured ensemble-based autoregressive framework integrating physiological state and feeding behaviour organisation. This supports the hypothesis that intake structure and behavioural variability encode mechanistic information associated with inter-individual differences in feed efficiency. The stability of predictive performance across independent data origins further confirms the transferability of the modelling approach. The proposed framework provides a scalable analytical structure for transforming high-frequency behavioural data into biologically interpretable growth trajectories and feed efficiency indicators within precision livestock systems.

Opportunity for welfare breeding: An automated registration system to record foraging activity of individual pigs as an indicator trait for positive welfare

R. M. Zaalberg[1], J. Malmkvist[2,3], N. S. Madsen[2], M. L. V. Larsen[2], J. D. Bus[2], T. T. Chu[1], R. Thomsen[4], H. Bovbjerg[5], L. J. Pedersen[2]

[1] Aarhus University, Center for Quantitative Genetics and Genomics, C. F. Møllers Allé 3, 8000 Aarhus, Denmark, [2] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Alle 20, 8830 Tjele, Denmark, [3] The Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Ulls väg 26, 750 07 Uppsala, Sweden, [4] Innovation Centre for Organic Farming, Agro Food Park 26, 8200 Aarhus, Denmark, [5] Bovbjerg Økologi A/S, Mosegårdvej 1, 7323 Give, Denmark

Welfare breeding in pigs traditionally refers to selective breeding strategies to reduce pigs' negative experiences (e.g. lameness, tail biting, piglet morality). The WelBredPOrg project challenges this philosophy and argues that welfare breeding should also include selectively breeding for motivation to express natural behaviour related to positive experiences. Therefore, we aim to develop an automated system that can register natural foraging behavior of individual grower pigs. Data were recorded on an organic commercial finisher farm in Denmark. Each stable unit housed ~350 pigs and had both indoor and outdoor areas with straw bedding and sawdust beds, a concentrate feeder with an entrance gate with a scale, and a designated area in the outdoor area where roughage (i.e. grass silage) was provided ~5 times a day using an automated feeding robot. Individual pig body weight was recorded every time the pig entered the concentrate area. Antennas installed on the walls near the roughage area received signals from pigs' UHF-RFID ear tags. Signals were recorded up to ~2m from the wall. After each roughage provision, pigs were registered as (not) present for six consecutive 5min-intervals (present: ≥1 RFID-registration). Data from >3000 pigs were collected from October 2024 through December 2025. Preliminary results showed variation between pigs in how often they visited the roughage area after a roughage provision event (μ=35%, min=10%, max=80%). There was a positive correlation (r = 0.87 to 0.92) between the time a pig spent in the roughage area after roughage provision and how often pigs attended a roughage provision event. Throughout the entire growing period, pigs were most active in the late afternoon and evening (3:00 PM – 6:00 PM), and least in the morning (6:00 AM). No clear correlations were observed between average daily gain and a pig's activity in the roughage area (r = -0.20 to 0.30). Genetic parameters (h^2 and rg) will be estimated for activity in the roughage area and the average daily gain. This study presents a novel approach to use an indicator of natural behavior to selectively breed for enhanced positive welfare in pigs.

Impact of bronopol preservation on milk metabolomic stability

N. Frías-Reid[1], R. R. Lobo[2], G. Conta[2], J. L. Mejía Méndez[1], D. E. Navarro López[1]
[1] Tecnológico de Monterrey, Escuela de Ingeniería y Ciencias, Epigmenio González 500, 76130 Santiago de Querétaro, Mexico, [2] Nestlé Research, Department of Animal Sciences, Route du Jorat 57, 1000 Lausanne, Switzerland

With increased implementation of robotic milking systems, cows are milked at irregular intervals, which complicates the immediate freezing of milk samples. Since raw milk rapidly undergoes biochemical changes post-milking, there is uncertainty regarding the stability of metabolites when bronopol-preserved samples are collected at varying times and temporarily stored prior to freezing. Assessing bronopol's effectiveness under these circumstances is crucial for accurate milk profiling in contemporary dairy operations, where consistent metabolomic markers are vital for developing milk-based tools used for precision feeding and animal health evaluation. The objective of the project was to evaluate how bronopol preservation and short-term room-temperature exposure (0 h vs. 16 h) influence the metabolomic profile of lyophilized raw milk. Bulk milk (~50 mL) was collected over three days from a commercial dairy farm in Vaud, Switzerland, frozen at −20 °C, thawed, homogenized, and divided into four 10 mL aliquots per day. Half of the aliquots received bronopol following the manufacturer's recommendation. Within each treatment (with and without bronopol), half of the aliquots were immediately stored at −80 °C, while the remains were incubated at 25 °C for 16 h before −80 °C storage. Frozen samples were thawed at room temperature; for each sample, 5 aliquots of 1 mL were prepared and lyophilized, then reconstituted using 1 mL deionized water, vortexed and centrifuged at 15'000×g at 4°C for 20 min. Supernatant was then mixed with a buffer containing internal standards and analyzed by NMR for metabolites profiling. The experiment followed a randomized design, with treatments arranged in a factorial structure consisting of two factors: bronopol use (with or without) and incubation time (0 h or 16 h). Within the metabolomic profile, we identified 45 different metabolites. PLS-DA analysis showed strong discriminatory performance (R2Y = 0.93; Q2 = 0.788), explaining 56.9% of the X-variance, where bronopol treatment drove the primary separation along Component 1, largely influenced by bronopol concentration, while incubation at 25 °C contributed to additional variation along Component 2. Notably, when bronopol was added, samples incubated for 16 h did not differ statistically from their non-incubated counterparts, indicating substantial stabilization of the metabolomic profile. ANOVA supported these multivariate patterns, identifying a significant bronopol × incubation interaction for bronopol concentration. In addition, bronopol blocked the strong 16-h increases in fermentative metabolites observed in untreated milk, including lactic acid (~19-fold), pyruvate (~8-fold), acetate (~6-fold), and acetoin (~2-fold), indicating effective inhibition of fermentation. These findings demonstrate that bronopol stabilizes the milk metabolome during short ambient-temperature exposure, supporting its use when immediate freezing is not feasible. This contributes to more robust metabolomic monitoring pipelines for precision feeding and on-farm decision-support systems.

Pilot GWAS of male reproduction traits in Slovak farmed Rainbow trout

R. Kasarda[1], N. Moravčíková[1], A. Halvoník[1], K. Pálešová[1], J. Andreji[1], M. Fik[1]
[1] Slovak University of Agriculture in Nintra, Tr. A. hlinku 2, 94976 Nitra, Slovakia

Rainbow trout (Oncorhynchus mykiss, Walbaum 1792) represents one of the most important aquaculture species in Slovakia, with a long-standing tradition of intensive and semi-intensive farming, contributing substantially to national fish production and local food supply. As reproductive efficiency is a critical factor in aquaculture production systems, identifying genomic regions associated with male reproduction traits may support the optimisation of effective selective breeding strategies in this species. Thus, this study aimed to conduct a pilot genome-wide association study (GWAS) to identify genomic regions and certain genetic variants associated with male reproduction traits in a farmed rainbow trout population from Slovakia. Nuclear DNA from 20 males was genotyped using the GGP Rainbow Trout 20K array, and after standard quality control, the dataset comprised 17,329 informative SNP markers for each individual. The four reproduction traits, sperm concentration (10^6/ml), progressive motility (%), total motility (%) and immotile sperm (%), were measured directly on the farm as part of the routine annual evaluations of broodfish. The GWAS was performed for each trait separately using univariate linear mixed models, and the significance of associations was assessed via likelihood ratio tests. Candidate SNPs were identified using a false discovery rate (FDR) threshold of <0.1 and annotated by detecting the closest protein-coding genes (Ensembl BioMart, genome assembly USDA_OmykA_1.1). Sperm concentration in the studied broodfish averaged 23,200.35 $\times 10^6$/ml (SD = 5,066.07; range: 8,720–30,844), while progressive motility was on average 61.06 % (SD = 10.61%; range: 45.66–85.92%). Average total motility was 63.78 % (SD = 9.48%; range: 49.79–85.92%), and the proportion of immotile sperm was 36.22 % on average (SD = 9.48%; range: 14.08–50.21%). All four male reproductive traits showed relatively low heritability, with the majority of phenotypic variation explained by environmental (residual) factors. GWAS identified several significant SNPs associated with sperm concentration and sperm motility traits, with some loci affecting multiple motility traits simultaneously. Annotation of these SNPs revealed proximity to genes involved in neuronal regulation, cell signalling, and sperm development, including sv2bb, synm, SHANK3, ide, opcml, MCTP1, EDIL3, adora2aa, and sox6, while a few loci were unassigned. The detected SNPs represent potential candidate markers for selective breeding programs, enabling the identification of males with favourable alleles to enhance sperm concentration and motility, thereby improving fertilisation success and overall reproductive efficiency in farmed rainbow trout.
This study was supported by the Ministry of Education, Research, Development and Youth of the Slovak Republic (grant no. 1/0316/25) and the Slovak Research and Development Agency (grant no. APVV-20-0161).

Modelling post-farrowing body weight in sows from gestation and litter data

N. Quiniou[1], J. Thomas[1], A. Letort[1]
[1] Ifip, 9 Bd du Trieux, 35360 Pacé, France

Regular weighing of sows during the reproductive cycle is useful to assess the relevance of feeding management. When available in commercial farms, manual scales are used when sows are moved between gestation and lactations rooms, while automatic scales are installed in collective pens in the gestation unit. Thus, body weight at farrowing usually corresponds to data collected at the latest a few days before farrowing (stage G, days after the first insemination) and provides the total BW of the sow, including reproductive compartments. In this study, modelling was considered to estimate the sow's weight after farrowing (BWAF). Based on the literature that describes the growth of reproductive compartments, two nested models were built. The dynamic mechanistic approach allows the BWAF to be calculated from the total body weight at stage G by subtracting and adding the estimated reproductive compartments (i.e., uterus, placentas, fluids, foetuses, and mammary glands) at each stage to reflect their changes between stage G and farrowing. The first model (MOD1) estimated BWAF without accounting for maternal energy balance between stage G and farrowing, whereas the second model (MOD2) included body energy variation in maternal tissues, assuming an energy content of 8.37 MJ per kg of BW (the lowest value found in the literature for Large White x Landrace sows). The inputs were stage G, total body weight at stage G (BWG), gestation length, litter size and weight at birth, and, for MOD2, metabolizable energy (ME) supplied between stage G and farrowing calculated from the ME content of the feed and the daily ration. Models were evaluated using data collected in a demonstration farm from 1,067 sows weighed between 90 and 94 days of gestation and again within 24 hours after farrowing. Mean observed BWAF was 274 ± 40 kg. Predicted BWAF averaged 244 ± 37 kg with MOD1 and 270 ± 33 kg with MOD2. Including energy balance markedly reduced the prediction bias from 30 to 4 kg, the root mean square error of prediction from 33 to 15 kg, and the mean absolute error from 30 to 12 kg. With a 5% margin of error, the model MOD2 is accurate enough to estimate BW dynamics at herd level and support interpretation of routine BW measurements on commercial farms. However, its accuracy remains too low to allow for individual characterisation of sows in research contexts. Given genetic changes in prolificacy and body composition of sows, accuracy could be improved by updating knowledge on the growth of the reproductive compartments and on the maternal energy retention.

Analysis of fecal particle distribution in dairy cows with different assessment approaches

H. Scholz[1], L. Hentschel[1], P. Kühne[2]
[1] Anhalt University, Faculty LOEL, STrenzfelder Allee 28, 06406 Bernburg, Germany, [2] State Institute for Agriculture and Horticulture Saxony-Anhalt, Lindenstraße 18, 39606 Iden, Germany

Fluctuating feed intake, changes in the nutritional content of silage within a silo, and potential selection during feed intake can lead to deviations between the actual ration consumed and the calculated ration. However, the content of various carbohydrates such as starch or NDF must also be taken into account as an indicator of the ration. Against this background, the use of various key figures from feed control to monitor dairy cows is essential. Among the multitude of parameters, the evaluation of manure in dairy cows is a good option for individual animal-related or group-related analysis, as the very good mixing in the digestive tract and the longer retention time mean that a representative sample can be assumed. For the present study, based on the carbohydrate trial conducted by LLG Iden in 2022, manure samples from the dairy cows in the two feeding groups were analyzed on various dates to determine potential differences in the animals' digestion. The focus was on whether differences in fecal particle distribution could also be observed between a starch-rich and an NDF-rich TMR. The second part of the study was to examine possible differences between the fecal particle distribution of cows in the high-yield phase, cows at the end of lacation and dry cows. For the present investigations, the "RETSCH AS 200 BASIC" system was used in the LLG Iden laboratory. The following sieves were used: [1] 4 mm, [2] 1 mm, and [3] 0.125 mm. The fecal samples were poured onto the top sieve and doused with approximately one liter of water. On average, 28% of the fecal particles were larger than 4 mm, but there was a significant difference between the two feeding groups, with higher proportions in the fiber group. In contrast, the particles on the 1 mm sieve were significantly higher in the starch group (21%) than in the fiber group (16%). However, no statistically significant differences between the two feeding groups could be detected on the smallest sieve. A comparison of the lactation stages showed that the cows in the high-performance group had the highest 4 mm sieve percentage at 37%. In contrast, dry cows had the significantly highest proportion on the 0.125 mm sieve at 64%, compared to 53% for the other two groups. In summary, it can be concluded that sieving manure is very useful for detecting differences in feeding trials and also between different ration types. For further investigations and to increase the informative value of the fecal screenings, it should be examined whether the proportion of washed-out feces in the weighed quantities should also be taken into account.

Methane Yield Integrated into Feeding Strategies as a Measure of Production Efficiency in Tropical Commercial Dairies: Case Study in Tamil Nadu, India

K. M. Tirimba[1], T. Ravichandran[2], M. G. G. Chagunda[1,3]
[1] University of Hohenheim, Dept. Animal Breeding and Husbandry in the Tropics and Subtropics, Garbenstr. 17, 70599 Stuttgart, Germany, [2] Kumaraguru College of Liberal Arts and Sciences, Saravanampatti, 641001-641105 Coimbatore, India, [3] University of Edinburgh, Centre for Tropical Livestock Genetics and Health, Roslin Institute, Easter Bush Campus, EH25 9RG Edinburgh, United Kingdom

A feeding trial was conducted on a commercial farm in Tamil Nadu, India, to investigate the use of enteric methane emissions (CH4) as a metric of production efficiency in tropical dairy systems. The study was carried out from October to December 2024, during the heavy-rain monsoon season. Twenty lactating cows of the indigenous Kankrej cattle, in their third lactation and aged 6 -7 years were selected from a herd of 200 animals using a randomized block design (RBD) based on milk yield (Group 1: <10L/day; Group 2: >10L/day). The trial was set up as a repeated-measures design with two dietary phases, where milk yield and CH4 emissions were recorded over five consecutive days in each phase. The diet consisted of a maize silage-based TMR with a concentrate, crude protein (CP) levels of 11.96% in the first phase and 14.62% in the second phase. A 14-day adaptation period was included between the two dietary phases prior to the second phase of measurements. Enteric CH4 emissions were measured directly using a laser methane detector (LMD). Methane emission intensity, milk yield and methane production were analyzed using a linear mixed-effects model with diet (original vs. adapted), lactation stage and milk yield group as fixed effects. Raw means (SD) of CH4 production and milk yield were 150.6 (76.4) g/day and 8.9 (3.37) L/day respectively. Diet had a significant effect on milk production and CH4 ($p<0.05$). Following the adapted diet, both CH4 production and milk yield increased significantly ($p<0.05$) compared with the original diet (LS means, 175.4 ± 9.26 g/day vs. 114.4 ± 9.33 g/day for CH4 ; 10.2 ±0.61 vs. 8.5 ±0.61 L/day for milk yield). Alternatively, CH4 emission intensities remained similar (LS means, 0.02 ± 0.003 vs. 0.017 ± 0.003 kg CH4/kg milk; $p>0.05$) in the original and adapted dietary phases respectively. Lactation stage did not significantly influence CH4 emissions or milk yield. The results show that a higher CP-diet increased both CH4 production and milk yield without significantly increasing CH4 emission intensity. These findings suggest that methane emission intensities could serve as a useful metric when designing feeding strategies aimed at balancing emission reduction and dairy productivity. This is especially important in countries such as India, where high milk demand coincides with a limited feed resource. In conclusion, the study highlights that integrating methane-based efficiency metrics into feeding practices can support sustainability in dairy farms by maintaining methane emissions intensities while improving milk production.

"Collar-Tag": A Novel, Rapid, and Secure Electronic Identification Method for Lambs

F. Chessa[1], N. Lei[1], L. Mara[1], G. Epifani[1], M. Dattena[1], V. Giovanetti[1], N. Charbel[1]
[1] Agris, Department of Animal Science, SS 291 Km 18.600 Loc Bonassai, 07100 Sassari, Italy

Accurate identification of newborn lambs represents a critical step in sheep production systems for reproductive management, performance recording, traceability, and genetic evaluation. Despite the widespread adoption of official electronic identification systems in Europe, early-life recording on farms often still relies on paper-based notes or delayed digital entry, increasing the risk of mismatches between lambs and dams, transcription errors, and data loss during the lambing period. This issue is particularly relevant in prolific flocks and in large-scale operations, where rapid and reliable identification at birth is essential. This work presents a rapid, low-cost electronic method for temporary identification and early-life data collection in newborn lambs, using a microchip-equipped collar (Collar-Tag) combined with programmable electronic readers. The system is designed to bridge the time gap between birth and the insertion of the official national bolus (BDN), replacing traditional paper-based recording and allowing immediate digital registration of key maternal and neonatal information from birth until official identification. Each Collar-Tag links a visible progressive number to an ISO electronic ID, enabling fast field recognition and error-free association through a handheld reader. Data are collected using customized templates created with herd-management software (Rumisoft, Tru Test), transferred to the reader, and downloaded in TXT or CSV formats for further processing and integration into farm databases. Regular updates of equivalence files ensure accurate linkage between temporary collar IDs and their dams throughout the lambing period. Additional functionalities include automated weight recording via a scale equipped with an integrated reader, supporting continuous growth monitoring and management decisions such as selection of replacement or slaughter destination. Within the framework of precision livestock farming and digital traceability in small ruminants, this approach improves data accuracy, reduces labor time, and provides a standardized, fully digital workflow suitable for large and small sheep farms aiming to enhance reproductive and performance monitoring. The system is developed for sheep production and is relevant to animal science disciplines including herd management, breeding, and livestock informatics. Stakeholders potentially benefiting from this tool include farmers, breeders' associations, genetic evaluation bodies, advisory services, and institutions involved in livestock traceability and digital innovation. Presenting this contribution at EAAP 2026 aims to stimulate discussion on practical and scalable solutions to improve early-life data quality and management efficiency in European sheep production systems.

Can feed color drive feeding behavior in piglets?

O. Tej[1,2], J. Leskovec[1], M. Colom-Pellicer[1], C. Güell Saperas[2], M. Ferrando Cogollos[2], D. Torrallardona[1]
[1] IRTA, Animal Nutrition, TP-7225, Km 3,8 Constantí, 43120 (Tarragona), 43120 Constantí, Spain, [2] URV, Chemical Engineering, Campus Sescelades,, 43007 Tarragona, Spain

Feeding behavior in weaned piglets is influenced by multiple factors, but the contribution of feed appearance, and specifically feed coloration, to feed preference has received limited attention. The aim of the study was to evaluate the effect of feed color (red, green, and blue) on feed preference in weaned piglets. A total of 108 weaned piglets ([Large White × Landrace] × Pietrain) were allocated to 36 pens (3 piglets per pen) in two rooms (24 and 12 pens, respectively). A double-choice preference trial was conducted following a randomized complete block design with 9 blocks and four feed comparisons per block. Piglets were offered the choice between a control (uncolored) diet versus blue-, red-, or green-colored feeds obtained by using the feed colorants Patent Blue V 85%, Red 40 CONACERT, and Mint Green 839 CONACERT, respectively (all provided by PROQUIMAC PFC, Barcelona, Spain). Feeds were offered in pelleted form. Disappearance, over 3 days, of the two feeds offered to each pen was measured at pen level and their relative preference was expressed as percentage of total feed intake. Feed preferences were analyzed with the GLM procedure of SAS. Piglets showed significantly higher preferences for the green- and red-colored feeds than for the control diet (74 vs. 26% and 76 vs. 24%, respectively; $P < 0.05$). No difference in preference was observed for the blue-colored feed (54 vs. 46%; $P > 0.05$). To assess whether these effects of the colorants were certainly due to changes in color, and not to other possible sensorial properties of the colorant (i.e. taste or odor), the preference test was performed again under the same conditions, with the exception that it was performed under complete darkness. In addition, to minimize carryover effects, piglets were not re-exposed to the same feed color across testing periods. Under dark conditions, no significant differences in preference were observed between the green- or blue- feeds and the control diet (53 vs. 47% and 53 vs. 47%, respectively; $P > 0.05$). On the other hand, piglets maintained a strong preference for the red-colored feed in absence of light (72 vs. 28%; $P < 0.05$). The persistence of red feed preference under dark conditions suggests that in the case of Red 40 CONACERT dye, sensorial properties other than color may have been responsible for the preference observed. It is concluded that the green color of feed improves feed preference in weaned piglets.

Chronic stress reshapes the pig gut microbiome: insights from metaproteomics

R. Río-López[1], J. Guitart-Matas[2,3], M. Ø. Arntzen[4], A. Clavell-Sansalvador[3], I. T. Voularki[3], O. González-Rodríguez[3], L. J. García-Gil[5], X. Xifró[6], A. Dalmau[1], Y. Ramayo-Caldas[3]

Chronic stress compromises pig welfare and productivity, mainly through the impact on the microbiota-gut-brain axis. While multi-omics is a promising tool for uncovering its underlying mechanisms, the application of metaproteomics to chronic social stress in pigs remains unexplored. The objectives of this study were to characterise how stress reshapes the functional activity of the pig gut microbiome and to identify metaproteomic signatures that classify the groups. At the end of the growing period, hair and faecal samples were collected from 60 two-month-old Duroc pigs that had been exposed to either chronic social stress (n=30; reduced space allowance and repeated mixing) or control conditions (n=30). Significant differences ($p<0.05$) in hair cortisol levels were observed between groups. Faecal samples were analysed using a genome-resolved metaproteomic approach. Metaproteomic profiles were generated using nano LC-MS/MS and searched against a custom database of 911,040 microbial genes derived from 484 metagenome-assembled genomes (MAGs) generated from the samples. This enabled the direct linkage of expressed proteins to their microorganisms and the quantification of active MAGs based on protein abundance. Discriminant and differential abundance analyses identified stress-responsive taxa and functions, with group discrimination accuracy based on individual proteins up to 99.51%. Functional profiling, through enrichment analysis and metabolic pathway reconstruction, revealed a clear distinction between the metabolic strategies of condition-associated MAGs. Discriminant MAGs that distinguished the stress condition included Treponema_D, Catenibacterium, and members of the Erysipelotrichaceae family. In contrast, those associated with the control condition were predominantly represented by PeH17, Roseburia, Butyricicoccus, and a novel species belonging to the Christensenellales order and the Lachnospiraceae family. The functional profile of the control-associated community was characterised by capabilities for short-chain fatty acid production, vitamin synthesis, and stress resistance, as well as significant metabolic dependencies, supporting a role for specialisation and symbiosis in a homeostatic, cooperative gut environment. In contrast, the stress-associated microbial ecosystem was defined by resource competition, including motility, diverse transport systems, and a more autonomous metabolism geared towards nutrient scavenging and utilisation under fluctuating conditions, aligning with a dysbiotic state. These findings demonstrate that chronic social stress drives a functional reorganisation of the pig gut microbiome, shifting it from a specialised, symbiotic consortium towards a competitive, dysbiotic community. The identified metaproteomic signatures provide highly accurate functional biomarkers for chronic stress, establishing a powerful tool for welfare assessment in pigs and offering translational insights into human stress-related dysbiosis.

Step into the Udder Zone – Identifying behavioural proxies of fallback piglets under heavy occlusion

S. P. Brouwers[1], C. Ducrue[1], L. A. Boyle[1]
[1] Teagasc, Pig and Poultry Research and Knowledge Transfer Department, Moorepark, P61 C996 Fermoy, Ireland

In pig production, larger litters have increased the risk of piglets dying from starvation arising from intensified teat competition, particularly in the first week of life. Clearly, such animals will appear as malnourished or 'fall-back' piglets prior to death. Early identification of fallbacks could enable targeted management interventions, yet routine weighing or behavioural observations are labour intensive and disruptive. Video recording offers a scalable and non-invasive alternative. Recent advances in Computer Vision (CV) have further increased the feasibility of automated behavioural monitoring in livestock systems. However, farrowing pens present suboptimal environments for CV because piglets are frequently occluded by housing structures and littermates, complicating continuous individual tracking and behaviour classification. We therefore explored whether behavioural differences during nursing bouts are associated with fallback risk using an observation approach designed to remain informative under heavy occlusion. Rather than relying on continuous tracking, the method exploits the distinct functional areas of the farrowing pen, based on the principle that piglets cannot teleport between zones. Specifically, we hypothesised that behaviour during nursing bouts, when scored manually using a simple zone-based ethogram, would be associated with fallback risk. Average piglet daily weight gain (ADG) during lactation was recorded by weighing the piglets of individually penned, permanently crated sows on days 1, 2, 6, and 14 postpartum. Piglet behaviour during the first eight nursing bouts after each weighing was scored from video recordings using an ethogram including: "in Udder Zone", "walking, "lying", or "out of sight". The Udder Zone was defined as a rectangular area surrounding the sow's udder from anterior to posterior shoulder and one piglet body length in width. Derived metrics summarised nursing bout participation, initiation, and teat fidelity. Piglets that died or fell within the lowest 15% of ADG within each litter × weighing interval were classified as fallbacks. Principal component analysis (PCA) was used to reduce correlated behavioural metrics into orthogonal components, which were subsequently analysed using generalised linear mixed-effects models. Preliminary analyses on three litters showed that PCA reduced the behavioural metrics to a dominant engagement axis (PC1), characterised by lower bout initiation and participation together with longer latencies and more re-entries into the Udder Zone. This engagement axis was associated with fallback risk ($P = 0.019$), with higher PC1 scores (reflecting reduced and less stable nursing engagement) corresponding to increased odds of growth failure. Additional behavioural components did not improve model fit and were not independently predictive. Within-litter standardised birth weight was not associated with fallback risk. Random intercept variance at the piglet level was large, indicating substantial intrinsic heterogeneity. These results suggest that simple, zone-based behavioural scoring captures a dominant nursing engagement dimension associated with fallback risk without requiring continuous individual tracking. Although we found substantial piglet-level heterogeneity in growth trajectories, such behavioural indicators may provide a biological foundation for future CV monitoring systems operating under the heavy occlusion conditions typical of commercial farrowing pens.

Influence of different sow and farrowing parameters on colostrum quality in a free farrowing system

P. T. Egli[1,2], J. Adam[1], C. Rüegg[1], G. Schüpbach-Regula[3], J. J. Gross[4], A. Grahofer[1]
[1] Clinic for Swine, Department for Clinical Veterinary Medicine, Bremgartenstrasse 109a, 3012 Bern, Switzerland, [2] Graduate School for Cellular and Biomedical Sciences, Mittelstrasse 43, 3012 Bern, Switzerland, [3] Veterinary Public Health Institute (VPHI), Department of Clinical Research and Veterinary Public Health, Schwarzenburgstrasse 161, 3097 Liebefeld, Switzerland, [4] Veterinary Physiology, Department of Clinical Research and Veterinary Public Health, Bremgartenstrasse 109a, 3012 Bern, Switzerland

Colostrum is vital for neonatal piglets, with both quantity and quality determining survival and performance. Inadequate colostrum quality is a major risk factor for impaired health, growth and welfare. This study aimed to investigate the influence of sow and farrowing parameters on colostrum immunoglobulin (IgG) concentration. In total, 151 crossbred sows housed in free-farrowing pens were included. Sow-related data (parity, body weight, body condition score, backfat, birth induction, gestation length) and farrowing parameters (total piglets born, farrowing duration, obstetrical intervention, placental expulsion, litter and placental weight) were recorded. Ambient temperature and humidity were recorded within 24 hours prior to farrowing. Colostrum samples were collected after the expulsion of the first piglet and analysed for IgG concentration using a porcine-specific ELISA (Pig IgG ELISA, E101-104, Bethyl Laboratories Inc., Montgomery, TX, USA; dilution 1:1,000,000; intra- and inter-assay CV 5.4% and 4.4%), with parallel measurement by digital Brix refractometry. Linear regression with log-transformed IgG values was applied. Predictor variables were selected based on biological plausibility and descriptive analyses; the final model included total piglets born, parity, induction of farrowing, relative humidity, and the parity × induction interaction. Mean parity was 4.23 ± 2.46 (range 1–9), and mean litter size was 15.98 ± 3.55 piglets. Mean Brix value was 27.20 ± 2.95%, and mean colostrum IgG concentration was 66.57 ± 24.70 mg/mL. Brix values strongly correlated with ELISA IgG ($r = 0.66$, $p < 0.001$). The final model ($R^2 = 0.43$, $p < 0.001$) revealed significant effects of parity ($p < 0.001$), birth induction ($p = 0.001$), humidity ($p = 0.004$), and the interaction between parity and induction ($p = 0.034$). Higher parity was associated with increased IgG levels, whereas birth induction reduced IgG, particularly in gilts, with diminishing effects in older sows. A positive association between ambient humidity and IgG was observed, though its biological relevance is unclear. In conclusion, parity, birth induction, and environmental factors significantly influenced colostrum IgG. The negative impact of birth induction highlights the importance of farrowing management. On-farm colostrum assessment by Brix refractometry appears feasible for integration into sow and piglet management in free-farrowing systems.

Effect of early and late postnatal administration of two artificial colostrum formulas on piglets' growth performance, blood metabolic profile and intestinal health

S. Bencivenni[1], E. Huenul[2], F. Palumbo[1], M. Mazzoni[3], G. Metti[3], G. Rocchetti[4], F. Correa[1], D. Luise[1]
[1] University of Bologna, Department of Agricultural and Food Sciences, Viale Giuseppe Fanin 40-50, 40127 Bologna, Italy, [2] Autonomous University of Barcelona, Department of Animal and Food Science, Travessera dels Turons, 08193 Bellaterra, Spain, [3] University of Bologna, Department of Veterinary Science, Via Tolara di Sopra 43, 40064 Ozzano dell'Emilia, Italy, [4] Università Cattolica del Sacro Cuore, Department of Animal Science, Food and Nutrition, Via Emilia Parmense 84, 29122 Piacenza, Italy

Artificial colostrum supplementation, provided after birth and during the pre-weaning phase, may enhance piglet resilience especially in large litters and in low-birth-weight piglets; however, its efficacy is inconsistent, partly due to compositional differences from sow colostrum. Notably, bovine-based formulas lack key bioactive compounds such as taurine and vitamin E, which are linked to improved metabolic function, intestinal health, and survivability. This study evaluated the effects of a standard bovine-based formulation (COL) or the same formulation enriched with taurine and vitamin E (PLUS), administered early (first 3 days after birth: d0-d2) and late before weaning (d26-d28), on piglet survival, growth, welfare, blood metabolic profile, and intestinal health. Fifty sows and their litters were allocated to 5 groups (10 litters/group): CO (no artificial colostrum); COL3 (COL d0-d2); COL28 (COL d0-d2 and d26-d28); PLUS3 (PLUS d0-d2) and PLUS28 (PLUS d0-d2 and d26-d28). Doses were administered by gavage d0-d2 and by feeders pre-weaning. At birth (d0), piglets were weighed and classified in body weight category (BWC): low (LBW, <1300 g), normal (NBW, 1300–1700 g), and high (HBW, >1700 g). Piglets' growth performance, ear lesions, and litter size were recorded until weaning (d28). At d28, 80 piglets (balanced for BWC) were euthanised for blood (Igs and untargeted metabolomics analysis), and jejunal sampling (morphometry, scoring of Cldn4, Ocln, and ZO-1 immunoreactivity (-IR), transcriptomics). Data were analysed using generalised linear and mixed models followed by ANOVA on R software. Metabolomic data were analysed using PLS-DA approach and RNA-seq differential analysis was performed with DESeq2, followed by KEGG-based Gene Set Enrichment Analysis. Sow performance and colostrum composition did not differ among groups. Neither COL nor PLUS improved overall growth and survivability compared with CO. However, COL28 piglets had greater body weight (d28) and higher ADG (d0-d28) than COL3 ($P < 0.05$), indicating a beneficial effect of late supplementation. All supplemented groups had reduced ear lesion scores at d5 and d28 ($P < 0.05$). Blood Igs were unaffected by treatment. Metabolomic analysis (1,066 metabolites) revealed treatment-related clustering (sPLS-DA), with COL groups diverging from CO more than PLUS groups. Jejunal morphometry was unchanged, but COL3 piglets showed lower Cldn4 and Ocln-IR ($P < 0.05$), suggesting impaired barrier integrity. Transcriptomic analysis identified 30 differentially expressed genes between COL3-LBW and COL28-LBW piglets (Padj < 0.05; log2FC >1.5), with suppressed basal transcription/metabolic pathways and activation of cytoskeleton-related pathways in COL3-LBW, consistent with epithelial stress. In conclusion, artificial colostrum supplementation did not improve piglets' growth and survivability; however, it improved piglet welfare by reducing ear lesions. Late administration of COL before weaning showed positive effects by enhancing growth and improving intestinal integrity compared with the early supplementation. Finally, taurine and vitamin E enrichment did not improve growth compared to COL.

Modulation of Dietary Acid-Binding Capacity by Limestone Flour Omission and Fumaric Acid Supplementation in the First 14 Days Post-Weaning: Effects on Pig Performance and Health

J. Glynn[1,2], G. Gardiner[2], J. O'Doherty[3], T. Sweeney[4], P. Lawlor[1]
[1] Teagasc, Pig Development Department, Moorepark, Fermoy, P61 C996 Cork, Ireland, [2] South-East Technological University, Eco-Innovation Research Centre, Department of Science, Waterford, X91 K0EK Waterford, Ireland, [3] University College Dublin, School of Agriculture and Food Science, Belfield, Dublin 4, D04 V1W8 Dublin, Ireland, [4] University College Dublin, School of Veterinary Medicine, Belfield, Dublin 4, D04 V1W8 Dublin, Ireland

The pig's ability to produce gastric hydrochloric acid in the early post-weaning (PW) period is limited. Therefore, reducing dietary acid-binding capacity to a pH of 4.0 (ABC-4) has been proposed to help maintain gastric acidity and improve growth and health PW. Limestone flour is the main calcium source in the diet and has a very high ABC-4 of ~12,932 meq/kg. Contrary to this, fumaric acid has a very low ABC-4 of ~-10,862 meq/kg. Complete PW diets can be formulated to have a low ABC-4 by omission and inclusion of high and low ABC-4 dietary ingredients, respectively. The objective here was to determine the effect of reducing dietary ABC-4 for 14 days PW on pig growth and health. At weaning (27 ± 1.02 days), pigs were formed into same-sex (entire male or female) pen groups of 10 pigs of even weight (8.2 ± 1.10 kg). Pen groups were blocked on sex and weaning weight. Within block, pen groups were randomly assigned to one of four dietary treatments (N=14 pen replicates per treatment) as follows: 1. With limestone flour (10g/kg; ABC-4 = 435 meq/kg; CONTROL), 2. Without limestone flour (0g/kg; ABC-4 = 305 meq/kg; LF-), 3. With limestone flour plus fumaric acid (21.5 g/kg to target a dietary ABC-4 of 200 meq/kg; FA+) and 4. Without limestone flour plus fumaric acid (10g/kg to target a dietary ABC-4 of 200 meq/kg; LF-/FA+). Experimental diets were fed from weaning until day (D) 14 PW after which common weaner (D14-43 PW) and finisher (D43-120 PW) diets were fed. Average daily gain (ADG), average daily feed intake (ADFI) and feed conversion ratio (FCR) were calculated, and statistical analysis was conducted using PROC MIXED in SAS. Treatment was included as a fixed effect with block included as a random effect and weaning weight, when significant in the model, was included as a co-variate. Titrations of diets revealed that actual ABC-4 values were 404, 281, 163 and 171 meq/kg for CONTROL, LF-, FA+ and LF-/FA+, respectively. There was a treatment effect observed for pig body weight (BW) at D14 PW ($P<0.001$) and ADG from D0-14 PW ($P<0.001$). Feeding FA+ resulted in a 5.3% increase in BW at D14 PW ($P<0.05$) and a 25.6% increase in ADG compared to control during the period from D0-14 PW ($P<0.05$). Feeding LF- resulted in a 7% increase in BW at D14 PW ($P<0.05$) and a 31.3% increase in ADG compared to control during the period from D0-14 PW ($P<0.05$). Feeding LF-/FA+ did not affect BW at D14 PW or ADG from D0-14 PW ($P>0.05$). There was a treatment effect observed for FCR from D0-14 PW ($P<0.001$). The LF-, FA+ and LF-/FA+ diets all improved FCR compared to CONTROL ($P<0.05$). There was no treatment effect observed for any growth parameter of interest at any timepoint from D14-120 PW ($P>0.05$). In conclusion, reducing calculated dietary ABC-4 by ~130 meq/kg by removing limestone flour from the formulation or by targeting a calculated dietary ABC-4 of ~200 meq/kg by including 21.5 g/kg fumaric acid in the diet both increased BW and ADG and improved feed efficiency during the first 14 days PW. However, reducing dietary ABC-4 to a target level of ~200 meq/kg by removal of limestone flour and fumaric acid addition to the formulation did not increase pig BW or ADG but did improve feed efficiency compared to the CONTROL during the first 14 days after weaning.

Effect of dietary inclusion of a by-product of Gelidium sesquipedale on post-weaning growth and health of pigs

C. Negrini[1], J. Glynn[1,2], G. Gardiner[2], R. Oliver-Simancas[3], A. Jiménez-Quero[3], L. Giblin[4], P. Lawlor[1]
[1] Teagasc, Pig & Poultry Research and Knowledge Transfer Department, Teagasc, Moorepark, Fermoy, Ireland, P61 C997 Fermoy, Ireland, [2] South East Technological University, Department of Science, Cork Rd, Lisduggan Big, Waterford, X91 K0EK Waterford, Ireland, [3] Chalmers University of Technology, Division of Industrial Biotechnology, Department of Life Sciences, Kemigården 1, SE-412 96 Göteborg, Sweden, [4] Teagasc, Food Research Centre, Moorepark West House, P61 C996 Fermoy, Ireland

Gelidium is a red macroalga rich in bioactive compounds (polyphenols, sulphated galactans, dietary fibre) known to promote intestinal health and support immune status. A by-product was obtained after agar extraction from Gelidium sesquipedale via enzymatic hydrolysis and water extraction processes. The protein (27%), carbohydrate (31%), and sulphated polysaccharide content of the by-product may make it suitable for use as an alternative feed ingredient in pig diets. This study evaluated the effect of dietary inclusion of this Gelidium sesquipedale by-product in post-weaning (PW) diets on piglet growth, whole blood haematology and biomarkers of small intestinal health. At weaning (29±0.95 days; 9.3±0.05 kg), 126 pigs were formed into 30 pen groups containing 3 pigs and 18 pen groups containing 2 pigs. Pen groups were blocked on pen group size at weaning, sex (entire male and female) and weaning weight. Within block, pen groups were randomly assigned to one of three dietary treatments (n=16 pens/treatment): 1. Control diet; 2. Control + 1% Gelidium by-product (GEL1); 3. Control + 3% Gelidium by-product (GEL3). Pigs were fed the experimental diets from weaning until day (d)21 PW, after which a common weaner diet was provided until d44 PW. Individual pig weights were recorded at weaning (d0), d6, 14, 21, 27 and 44 PW. Feed disappearance was recorded for the intervals between pig weighings. At d6 PW, one pig from each pen containing 3 pigs (n=10 pigs/treatment) was euthanised to collect whole blood for haematology and intestinal tissue (duodenum, jejunum, and ileum) for histology and mRNA analysis. Pig growth was analysed using PROC MIXED with day as the repeated measure; haematology and mRNA expression were analysed using PROC GLIMMIX in SAS. Dietary treatment was included as fixed effect, block as random effect and weaning weight as covariate when significant in the model. Pen was the experimental unit for growth parameters, while individual pig was the experimental unit for haematological, histological and mRNA data. Dietary treatment did not affect body weight or average daily feed intake up to d44 PW. Feed conversion efficiency was improved for GEL1 compared to Control and GEL3 during the period d0-6 PW (P=0.05), with a similar tendency observed compared to Control during the period d0-44 PW (P=0.08).). Duodenal villus height to crypt depth ratio tended to be higher in GEL1 and GEL3 compared to Control (P=0.08), while ileal villus height tended to be higher in GEL1 compared to Control (P=0.09). Duodenal CLAUD4 was increased in GEL3 pigs compared to GEL1 and Control (P<0.01) with a tendency for it to increase in GEL3 compared to Control in the jejunum (P=0.10). This may be due to a local epithelial response to higher levels of Gelidium derived bioactive compounds. In summary, dietary inclusion of the Gelidium by-product at 1% or 3% in post-weaning diets had minimal effects on pig growth, blood haematology or intestinal function. Therefore, this by-product can be effectively used as an alternative feed ingredient in post-weaning pig diets at inclusion levels of up to 3%.

Effects of the combination of potentiated zinc oxide and monovalent copper in low acid-binding capacity-4 diets on growth performance and plasma zinc and copper concentrations

J. Lee[1], M. Tokach[2], J. Derouchey[2], A. Monteiro[3], Y. Manaig[3], P. Trevisi[1]
[1] University of Bologna, Viale Giuseppe Fanin, 44, 40127 Bologna, Italy, [2] Kansas state University, 1424 Claflin Rd, 66506 Manhattan, United States, [3] Animine, 10 Rue Léon Rey Grange, 74960 Annecy, France

This study evaluated the effects of the combination of potentiated zinc oxide (pZnO, HiZox, Animine Precision Minerals, Annecy, France; source with small aggregates and agglomerate particles) and monovalent copper oxide (Cu2O, CoRouge, Animine Precision Minerals) as alternatives to pharmacological levels of ZnO in low acid-binding capacity (ABC)-4 diets on growth performance and plasma Zn and Cu concentrations of nursery pigs. A total of 360 nursery pigs (18 ± 1 d old; initially 5.7 ± 0.2 kg) were allotted within three body weight (BW) blocks to one of six treatments (12 pens/treatment; 5 pigs/pen). Treatment diets were fed in phase 1 (d 0 to 10), phase 2 (d 10 to 24), and phase 3 (d 24 to 46) diets. Treatments were arranged in a 3 × 2 factorial with main effects of Zn: low (150 mg/kg) and high (800 mg/kg) levels of Zn from pZnO for both phase 1 and 2, and pharmacological levels of Zn from standard ZnO (Maximo720; Zinc Nacional, Monterrey, Mexico; source with large and dense particles) at 3,000 and 2,000 mg/kg for phases 1 and 2, respectively, and Cu levels:18 vs. 150 mg/kg of Cu from Cu2O. In phase 3, treatment diets included two different Cu from Cu2O levels (18 and 150 meq/kg) with 150 mg/kg of Zn from pZnO. The ABC-4 levels of basal diets were 199 and 248 meq/kg for phases 1 and 2, and 437 meq/kg for phase 3. Neither Zn × Cu interactions nor Zn and Cu main effects were observed in d 10 and 24 BW. However, Cu main effects were significant ($P \leq 0.05$) for d 46 BW and phase 3 average daily gain (ADG), in which pigs fed high-Cu2O diets had greater BW and ADG, compared to those fed low-Cu2O diets. For d 46 plasma Zn and Cu concentrations, neither Zn × Cu interactions nor Zn and Cu main effects were observed. In conclusion, without sanitary challenges, lower dietary inclusion of pZnO had comparable effects on piglets' growth to pharmacological levels of ZnO in low ABC-4 diets, while the inclusion of a high level of Cu2O improved growth performance without influencing the plasma Cu concentrations during phase 3.

Effect of Lactiplantibacillus Plantarum on nitrogen, calcium and phosphorus balance in weaned piglets challenged with Fumonisins B1

L. Ikanya[1], B. Libisch[2], T. Keresztény[2], F. Olasz[2], M. Kovács[3], V. Halas[1]
[1] Department of Farm Animal Nutrition, Institute of Physiology and Animal Nutrition, Hungarian University of Agriculture and Life Sciences, Kaposvár Campus, Guba Sándor utca 40, 7400 Kaposvár, Hungary, [2] Agribiotechnology and Precision Breeding for Food Security National Laboratory, Institute of Genetics and Biotechnology, Hungarian University of Agriculture and Life Sciences, Szent-Györgyi. Str.2100, 2100 Gödöllő, Hungary, [3] Agribiotechnology and Precision Breeding for Food Security National Laboratory, Department of Animal Physiology and Health, Institute of Physiology and Animal Nutrition, Hungarian University of Agriculture and Life Sciences, Guba Sándor utca 40, 7400 Kaposvár, Hungary

Abstract Fumonisin B1 (FB1), a mycotoxin produced by Fusarium fungi frequently contaminating maize and maize-based feeds posing health risks to swine by disruption of intestinal integrity and nutrients metabolism. Although dietary probiotic Lactiplantibacillus plantarum (L. plantarum) modulates nutrients utilization, its efficacy in FB1-intoxicated conditions remain undocumented. The aim of the study was to investigate the effect of L. plantarum on nitrogen (N), calcium (Ca) and phosphorus (P) balance in weaned piglets challenged with FB1. Twenty-four piglets aged 28 days with an initial body weight of 7.92 ± 0.15 kg were randomly assigned to four dietary treatments groups: commercial feed (Control, C), 50 mg/kg FB1-contaminated commercial feed (F), commercial feed supplemented with 1×10^9 CFU/pig/day L. plantarum (LP), 50 mg/kg FB1-contaminated commercial feed supplemented with 1×10^9 CFU/pig/day L. plantarum (FLP). The experimental period included 14 days of acclimatization and 28 days of trial. Statistical analysis was by GLM procedure of SPSS software version 29.0.1.0. Results showed no significant interaction effect ($p>0.05$) between FB1 and L. plantarum. Similarly, N intake, apparent total tract digestibility (ATTD), absolute and relative N retention was not affected by dietary treatments ($p>0.05$). However, a significant main effect of FB1 was reported in Ca and P metabolism ($p<0.05$). Pigs challenged with FB1 showed a significantly ($p=0.022$) lower ATTD of Ca ultimately decreasing its retention by 5.3 % points of intake ($p=0.038$). While P ATTD remained unaffected ($p>0.05$), pigs challenged with FB1 showed a significantly higher urinary P excretion ($p<0.001$) which in turn led to a significant reduction in the rate of retained P to intake ($p=0.043$) and digested P ($p<0.001$). Supplementation of probiotic L. plantarum did not mitigate the negative effects of FB1. The results confirm that FB1 impact on P balance is post-absorptive. The significant reduction in the Ca ATTD and high P urinary excretion in FB1 challenged piglets in our study, suggests disruption of Ca:P homeostasis which may dispose the pigs to skeletal demineralization with time warranting future investigation. Keywords: weaning pigs; Fumonisin; digestibility; retention; Lactiplantibacillus plantarum

Evaluating social genetic models in pigs with precision feeding data and stochastic simulation

P. Nuñez[1], L. Varona[2], J. Casellas[3], N. Ibáñez Escriche[1]
[1] Universitat Politècnica de València, , 46022 València, Spain, [2] Universidad de Zaragoza, , 50013 Zaragoza, Spain, [3] Universidad Autónoma de Barcelona, , 08193 Barcelona, Spain

Including social genetic effects into breeding strategies can improve accuracy of genetic evaluations, limiting the negative-competitive effects in group-housed pigs. Technologies applied in pig production systems allow a characterization of social interactions in groups of pigs. This study aimed to assess (1) the impact of including social effects versus a classical animal model in the genetic evaluation of productive traits in a limited real population and simulated data, and (2) to evaluate differences in performance of a classical binary social model and a model including the level of interaction between animals. Real data included 1,195 Iberian pigs housed in pens of 12 animals, with feed intake recorded through automatic feeders. Pigs were housed in pens with an average of 13 pigs per pen. Animals entered the testing period with an average initial weight of 31.4 kg and finished with 80.4 kg. In parallel, a stochastic simulation was conducted to generate 10,080 phenotypes with direct and social genetic effects. Animals were allocated into 840 pens of 12 individuals, with an average within-pen relatedness of 0.068. Direct and social breeding values for founders were sampled, assuming a direct heritability of 0.2 and a direct–social genetic correlation of −0.3. Breeding values of descendants were generated as the mid-parent value plus a Mendelian sampling term. The effect of contemporary mates on the phenotype of animal i was obtained as $\sum ws$, where w is the intensity of interaction between i and each of its (n-1) mates, and s is the social breeding value of each contemporary mate. The interaction was simulated using an exponential weighting function of standardized social breeding values: where $\beta=3$ controls the degree of heterogeneity. This formulation results in lower displacements by animals with higher social breeding values, and vice versa. Ten independent replicates were simulated, and variance components were computed for each replicate. Three models were compared for daily feed intake of both real and simulated data: an additive genetic model (GM), a classical binary social model (SBM), and a social model with continuous interaction intensities (SCIM). While SBM assumed equal interaction among contemporaneous animals, SCIM incorporated continuous interaction intensities, quantified (in real data) as the frequency of displacements between pairs of animals. Displacements were defined as feeder visits in which the interval between consecutive animals was less than 60 seconds together with a reduction in feed intake of the displaced animal. Variance component estimation was performed with blupf90+. Correlations between estimated and true breeding values were assessed for each replicate and averaged across replicates to compare prediction ability between models. Results from GM model showed that social genetic variance was largely absorbed into the pen effect, being in line both real and simulated data. While EBV predictions were similar across models (0.77), SCIM improved the estimation of social values (from 0.59 to 0.63) and total genetic values (from 0.52 to 0.57), reflecting the benefit of including interaction intensities. These findings suggest that modeling heterogeneous interaction intensities produces more realistic results and helps mitigate the classical confounding between pen and social effects. Automatic feeder data offers a scalable way to quantify intensities without additional labour or cost. Nonetheless, further studies using larger real populations are needed to validate the application of social genetic models with intensity. Funding: COST Action CA22112 (EU-LI-PHE).

Enrichment with live insect larvae (Hermetia illucens) on productive results in slow- and fast-growing broiler chickens

M. Pravato[1], M. Cali[2], F. Bordignon[1], D. Meo Zilio[2], M. Molin[1], S. Caré[3], S. Bellezza Oddon[4], A. Trocino[1], G. Xiccato[1], D. Bochicchio[5]

Braccini 2, 10095 Grugliasco (TO), Italy, [5] Council for Agricultural Research and Analysis of Agricultural Economics, Department of Zootechnics and Aquaculture, Via Beccastecca 345, 41018 Modena, Italy

Fast-growing broiler genotypes are raising many concerns about animal welfare and meat quality defects. These include a high incidence of growth-related myopathies such as white striping, wooden breast, and spaghetti meat. Together with reduced locomotor activity and behavioural expression, these issues have raised ethical concerns. Consumer awareness is growing, which has led to initiatives like the European Chicken Commitment, encouraging the use of slower- and medium-growing genotypes in alternative production systems which can also use insect, such as live Hermetia illucens (HI) larvae, as promising feed ingredient with high nutritional value and potential environmental benefits. Providing live HI larvae can also stimulate natural foraging behaviour, which could have a positive effect on productive performance and animal welfare. Consistently, to evaluate the effect of live HI larvae supplementation on the performance and meat quality in fast-growing and slow-growing broiler chickens, a total of 498 one-day-old male chicks (325 Ross 308 and 173 Ranger Savanna, Aviagen, Huntsville, AL) were housed in 12 collective pens (Ross, 54 birds/pen and Ranger, 29 birds/pen, 3 pens per experimental group) fed a control diet and receiving or not 10% HI live larvae (on the litter) until commercial slaughtering (42 and 59 days of age for fast-growing and slow-growing chickens, respectively). Data were analysed using a mixed model with live-larvae enrichment and genotype as a fixed effects and pen as a random effect. Live weight (3405 g vs. 4543 g; $P<0.001$) and cold carcass weight (2479 g vs. 3347 g; $P<0.001$) were higher in slow- compared to fast-growing chickens. The rates of breast yield (40.3% vs 39.4%; $P<0.05$) and pectoralis major (26.2% vs. 25.7%; $P=0.06$) and the occurrence of wooden breast (35.4% vs 15.6%; $P<0.001$) were higher in fast- compared slow-growing chickens. The pectoralis major pH (6.18 vs. 5.83; $P<0.001$) and cooking losses (27.7% vs. 23.1%; $P<0.001$) were higher in fast- compared to slow-growing chickens. On the contrary lightness index (47.9 vs. 49.3; $P<0.001$), redness (0.18 vs. 0.58; $P<0.001$), and yellowness (9.79 vs. 11.3; $P<0.001$) were lower in former compared to the latter chickens. Overall, live HI larvae enrichment did not affect carcass traits or meat rheological traits ($P>0.05$). In conclusion, genotype had a significant impact on productive results, and carcass and meat quality traits, where both slow-and fast-growing genotypes showed wooden breasts, even if at a lower extent in the latter ones. This emphasises the key role of genetic background in determining growth performance and meat quality in broiler chickens. This work was co-funded by European Union's Horizon Europe Project 101136346 EUPAHW (SOA13, Task 2.3; SOA17, Task 1.4).

From tissue to transcriptome: Exploring differential gene expression in porcine scrotal hernia using a QuantSeq approach

J. De Kort[1], S. Van De Voorde[1], B. Chakkingal Bhaskaran[1], R. Meyermans[1], K. Hooyberghs[1,2], S. Janssens[1], N. Buys[1], W. Gorssen[3]

[1] KU Leuven, Center for Animal Breeding and Genetics, Department of Biosystems, Kasteelpark Arenberg 30, 3001 Leuven, Belgium, [2] University of Liège, Unit of Animal Genomics, GIGA and Faculty of Veterinary Medicine, Avenue de l'Hôpital 11, 4000 Liège, Belgium, [3] ETH Zürich, Animal Genomics, Universitätsstrasse 2, 8092 Zürich, Switzerland

Scrotal hernia (SH) is a common congenital disorder in pigs and is characterized by the protrusion of abdominal contents into the scrotum, creating a visible bulge. Affected boars have an increased mortality risk due to intestinal strangulation, infections, and potentially fatal complications at castration. Beyond its effects on health and survival, SH also leads to considerable economic losses through reduced growth performance, increased veterinary care, and penalties at slaughter for intact boars, making it a substantial challenge for pig production. Despite its impact, the genetic basis and molecular mechanisms underlying scrotal hernia remain largely unknown. In this study, gene expression differences associated with SH were investigated using QuantSeq 3′ mRNA sequencing. As SH is closely linked to testicular descent and the anatomy of the inguinal canal, structures from the scrotal region were sampled, including the tissues composing the deep inguinal ring, the cremaster muscle, and the testis. These tissues were sampled bilaterally in both affected and unaffected piglets. In addition, the pituitary gland and hypothalamus were collected. Tissue samples were collected from affected (n = 13) and unaffected (n = 9) three-week-old crossbred piglets (Large White boar × Landrace sow) originating from four litters. Among the affected piglets, hernias were left-sided (n = 8), right-sided (n = 1), or bilateral (n = 4). All litters were sired by the same boar, and the dams were closely related as sisters or half-sisters. The relatively high incidence of SH within these related litters suggests a potential genetic contribution to the condition. RNA was extracted following standard protocols, after which QuantSeq libraries were prepared and sequenced. Resulting FASTQ files were mapped to the Sus scrofa 11.1 reference genome, and differential gene expression analysis was performed using DESeq2. Gene expression was compared between affected and unaffected animals in tissue samples collected from the deep inguinal ring region. QuantSeq analysis identified 140 differentially expressed genes ($\log2FC \geq |2|$; padj < 0.1), including 9 upregulated and 131 downregulated genes in deep inguinal ring tissue from affected animals compared with controls. The most significantly downregulated gene ($\log2FC = -3.69$, padj $= 8.55 \times 10$□6) functions as a transcriptional regulator of cell-type-specific differentiation pathways and has been implicated in the regulation of GnRH expression. Pathway analysis using Gene Set Enrichment Analysis and the Kyoto Encyclopedia of Genes and Genomes indicated enrichment of mitochondrial processes, particularly the electron transport chain and oxidative phosphorylation. Further analyses are ongoing, including differential gene expression analyses in additional tissues such as testis, cremaster muscle, pituitary, and hypothalamus, as well as analyses of genotype data to identify variants associated with scrotal hernia. Together, these findings suggest that altered transcriptional regulation and mitochondrial function may contribute to the pathophysiology of scrotal hernia and demonstrate the value of transcriptomic approaches for gaining molecular insight into this condition.

Biosecurity in challenging times: recognizing overlooked hygiene pathways in livestock production

N. Kemper[1]
[1] University of Veterinary Medicine Hannover, Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour (ITTN), Bischofsholer Damm 15, 30173 Hannover, Germany

On-farm biosecurity has long been recognized as a cornerstone of disease prevention in livestock production. However, recent outbreaks of African swine fever and highly pathogenic avian influenza in Europe underline that biosecurity is not merely a theoretical concept but a practical necessity requiring continuous vigilance. While many preventive measures are well established, certain hygiene-related transmission pathways may still be underestimated in everyday farm management. Identifying and addressing these overlooked routes is therefore essential for improving disease prevention and strengthening farm resilience. This contribution summarizes findings from three recent studies investigating different hygiene-related risk pathways in livestock production systems. Airborne transmission was examined in a field study evaluating modified air-filter modules in a naturally ventilated turkey barn. Filtration reduced airborne particles and microorganisms by approximately 94 to 96%, and pathogens such as Ornithobacterium rhinotracheale were detected before but not after filtration, indicating the potential of air filtration as an effective biosecurity barrier. In another study, environmental persistence of pathogens was assessed through systematic sampling in broiler houses across several production cycles. Enterococcus cecorum was repeatedly detected in environmental samples, with increasing detection towards the end of the production period and occasional persistence even after cleaning and disinfection. These findings highlight the role of environmental reservoirs and illustrate the limitations of routine hygiene procedures in fully eliminating pathogens. A third study analysed drinking water quality on pig and poultry farms in Northwest Germany over a ten-year period. A considerable proportion of samples exceeded recommended guideline values, with 58.0% exceeding chemical limits and 47.4% exceeding microbiological limits, indicating that drinking water systems may represent an underestimated hygiene risk requiring improved monitoring and management. Taken together, these findings demonstrate that biosecurity challenges arise from multiple and sometimes underestimated pathways, including air, farm environment and water systems. Effective prevention strategies must therefore address these routes simultaneously and combine technical solutions with consistent hygiene management. In times of increasing disease pressure, strengthening animal hygiene and biosecurity is essential not only for farmers but also for veterinarians, advisors and scientists visiting farms, who all share responsibility for preventing pathogen transmission.

Live animal transport and disease spread: the public health case for meat and carcass trade

E. Massalin[1], M. Klimczak[1]
[1] Eurogroup for Animals, Rue Ducale 29, 1000 Brussels, Belgium

Live animal transport is a significant, yet often under-recognised, contributor to the spread of infectious diseases transmission, with implications for animal health, public health, antimicrobial resistance (AMR), and livestock management. This presentation synthesizes evidence from peer-reviewed studies, EFSA reports, and outbreak analyses to examine the relationships between live animal transport, stress-induced disease susceptibility, and pathogen spread, and to evaluate the potential impact of alternative trade modalities, such as meat and carcass transport, on these risk pathways. Transport exposes animals to multiple stressors—including feed and water deprivation, confinement, thermal stress, and mixing with animals from different farms—which impair immune function and elevate disease susceptibility. In unweaned calves, transport coincides with the "immunity gap," when maternal antibodies decline before the calf's own immune system is fully developed, amplifying vulnerability. Empirical studies link transport stress with increased incidence of respiratory and enteric diseases, as well as higher mortality. Mixing animals during transport further amplifies pathogen transmission, illustrating the complex interplay between animal management, pathogen dynamics, and human exposure—core components of the One Health framework. Transport stress also has implications for AMR. Increased disease incidence during transport often necessitates antimicrobial treatment: according to a Canadian study on unweaned calves, reported treatment prevalence can reach 60–80%, reflecting substantial antimicrobial exposure. EFSA's scientific opinion on animal welfare during transport identifies handling practices as key drivers of pathogen dissemination, reinforcing the One Health connection between animal welfare, disease spread, and human health risks. From a One Health perspective, alternative trade strategies—particularly shifting to meat and carcass transport—may reduce these risks. Unlike live animal transport, carcass transport removes many direct pathways for pathogen amplification. Proper chilling and handling in meat supply chains reduces bacterial growth and limits viral transmission potential. European case studies illustrate the vulnerabilities of live animal trade: disruptions from disease alerts, such as foot-and-mouth disease outbreaks, and reconsideration of large-scale calf imports highlight the biosecurity challenges posed by live transport. This presentation highlights that reducing long-distance live animal transport could support animal welfare, mitigate disease spread, and potentially reduce the need for therapeutic antimicrobial use. Through a One Health lens, the findings indicate that prioritizing meat and carcass trade can strengthen connections between animal health, public health, and sustainable livestock management, underscoring how transport practices influence the health of animals, humans, and ecosystems.

Toward oral African swine fever vaccines: Harmonized evaluation and strategy optimization

T. Holzum[1], V. Friedrichs[1], U. Blohm[1], M. Beer[1], S. Blome[1], A. Schäfer[1]
[1] Friedrich-Loeffler-Institut, Südufer 10, 17493 Greifswald - Insel Riems, Germany

Keywords: African swine fever virus, live-attenuated vaccine candidates, oral administration, bait vaccination, harmonized infection models The African swine fever virus (ASFV) causes African swine fever, a severe disease with hemorrhagic-like fever and high mortality in suid species. African swine fever has developed into a global panzootic, affecting wild boar populations and the pig industry. Despite extensive biosafety measures and surveillance programs, ASFV control remains challenging. Eurasian wild boar act both as a reservoir of infection and as a species at risk for virus spread. Vaccination could serve as a crucial tool for containment, yet effective immunization of wild boar is only feasible via oral administration through baits. Although several live-attenuated vaccine candidates are promising, no widely approved vaccine is yet available for field use, and comprehensive data on oral ASFV vaccination strategies remain limited. Within an EU-funded research consortium, a harmonized multi-center study was conducted to standardize methods and readouts, and to compare three oral vaccine candidates. Therefore, domestic pigs were orally immunized with one of the three live-attenuated strains “ASFV-G-ΔI177L”, “ASFV-G-ΔMGF”, and “ASFV-G-Δ9GL/ΔUK”, followed by a challenge with the highly virulent ASFV strain “Armenia08”. Clinical signs, viral replication, and serological responses were monitored. Vaccination was well tolerated but general response rates were low. The best-performing candidate, “ASFV-G-ΔI177L”, achieved seroconversion in 20% of animals, with all responders fully protected. Building on these results, “ASFV-G-ΔI177L” was further tested in an optimization study using increased inoculation doses, adjuvant supplementation, and modified bait formulations. A ten-fold increase in vaccine dose raised seroconversion to 80%, while combining higher doses with walnut shell-shred baits or adjuvants achieved rates of 40%. The findings underscore the protective potential of the oral vaccine candidate and highlight the need for continued refinement of vaccine formulations and delivery systems to achieve an efficacious oral ASFV vaccine.

Staphylococcus aureus at the Wildlife–Livestock Interface: Occurrence and Genomic Characterization in Northern German Production Systems

R. H. Mateus-Vargas[1], I. Grafelmann[1], K. Büter[1], T. Fenker[1], J. Tetens[1], J. A. Hammerl[2], T. Lienen[2]
[1] University of Göttingen, Department of Animal Sciences, Burckhardtweg 2, 37077 Göttingen, Germany, [2] German Federal Institute for Risk Assessment, Department Biological Safety, Diedersdorfer Weg 1, 12277 Berlin, Germany

Introduction: Wildlife plays an important role in the maintenance and spread of endemic as well as emerging infectious diseases. The outbreak and continued spread of epizooties in Germany have highlighted the risks and challenges associated with disease control at the wildlife–livestock interface. At the same time, livestock production systems are becoming increasingly diverse, with growing interest in less intensive and more extensive husbandry systems. This development raises the question of which biosecurity measures, considering the structural characteristics of farms, are effective in preventing the introduction and spread of infectious pathogens. The aim of this study was to investigate the occurrence and genetic characteristics of staphylococci as microbiologic indicators, with particular emphasis on methicillin-resistant Staphylococcus aureus (MRSA), in huntable wildlife species and livestock sharing the same habitat. Material and Methods: Three locations in livestock-dense regions of northern Germany were selected for the investigation. A total of 14 farms were included, representing cattle, sheep, swine, and poultry production systems. Cattle farms included both intensive and extensive management systems. Sampling was conducted twice on each farm and throughout one hunting season for wildlife. Nasal swabs were collected from cattle and sheep, while boot swabs were used in intensive pig and laying hen production systems. Wildlife samples consisted of nasal swabs taken immediately after hunting. Recovered isolates were further subjected to in-depth characterization, including whole-genome sequencing. Results: In total, 127 wild animals were sampled, including roe deer (n = 59), wild boar (n = 23), fallow deer (n = 21), and European hare (n = 24). Although MRSA isolates were obtained from livestock or farm environments, no wildlife samples tested positive for MRSA. However, S. aureus was detected in several wildlife species, including roe deer (n = 24), wild boar (n = 11), fallow deer (n = 11), and European hare (n = 13). Genomic characterization revealed various spa types with only a few shared genotypes between wildlife and livestock. Discussion: The results do not allow a direct conclusion that extensive livestock systems facilitate the circulation of S. aureus between wildlife and livestock. However, some examples suggest a potentially increased risk of exchange in such systems. The intensity and duration of contact between wildlife and livestock may play an important role in shaping transmission dynamics. These findings contribute to a better understanding of pathogen circulation in shared habitats and support the development of targeted biosecurity measures in diverse livestock production systems.

Identifying the immunocompetence markers at weaning to predict vaccine response and persistence in pigs

A. A. M. Sabuj[1], C. Denis[1], J. Estellé[1], C. Rogel-Gaillard[1], M. H. Pinard-Van Der Laan[1], F. Blanc[1]
[1] Université Paris Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy-en-Josas, France

Identifying biomarkers of immunocompetence that predict vaccine response is crucial for preventing diseases, reducing antibiotic use, and enhancing vaccine efficacy in pigs. In this study, we aimed to identify immune markers measured at weaning (28 days of age) that could predict long-term antibody response and their persistence following vaccination against Mycoplasma hyopneumoniae (MH) and Influenza A virus (IAV) in pigs. We also investigated whether there were common predictive markers between the two vaccines. A cohort of 400 Large White pigs was vaccinated against MH (n=200) and IAV (n=200) at weaning and received a booster 21 days later. Vaccine responses were evaluated by measuring serum-specific antibody (Ab) levels against the pathogen at 28-, 35-, and 118-days post-vaccination (dpv). For each vaccine, the long-term response was classified as positive or negative based on antibody titre at 118 dpv. Antibody persistence was determined by calculating the decline from the peak titre (at 28 or 35 dpv) to the titre at 118 dpv, and animals were categorized as persistent or non-persistent. At weaning, a total of 58 key immune traits, including blood cell composition, hematocrit, plasma coloration, immunoglobulins, natural antibodies, electrophoretic protein profiles, enzymatic activities, C-reactive protein (CRP), and vitamin D, were measured to identify potential predictors of vaccine response. To evaluate predictive performance, we first applied sparse Partial Least Squares Discriminant Analysis (sPLS-DA) to identify the most informative markers using a tuning procedure. The markers selected through this process were subsequently used to build the final PLS-DA classification models. For MH vaccination, PLS-DA models achieved cross-validated accuracies of around 67.1% (AUC = 0.74) for long-term response and 66.6% (AUC = 0.71) for persistence classification. For IAV vaccination, the models reached accuracies of 66.4% (AUC = 0.71) for long-term response and 64.1% (AUC = 0.68) for persistence. Analysis of shared predictors indicated partially overlapping immune markers across vaccines. For long-term classification, mean corpuscular hemoglobin concentration (MCHC) and neutrophil percentage were consistently associated with a negative response in both MH and IAV. In contrast, hematocrit, plateletcrit (PCT), platelet count, and natural antibodies were consistently associated with positive responses. CRP exhibited opposite directional associations between vaccines. For persistent classification, vitamin D, alpha1 protein concentration, platelet count, and PCT were consistently associated with persistent responses across both vaccines, whereas MCHC and spectral absorbance traits were consistently linked to non-persistent responses. These findings indicate that early-life immuno-hematological traits contribute to variation in long-term vaccine responsiveness and antibody persistence. Incorporating these biomarkers into breeding or management strategies may enhance vaccine efficacy and improve overall herd health and resilience.

Semen storage at 5 °C enables omission of antibiotics in artificial insemination of pigs under field conditions

F. Reckinger[1], A. Riesenbeck[2], A. M. Luther[1], I. K. Maaßen[1], R. Waßmuth[3], D. Waberski[1]
[1] University of Veterinary Medicine Hannover, Unit for Reproductive Medicine, Clinic for Swine and Small Ruminants, Bünteweg 15, 30559 Hannover, Germany, [2] GFS Genossenschaft zur Förderung der Schweinehaltung SCE mbH, Zum Pöpping 29, 59387 Ascheberg, Germany, [3] University of Applied Sciences, Faculty of Agricultural Sciences and Landscape Architecture, Am Krümpel 31, 49090 Osnabrück, Germany

Pigs are the only species in which extended semen doses for artificial insemination (AI) are conventionally stored at 16-18 °C and cryopreservation remains not routinely available. To protect semen from potential harmful bacterial growth at this temperature, antibiotics are added to the semen extender. However, this prophylactic use increases the risk of antimicrobial resistance. With the development of novel cooling methods, despite the chilling sensitivity of boar spermatozoa, it is now possible to preserve semen in a liquid state while minimizing antibiotic use. The aim of this study was to test the semen storage at 5 °C in vitro and in vivo under field conditions as a strategy to reduce antibiotics in semen extenders. For in vitro testing, ejaculates from nine boars were split, diluted in Androstar® Premium semen extender (Minitüb GmbH) and stored at 5 °C or at 17 °C as a control. In a similar setup, the field trial used semen doses from a commercial AI-center to inseminate sows in two customer farms. Monitoring of bacterial count in antibiotic-free semen stored for 144 h revealed that storage at 5 °C effectively inhibits bacterial growth. Cold-stored samples spiked with drug-resistant, spermicidal Serratia marcescens kept bacterial counts below ~10^3 CFU/mL and maintained sperm quality up to 144 h of storage. In contrast, control samples stored at 17 °C showed significantly higher ($p < 0.05$) bacterial loads of > 10^{11} CFU/mL concomitantly with sperm agglutinations and loss of motility. Testing a population of 20 boars in an AI center, each with four consecutive ejaculates, revealed broad eligibility (> 90 % of the boars) for 5 °C semen storage based on sperm motility and membrane integrity. In semen doses of 10 boars used for AI, sperm motility in the 5 °C group was slightly lower than in control (< 5 %), which was significant in a two-way ANOVA ($p = 0.01$). All 5 °C samples met the standard requirements for AI defined by the German Livestock Association (BRS e.V.). The fertility of a total of 579 sows across two different farms was not affected by semen storage temperature, with no differences observed in pregnancy rates ($p = 0.29$, χ^2 test) or in litter size ($p = 0.16$, ANOVA). In conclusion, combining the results of in vitro experiments on bacterial growth and sperm quality with fertility data on customer farms, our findings demonstrate that storage of boar semen at 5 °C is a sperm-friendly and biosafe preservation method suitable for broad boar population. The novel 5 °C semen storage concept provides a sustainable alternative in pig reproduction by enabling the omission of antibiotics in semen extender while maintaining high fertility under field conditions. Supported by the Federal Ministry of Food, Agriculture and Regional Identity (BMLEH) based on a decision of the Parliament of the Federal Republic of Germany and by the Association for Bioeconomy Research (FBF e.V.) Exploration of somatic cell counts in sow colostrum

R. Muns[1], C. Mulvenna[1]
[1] Agri-Food and Biosciences Institute (AFBI), Large Park, BT26 6DR Hillsborough, United Kingdom

Sows can produce 3 to 5kg of colostrum and reach milk yields of above 10kg a day. In a pilot study we studied correlations between somatic cell counts (SCC) and key quality and health indicators. We hypothesized that SCC in sow colostrum would be positively correlated with the presence of pathogenic bacteria. We also hypothesized that SCC would be negatively correlated with colostrum quality. The study was conducted in accordance with UK Animal (Scientific Procedures) Act 1986 legislation. 36 sows (landrace x large white) housed in conventional individual farrowing crates/pens and managed as per commercial standards were used. On the farrowing day, colostrum samples from each sow were collected within 3 h of the onset of farrowing pooling from several teats (teats were cleaned before collection and the first stream of colostrum discarded). Samples were used for bacteriology examination (e.g., Staphylococcus spp., Staphylococcus Aureus, Enterococcus/Streptococcus, Total viable count of mesophilic organisms (TVC), and Total Lactic Acid bacteria (LAB)) and for composition analysis using a Milkoscan Model FT120 (Foss Electric), immunoglobulin G (IgG) content using digital Brix refractometer, and SCC determination using a fluoroscopy based SCC counter (Lactoscan SCC, Milkotronic Ltd.). The first 10 piglets born from each sow were weighed at birth and at 24h (used to calculate colostrum intake as per Devillers et al., 2004) and blood sampling attempted at day 5 of life to measure IgG levels. Statistical analyses were performed using Genstat 24th edition (Version 24.2). Descriptive statistics were calculated for all study variables. A correlation matrix was constructed to evaluate the relationships between SCC and bacteriological parameters, colostrum quality parameters, and IgG concentration in colostrum and blood. Correlation coefficients were estimated using Pearson's method and statistical significance was set at $P < 0.05$. SCC counter readings (x1000) averaged 1,344, range 148 to 14,004. SCC readings were positively correlated with cellular count from the lab/Milkoscan ($P=0.028$, $r=0.42$). Among bacteriology parameters, SCC was only correlated with Enterococcus/Streptococcus ($P=0.003$, $r=-0.54$). SCC readings were negatively correlated with total colostrum intake ($P=0.055$, $r=-0.37$). No further correlations were found between SCC and the recorded parameters. Cellular count from lab/Milkoscan was correlated with TVC ($P=0.004$, $r=0.56$) and LAB ($P=0.032$, $r=0.43$). Staphylococcus aureus was negatively correlated with protein ($P=0.053$, $r=-0.35$), casein B ($P=0.034$, $r=-0.38$), fat ($P=0.039$, $r=-0.37$) and solids-non-fat content ($P=0.011$, $r=-0.44$). Staphylococcus spp. was negatively correlated with fat ($P=0.093$, $r=-0.31$). Piglet serum IgG was correlated with digital Brix refractometer results ($P=0.023$, $r=0.41$). Despite both cellular determinations (i.e., SCC count and cellular count) were highly correlated and in agreement, only results obtained from lab/Milkoscan were positively correlated with bacterial growth (TVC and LAB). Fluoroscopy-based SCC did not yield significant correlations with classical bacteriology though it was negatively correlated with colostrum intake. However, no relationship was found between SCC and serum IgG levels in pigs. Further research is needed to validate SCC determination for sows. Nonetheless, the presence of pathogenic bacteria (i.e., Staphilococcus aureus) was negatively correlated with colostrum quality. Our work has identified links between the presence of bacteria in sow colostrum and its quality, with potential implications for piglet health. Further research is needed to better understand the implications such links could have for immunity transfer and piglet health. References: Devillers et al., 2004. Anim. Sci. 78: 305-313

Elevated blood glucose in late gestation is associated with increased mortality, particularly in gilts

F. R. Dunshea[1,2], R. Clarkson[1], K. Mcdermott[1], M. Magnon[1], S. O'Connell[3]
[1] National Pig Centre, School of Biology, University of Leeds, LS2 9JT Leeds, United Kingdom, [2] School of Agriculture, Food and Ecosystem Sciences, Faculty of Science, The University of Melbourne, 3010 Parkville, Australia, [3] Marigot Ltd, Strand Farm, P43 NN62 Currabinny, Ireland

Low-vitality newborn piglets are at increased risk of being overlain and are less able to access colostrum, substantially reducing their likelihood of survival. These piglets require additional care in the immediate postnatal period. There is increasing evidence that gestational diabetes in sows may lead to perinatal asphyxia which is hypothesised to cause foetal hyperinsulinemia and increased oxygen demand which in turn can lead to chronic hypoxia and vulnerability to intrapartum asphyxia, neonatal hypoglycaemia and mortality. Therefore, the aim of the present study was to determine any relationships between maternal indices of gestational diabetes and piglet growth and survival. Gestating sows (Large white x Landrace) x Danish duroc) were housed under commercial conditions in a dynamic herd. At approximately day 109 of gestation, 145 sows and gilts were weighed, body condition scored and had backfat measurement taken using an ultrasound scanner. The following day sows had a single blood sample taken from the mammary vein for analyses of glucose and insulin concentrations. The average plasma glucose concentration was 4.94±0.163 (mean±SEM) mM with a range of 3.37 to 17.3 mM while plasma insulin concentrations averaged 36.4±7.07 IU/L with a range of 0.03 to 375 IU/L. Regression analyses of sow and litter performance against actual glucose and insulin parameters failed to reveal any significant correlations perhaps because of the very large variations in range and skewness of the data. Therefore, plasma glucose data were categorised into quintiles with 1 being the lowest quintile and 5 the highest quintile and correlation analyses performed. Plasma glucose quintile was positively associated with number born alive and measures of piglet mortality. For example, the number of deaths in the first week ($r=0.16$, $p=0.031$) as well as birth ($r=0.18$, $p=0.016$) and reared litter mortality ($r=0.17$, $p=0.023$) all increased with increasing glucose quintile. Therefore, birth litter mortality increased linearly from 7% to 12% with increasing plasma glucose quintile. Interestingly, this response was most pronounced in gilts where birth litter mortality increased linearly from 0 to 23.5% with increasing glucose concentrations ($r=0.55$, $p=0.016$) whereas mortality was relatively constant for older parities ($r=0.076$, $p=0.41$). There were no significant relationships with plasma insulin concentrations. These data demonstrate that there is a wide variation in both plasma glucose and insulin concentrations in late gestating sows and that elevated plasma glucose in late gestation is associated with increased piglet mortality, particularly in gilts.

Aligning veterinary recommendations, farmer adoption, and costs of preventive measures for production diseases in Danish dairy herds

O. U. Lønberg-Jensen[1], V. M. Thorup[1], S. Østergaard[1]
[1] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark

Dairy cattle productivity has increased over the last 50 years. This brings each cow under more stress, increasing her susceptibility to disease. Diseases in dairy cows represent inefficiencies of economic and environmental impacts due to losses in feed intake, productivity, and longevity. Total costs of disease can be understood as the sum of failure cost (FC) and preventive cost (PC). Farmers' decisions are in part driven by economic incentives, but they tend to underestimate FC, leading to underuse of preventive measures (PM) from a financial perspective. We examined the PM and PC associated with lameness, mastitis and metabolic diseases. We aimed to obtain lists of PM ranked by veterinarians and farmers, to find whether the respondents in each group agreed on the ranking, and whether the farmers pay more for PM ranked higher based on PC. We surveyed 147 veterinarians, followed by interviews with 22 dairy farmers. The survey included 156 PM-disease complex combinations. For each combination, the veterinarians assessed the PM effect on the disease complex in 6 categories: Don't know, None, Some, Great, Conclusive, or Indirect. Farmers assessed the top 3 PM implemented on their farm within each disease complex. They provided an estimate of investments, labour time (LT) and operational cost (OC) of each PM. The PM assessed by the farmers were extracted from the interviews and treated such that measures with no information or on-farm implementation were excluded. Preventive measures where all of the investments, LT and OC could be split into separate measures were split, and separate measures that included the same costs were merged. The interrater agreement among veterinarians and farmers was found using the proportional overlap method. To compare PC and effect for each PM, the categories "None", "Some", "Great" and "Conclusive" were treated as a Likert scale. To estimate the PC of each measure, cost factors were calculated in EUR per cow per year. Investment costs were calculated with estimates of the investments' lifetimes and labour costs using the collective agreement wage for 2023. PC for each PM is the sum of IC, LC and OC scaled by the degree to which the PM was used for the disease complex and only calculated if all four values were available. Spearman's rank correlation was calculated for PC and effect, and LT and effect, for each disease complex. The ranked PM-lists only included PM's assessed as having "Great" or "Conclusive" effect. The veterinarians' ranked list included 141 PM, and the farmers' 43 PM. For lameness, mastitis and metabolic disease, the PM ranked highest by the veterinarians were systematic claw trimming, proper maintenance and settings of the milking system and rapid correction of diet on signs of problems. For the farmers, it was systematic claw trimming, having clean bedding and phase-feeding of dry cows. The interrater agreement for all PM ranked by veterinarians was $\kappa=0.22\pm0.0024$, for the farmers $\kappa=0.0091\pm0.021$. All Spearman's rank correlations were lower than 0.2, and none of the correlations differed significantly from 0. We concluded that interrater agreement within veterinarians' and farmers' assessments of PM was low. The farmers had different frames of reference for assessing the PM efficiency as they manage herds with different characteristics. There was no correlation between PC and the farmers' assessment of the effect on incidence for either lameness, mastitis, or metabolic disease. Farmers do not pay more for PM ranked higher based on the PC. Use of better decision support tools could benefit farmers in choosing the right PM's.

Mastitis in sows and its implications for colostrum quality

R. Muns[1], C. Mulvenna[1]
[1] Agri-Food and Biosciences Institute (AFBI), Large Park, BT26 6DR Hillsborough, United Kingdom

Mastitis in sows is frequently mentioned but has received little research attention in the past years. In a pilot study, we assessed the presence of mastitis in sows and we hypothesized that mastitis would be linked to the presence of pathogenic bacteria and to colostrum quality. We also hypothesized that mastitis would negatively effect piglet pre-weaning growth. The study was conducted at AFBI pig research farm in accordance with UK Animal (Scientific Procedures) Act 1986 legislation. 36 sows (landrace x large white) and their piglets (only the first 10 piglets born were monitored) housed in conventional individual farrowing crates/pens were used. On the farrowing day, sows were assessed for mastitis with a score adapted from Rosengart et al. (2021) based on formation/regression, redness, consistency, presence of nodes and painfulness of the udder. Colostrum samples from each sow were collected within 3 h after the start of farrowing, pooling from several teats (teats were cleaned before collection and the first stream of colostrum discarded). Colostrum was analysed for composition (protein, fat, lactose, and total solids) using a Milkoscan Model FT120 (Foss Electric) and for classical bacteriology: colony formation units (CFU/ml) of Staphylococcus spp., Staphylococcus aureus, Enterococcus/Streptococcus, total viable count of mesophilic organisms (TVC) and total lactic acid bacteria (LAB). In addition, presence of somatic cell counts (SCC) was determined using a fluoroscopy-based SCC counter (Lactoscan SCC, Milkotronic Ltd.). Piglets from sows were weighed at 24h after birth and at weaning (28 days), and blood sampling was attempted on day 5 of life for immunoglobulin G (IgG) serum determinations. Statistical analyses were conducted using Genstat (24th edition, version 24.1). Data were analysed using separate linear mixed models fitted by Restricted Maximum Likelihood (REML) to evaluate the association between sow mastitis score, colostrum composition and piglet performance. All variables included parity and sow body weight as covariate when significant, and piglet body weight at weaning also included piglet body weight at 24 h as covariate. Effects were considered significant at $P < 0.05$. Total mastitis score ranged from 0 to 5, though sows were finally classified into: 0, 1, 2 and ≥3. Nonetheless, 22% of the sows (n=8) had a score of ≥3 and only 19.4% had a score of 0 (n=7). There were 10 sows with a score of 1 and 11 sows with a score of 2. No purulent discharge or 'no feeding' were documented, only 2 sows showed painful reaction to udder touch and all sows completed lactation. Mastitis score had no significant effect on the presence of bacteria ($P>0.05$), though it is worth mention that sows with score ≥3 had numerically almost twice the amount of TVC (0.644 and 1.188 CFU/ml, respectively) and four times the amount of Enterococcus/Streptococcus (0.291 and 1.416 CFU/ml, respectively) than sows with score = 0. Similarly, mastitis score had no significant effect on colostrum composition. Finally, piglet weight at 24h (av. 1.38 ± 0.134kg) and weaning (av. 8.24 ± 0.618kg) did not differ among groups ($P>0.05$, respectively). Presence of mastitis was not linked to the presence of bacteria in sow colostrum. Similarly, presence of mastitis did not affect piglet body weight at weaning, although our data was limited to the first 10 piglets born as opposed to the whole litter. The lack of severe cases of mastitis could explain the lack of differences observed. Nonetheless, a high proportion of sows had some degree of mastitis. Further research with increased number of sows would be necessary to properly quantify mastitis incidence and its implications when presented in more sever forms. References: Rosengart et al., 2021. Agriculture 11, 1013

Assessment of the economic impact of swine influenza on Japanese swine commercial farms

T. Suzuki[1], J. Mine[2], K. Miayzawa[2], Y. Uchida[2], Y. Mizoguchi[1], Y. Sasaki[1]
[1] Meiji University, Graduate School of Agriculture, 1-1-1, Higashi-Mita, Tamaku, 214-8571 Kawasaki, Japan,
[2] National Institute of Animal Health, National Agriculture and Food Research Organization, 3-1-5, Kanondai, 305-0856 Tsukuba, Japan

Background: Swine influenza is a respiratory disease caused by influenza A viruses of swine (IAV-S), which is one of the major respiratory pathogens affecting pigs in the world. The virus typically spreads rapidly through a susceptible population due to its high transmissibility and the short incubation period that precedes virus shedding. Infection results in clinical signs of fever and coughing, which leads to decreasing productivity and substantial financial losses. However, no study has yet quantified the economic losses of IAV-S in Japanese swine commercial farms. Therefore, the objective was to quantify the economic impact of IAV-S infection on Japanese swine commercial farms using a stochastic simulation model. Methods: This study collected data from 11 farrow-to-finish commercial farms in Japan. Active surveillance was performed in July 2024, October 2024, and January 2025 to collect nasal swab samples that were randomly collected from 30 weaned pigs by veterinarians on each farm. The samples were examined for the presence of IAV-S by real-time RT-PCR. Farms were classified into two groups based on the frequency of IAV-S detection. Of the 11 farms, five farms had at least one IAV-S positive sample in all three surveillance, defined as high IAV-S farms, six farms had at least one IAV-S positive sample in zero, one or two surveillance, defined as low IAV-S farms. In this study, the economic impact is expressed in annual margin over feed cost per sow (MOFC), which was estimated by subtracting annual feed cost of marketed pigs per sow from annual revenue of marketed pigs per sow. A Monte Carlo stochastic simulation modeling with @RISK software was used to estimate MOFC under two scenarios: IAV-S high and IAV-S low farms. For each IAV-S status scenario, probability distributions were fitted to the observed data using @RISK's distribution fitting functions. Each scenario was simulated using 10,000 Monte Carlo iterations to generate the distribution of MOFC. Economic unit used in this analysis was Euro (€). In January 2026, the exchange rate is such that €1 equals 185 JPY. Results: The simulation input items based on farm data were post-weaning mortality, vaccine and medication costs per market pig, and carcass based feed conversion ratio. Based on these items and the references data, the simulation output results are as follows. Mean±SD and associated 90% confidence interval (CI, 5 to 95%) of MOFC under the IAV-S low scenario was €3,267±205 and €2,866 to 3,443, whereas those under IAV-S high scenario was €2,774±336 and €2,170 to 3,194. Under IAV-S low scenario, annual revenue of marketed pigs per sow was €6,085±78, feed cost of marketed pigs per sow was €2,817±204, and the number of market pig per sow was 26.5±0.3. Under IAV-S high scenario, these items were €5,518±304, €2,742±338, and 24.1±1.3 pigs, respectively. Discussion & conclusion: This study showed that IAV-S infection damaged economic performance, as IAV-S low farms had higher MOFC than IAV-S high farms. This is because IAV-S low farms had higher annual revenue of marketed pigs per sow, while feed cost of marketed pigs per sow were similar for both farms. Specifically, the lower revenue in IAV-S high farms is attributed to a reduction in the number of market pigs per sow, resulting from higher post-weaning mortality. In conclusion, result from model indicate that IAV-S infection damaged the profitability of Japanese swine commercial farms. Therefore, it is important to prevent IAV-S from spreading and not to ignore its impact on farm management.

Analysis of factors associated with preweaning mortality and cause-specific mortality

T. Sakakura[1], Y. Sasaki[1]
[1] Meiji University, Graduate School of Agriculture, 1-1-1, Higashimita, Tamaku, 214-8571 Kawasaki, Japan

Background: Preweaning mortality in pig production is an important issue from both productivity and animal welfare perspectives. In recent years, increasing litter size associated with genetic improvement may elevate mortality risk through a higher proportion of low birth-weight piglets. Preweaning mortality is a multifactorial problem influenced by maternal characteristics, litter size, birth weight, management-related factors, and environmental conditions. However, the determinants of cause-specific mortality under commercial production conditions remain insufficiently characterized. This study analyzed factors associated with preweaning and cause-specific mortality using production records from commercial swine farms in Japan. Material and Methods: Farrowing records (n = 22,418) collected between 2012 and 2015 from four commercial farrow-to-finish farms in Japan were analyzed. Three mortality outcomes—preweaning mortality, crushing mortality, and weakness-related mortality—were analyzed using separate binomial generalized linear mixed models with a logit link function, including sow ID as a random effect. Preweaning mortality was defined as the number of piglets that died during lactation divided by the number of piglets at the start of lactation after cross-fostering. Explanatory variables included parity, gestation length (GL), pigs born alive (PBA), piglet birth weight, cross-fostering, lactation length (LL), and farrowing season. Final models were selected using backward elimination, and statistical significance was declared at $P < 0.05$. Results: The mean ± SD rates for overall preweaning, crushing, and weakness-related mortality were 9.1±12.3%, 4.1±7.6%, and 2.1±5.9%, respectively. All mortality outcomes were significantly associated with parity, GL, PBA, piglet birth weight, cross-fostering, and farrowing season ($P < 0.05$), but not with LL. Higher rates for all mortality outcomes were observed in litters from high-parity sows, litters with a high PBA, litters with a low birth weight, litters that received fostered piglets, and sows that farrowed between April and June ($P < 0.05$). Regarding GL, a short GL was associated with higher overall and crushing mortality, whereas a long GL was associated with higher weakness-related mortality ($P < 0.05$). Discussion & conclusion: Using large-scale commercial production data, this study identified key determinants of preweaning and cause-specific mortality on Japanese swine farms. Litters with a lower PBA showed a reduced mortality risk, suggesting that larger litters may increase mortality through intensified competition among piglets and greater variability in birth weight. Low birth weight was strongly associated with an increased mortality risk, indicating that birth weight is a fundamental determinant of survival during the lactation period. Litters from high-parity sows may have greater variability in birth weight, which results in higher mortality. The higher mortality in litters that received fostered piglets is likely due to the addition of inactive piglets. Overall, targeted management of these high-risk litters may contribute to reducing preweaning mortality. This study provides quantitative evidence of the multifactorial determinants of preweaning mortality in commercial swine production.

Tricks of the trade: understanding cattle purchasing in the context of an endemic statutory disease and associated control efforts

A. Ferreira[1,2], N. L. Field[1], U. Kenny[3], C. G. Mcaloon[2], J. F. Mee[1], E. J. Murray[1], Á. Regan[4], A. W. Byrne[3]
[1] Teagasc, Animal and Bioscience Research Department, Animal & Grassland Research and Innovation Centre, Moorepark, P61 P302 Fermoy, Ireland, [2] University College Dublin, Centre for Veterinary Epidemiology and Risk Analysis, School of Veterinary Medicine, Belfield, D04 W6F6 Dublin, Ireland, [3] Department of Agriculture, Food and the Marine, One Health Scientific Support Unit, Agriculture House, D02 WK12 Dublin, Ireland, [4] Teagasc, Department of Agri-food Business & Spatial Analysis, Rural Economy and Development Programme, Teagasc Mellows Campus, H65 R718 Athenry, Ireland

Bovine Tuberculosis (bTB) is an endemic infectious disease of cattle in Ireland. Statutory eradication efforts began in the 1950s, but despite considerable progress, eradication has not been achieved. The movement of undetected infected cattle through trade into previously uninfected herds has been identified as an important transmission route between herds. Herds recently released from movement restrictions following the removal of test-positive animals have been shown to be at increased risk of subsequent breakdowns (i.e., detection of bTB within a herd). The limited sensitivity of the intradermal (tuberculin) diagnostic test results in some infected cattle remaining undetected. These animals may continue to spread bTB among herd mates. If such an animal is unintentionally sold, infection may be introduced into the buyer's herd. Thus, purchasing cattle is a known risk factor for disease incursion. Risk-informed and risk-based trading (RBT) has been suggested as a potential mitigation measure, facilitating the informed and responsible trade of cattle. However, as this approach hinges on farmer compliance, farmer acceptability is crucial to its success. Therefore, understanding how bTB is perceived in the context of the broader stressors experienced by farmers may provide policymakers with insights into how/why farmer buying decisions occur, and whether future policies would be accepted or resisted. Irish cattle farmers were recruited using purposive quota and snowball sampling within a qualitative social science framework. Ten dairy and eleven beef suckler farmers were interviewed. Interviews were audio-recorded, anonymised and transcribed. Reflective thematic analysis, following Braun and Clark's six-phase framework, was used to analyse the transcripts. Themes were discussed and refined with a second coder for improved validity. Interviews lasted an average of 19 minutes (range: 10-62). Four themes emerged: (1) the multifaceted nature of cattle purchasing, balancing desirable animal traits, affordability, and the risk of various infectious diseases; (2) the influence of the presence of bTB on purchasing decisions; (3) how farmers' lived experiences shape farmer welfare and influence perceptions of bTB control; and (4) hopes, fears, and adjustments of risk-based trading interventions necessary for improved acceptance by farmers. Cattle purchasing decisions are shaped by farmers' preferences, practical needs, finances, social influences, experience, and the broader political context. Understanding how bTB risk fits among these factors can help explain compliance with bTB risk–informed recommendations. Many farmers want more disease-risk information when purchasing, but support for RBT policies varied widely.

Genetic population structure and genomic associations with coat colour and conformation traits in the endangered Schleswig cold blood horse

S. C. Blomeyer[1], J. Stuhlträger[1], K. F. Stock[2], H. H. Swalve[1]
[1] Martin-Luther-University Halle-Wittenberg, Institute of Agricultural and Nutritional Sciences, Theodor-Lieser-Strasse 11, 06120 Halle (Saale), Germany, [2] IT Solutions for Animal Production (vit), Heinrich-Schroeder-Weg 1, 27283 Verden (Aller), Germany

With an active breeding population of less than 200 animals, the Schleswig coldblood horse is listed as an endangered livestock breed. As part of an ongoing project to support breed conservation while preserving genetic diversity within the closed studbook, the aim of this study was to analyse the variation within the population based on genomic data. Furthermore, available phenotypic information on body measures and owner-declared coat colour were used for a first screening for indications of candidate genes and chromosomal regions for relevant phenotypic traits as defined in the breeding program. Based on collected samples of Schleswig coldblood horses and single nucleotide polymorphism (SNP) genotyping with the Equine80select genotyping array (Illumina), a dataset of 398 horses with genotypes of 81,974 SNP markers was analysed. Body measures height at withers (WH), cannon bone circumference (CBC) and chest circumference (CC) from studbook registrations as well as genotypic and pedigree data were provided by the studbooks via IT Solutions for Animal Production (vit). Information on coat colour was taken from owner questionnaires. After quality control 392 horses with 67,545 SNP marker genotypes remained in the study. The number of genotyped horses among those with phenotypes were 275 for coat colour, 170 for WH and CC, and 171 for CBC. The principal component analysis (PCA) of the genomic datasets using PLINK implied clustering of within-population genetic variation by popular sires. A genome wide association study (GWAS) was conducted with the BLUPF90 software for each phenotype trait using ssGBLUP with a random animal effect. GWAS revealed a region on ECA 3 strongly associated with base coat colour. The region contains the MC1R gene, which is known to affect coat colour. GWAS for CBC implied an involvement of the ZFAT gene on ECA 9, previously reported for its influence on conformation traits in Thoroughbred and Swiss Franches-Montagne horses. Furthermore, putative regions associated with WH and CC were located on ECA 1 and ECA 15, but not in the well described region of LCORL on ECA 3. The results contribute to the limited knowledge on the genome of coldblood horses and indicate challenges that may arise when working with data from small populations of rare breeds. Methods for characterization of small breeds, tools for optimal suggestions of matings to preserve genetic diversity within breed, and potential associations of chromosomal regions with phenotypic traits are subject to further ongoing research.

Genetic investigations of the roan coat color in Icelandic horses: Population analyses and candidate variants on ECA3

K. Voß[1], I. Blaj[1], D. Becker[2], G. Thaller[1]
[1] Institute of Animal Breeding and Husbandry - Kiel University, Hermann-Rodewald-Str. 6, 24098 Kiel, Germany, [2] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

Roan is a coat color phenotype characterized by an intermixture of white and pigmented hairs on the body, while head and distal limbs remain unaffected. In several livestock species, roan is associated with variants in KIT or KITLG and may show pleiotropic effects, including sub-lethality or reproductive disorders. In horses, roan has been suspected to be homozygous lethal, although the causative mutation is still unknown. Given the documented health implications in other species, elucidating the genetic basis of roan in horses is relevant not only for fundamental research in coat color genetics, but also for animal health and welfare, particularly regarding breeding regulations aiming to avoid hereditary defects (e.g.§11b German Animal Welfare Act), and for evidence-based breeding strategies. This project integrates complementary approaches to (i) assess the population status of roan in Icelandic horses and statistically evaluate mating outcomes with respect to the lethality hypothesis, and (ii) identify candidate variants on equine chromosome 3 (ECA3) associated with the phenotype. The Icelandic horse represents a closed population with documented pure breeding for over one thousand years and an explicit breeding objective to preserve a broad spectrum of coat colors, underlining the particular relevance of roan for this breed. Using data from WorldFengur, the official international studbook for Icelandic horses, descriptive statistical analyses were conducted. The total number of Icelandic horses currently registered as roan amounts to 3,232, corresponding to approximately 0.5% of the global population. Evaluation of roan × non-roan matings (n = 3,940) confirmed dominant inheritance. Analysis of roan × roan matings (n = 103) did not support the hypothesis of homozygous lethality, as offspring ratios were consistent with Mendelian expectations and viable homozygous individuals were identified. In a first molecular approach, all 21 exons of KIT and adjacent intronic regions were sequenced in 30 roan and 23 non-roan Icelandic horses. Several variants showed significant association with the roan phenotype; however, none could be confirmed as causative. Nevertheless, the localization of associated variants within and near KIT further supported the hypothesis that roan in Icelandic horses maps to the ECA3 region encompassing this gene. Subsequently, whole-genome sequencing was performed in two roan Icelandic horses (one heterozygous, one marker-tested homozygous). Variant filtering focused on the candidate region on ECA3 (78–82 Mb) and was complemented by sequence data from additional Icelandic horses and roan and non-roan individuals of multiple breeds. Two filtering strategies were applied: (i) identification of a common roan-associated variant across breeds and (ii) detection of an Icelandic-horse-specific variant, indicating genetic heterogeneity. Both approaches revealed promising candidate variants near KIT. A structural Indel, initially considered a potential marker for roan in Icelandic horses, could not be validated after targeted resequencing in an extended Icelandic horse sample set. In conclusion, the combined population-based and molecular analyses provide evidence against homozygous lethality of roan in Icelandic horses and support linkage of the phenotype to the KIT region on ECA3. The absence of a confirmed shared causative variant across breeds suggests genetic heterogeneity of roan in horses. These findings contribute to understanding equine pigmentation genetics and provide a scientific basis for responsible, welfare-oriented breeding decisions.

Towards a comprehensive screening approach for detecting gene doping in racehorses and sport horses by targeting common and intrinsic plasmid sequences

A. Paz[1,2], S. Dhorne-Pollet[1], B. Loup[2], F. André[2], P. Garcia[2], L. Bailly-Chouriberry[2], E. Barrey[1]
[1] Université Paris-Saclay, INRAE, AgroParisTech, UMR1313 GABI, All. de Vilvert, 78350 Jouy-en-Josas, France, [2] GIE LCH, Laboratoire des Courses Hippiques, Research and Innovation, 15 rue de Paradis, 91370 Verrières-le-Buisson, France

The rapid evolution of biotechnology and gene therapy may unfortunately facilitate the emergence of gene doping. In horse racing and equestrian sports, this practice, defined as the use of genetic tools to modify the genome, its expression or its regulation, to enhance the individual's performance, is prohibited by the International Federation of Horseracing Authorities (IFHA) and the International Equestrian Federation (FEI). One of the main methods likely to be misused is the use of eukaryotic expression plasmids, as they are easy to produce, customisable, and capable of carrying a wide range of performance transgenes. [1-3]. Current detection methods are primarily based on the specific identification of transgene sequences, however if the sequence is unknown or modified, doping may go undetected [4-5]. The aim of this study was to overcome this limitation by developing an untargeted transgene screening approach based on plasmid detection. A database of 349 mammalian expression plasmids was compiled, enabling the identification, through in silico sequence analysis, of four consensus sequences: the ampicillin resistance gene (AmpR), the cytomegalovirus promoter (pCMV), and two unannotated plasmid backbone sequence located between functional element (named IF1 and IF2). Together these targets covered 100% of the plasmids in the database. A set of PCR hydrolysis probe assays targeting these sequences was developed and demonstrated excellent efficiency [97.8% – 100.5%], linearity ($R^2 > 0.99$) and robustness, as assessed by inter- and intra-day %CV, matrix effect and extraction yield in sample from 30 horses. By determining a screening cut-off value using statistical ROC curve analysis, the detection method was able to discriminate plasmid signals from background noise in 100% of the suspicious plasma samples down to 1,200 copies/mL. Following administration of the pcDNA3.1 plasmid containing AmpR, pCMV, IF1, and IF2 to a horse, all four targets remained detectable for up to 48 hours using qPCR and dPCR, demonstrating proof of concept in an in vivo application. To explore potential explanations following the observation of some amplification signals with very high Cq values in a few plasma samples not supplemented with plasmids, an inventory of circulating cell-free DNA (ccfDNA) in horses will be conducted using long-read sequencing on the PromethION 2 Solo benchtop device, before and after exercise performed by the animals. This will enable the characterization of endogenous circulating genetic material in horses. Overall, this work presents a sensitive, reliable, and transgene-independent method which strengthens plasmid doping detection, reinforces gene doping control, and enables a substantially improved characterisation of the genetic material circulating in the equine plasma matrix. Wearable-based continuous monitoring and omics profiling of thermal and exercise resilience in Thoroughbred racehorses

S. Mecocci[1], R. Ratto[2], E. Porzio[2], M. Pepe[2,4], G. Chillemi[3,5], E. Chiaradia[2,4], F. Beccati[2,4], K. Cappelli[2,4]
[1] University of Tuscia, Department for Innovation in Biological, Agro-Food and Forest Systems (DIBAF), Via San Camillo De Lellis, snc, 01100 Viterbo, Italy, [2] University of Perugia, Department of Veterinary Medicine, Via San Costanzo, 4, 06126 Perugia, Italy, [3] University of Rome, University of Rome "Tor Vergata", Via Cracovia, 50, 00133 Rome, Italy, [4] University of Perugia, Sports Horse Research Center, Via San Costanzo, 4, 06126 Perugia, Italy, [5] National Institute for Infectious Diseases Lazzaro Spallanzani - IRCCS, Bioinformatics Research Unit in Infectious Diseases, Via Portuense, 292, 00149 Rome, Italy

Horses are a valuable model to investigate resilience to combined heat and exercise stress. Heat load and exertion elicit systemic adaptations to maintain thermoregulation, but under strenuous conditions, these mechanisms may become insufficient, increasing maladaptation risk. This study aimed to characterize physiological and molecular responses to heat and exercise stress by integrating continuous wearable monitoring (Equimetre™), hematobiochemical parameters, and circulating microRNA (ci-miRNA) sequencing. Fifty-eight Thoroughbreds from one training centre (Rome, Italy) were monitored during trainer-defined workouts. Ambient temperature and humidity were recorded by Equimetre™ and horses were grouped as COLD <10°C (n=23), INT 10–20°C (thermoneutral; n=17) or HOT ≥20°C (n=18). GNSS/IMU locomotor metrics and ECG-based heart-rate (HR) and recovery indices were collected; rectal temperature was recorded post-exercise. Blood was sampled pre-exercise and 10 min post-exercise for complete blood count and lactate; serum small RNAs were sequenced (Illumina, 75-bp single-end). Group comparisons used ANOVA or Kruskal–Wallis ($p<0.05$). Reads were mapped to miRBase v22.1 and EquCab3; DESeq2 was used for differential expression (FDR<0.05, $|\log_2 FC|\geq 1$). Post-exercise lactate did not differ among environments (~10–11 mmol/L). Rectal temperature tended to be higher in HOT than INT (39.2±0.4 vs 38.8±0.5°C; p=0.065). Mean speed during fast work (Vmean) differed (p=0.015), being lower in HOT than INT, whereas distance, Vmax, stride variables and speed-at-target-HR indices were unchanged. Time >90% HRmax tended to increase in HOT, while HR at 15-min recovery was higher in INT than HOT (p=0.02) and COLD (p=0.04), suggesting delayed recovery when humidity was higher despite thermoneutral temperature. Post-exercise white blood cells (WBC), hemoglobin (HB) and hematocrit (HCT) were higher in HOT than COLD ($p\leq 0.04$), with higher mean cell volume (MCV) and increased monocytes, eosinophils and basophils, consistent with hemoconcentration and stress-related leukocyte mobilization. ci-miRNA differential expression emerged only post-exercise (HOT vs INT), identifying 15 miRNAs. miR-221/miR-326/miR-28 align with immune-cell activation and trafficking, supporting leukocyte shifts; miR-130a/miR-221 with endothelial remodeling and hypoxia signaling, consistent with higher cardiovascular strain and reduced speed efficiency; and miR-23a/miR-375 with metabolic–endocrine stress, coherent with heat-related homeostatic pressure and hemoconcentration. Together, these pathways suggest a coordinated inflammatory–vascular–metabolic response detectable immediately post-exercise. Overall, thermoneutral conditions supported the most favorable performance–physiology balance, whereas early-season warmth increased thermal and cardiovascular load and triggered a distinct post-exercise ci-miRNA signature. This integrated wearable–hematobiochemical–miRNA framework may help track acclimatization, tailor training intensity and support welfare by detecting early signs of maladaptation to thermal stress.

Mitochondrial and genomic factors in equine Recurrent Exertional Rhabdomyolysis

L. Pavlin[1], S. Dhorne-Pollet[1], M. Filipe-Ferreira[1], M. Bernard[1], A. Ricard[1,2], E. Barrey[1]
[1] Université Paris-Saclay, INRAE, AgroParisTech, UMR1313 GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [2] Institut Français du Cheval et de l'Equitation, Pôle Développement, Innovation et Recherche, Avenue du Cadre Noir, 49400 Saumur, France

Introduction: Recurrent Exertional Rhabdomyolysis (RER) is a muscle disorder affecting Standardbred horses, a breed selected for high-speed trotting performance. Affecting approximately 6% of the population[1], RER is characterized by exercise-induced muscle cramping that impairs locomotion. Previous studies[2] have shown moderate heritability in several breeds, including Standardbreds, with heritability estimates ranging between 0.39 and 0.49. Although transcriptomic alterations in metabolism and calcium homeostasis have been reported[3], the underlying genetic determinants of RER remain unknown. We hypothesized that RER has a complex polygenic determinism involving probably both nuclear and mitochondrial genetic variants. Material & Methods: Following ethical approval, 48 French Standardbred horses (25 affected by RER and 23 matched controls) were sampled. Inclusion criteria included regular training for trotting races, age >2 years, at least two confirmed RER episodes for affected horses, and no history of RER for controls. Blood (10 mL) was collected in EDTA tubes, and DNA was extracted and quality-controlled prior to sequencing. Whole-genome sequencing was performed using Illumina paired-end short-read technology (150 bp). Bioinformatic analyses included sequencing quality control, alignment to the EquCab3 reference genome, and nuclear variant calling using GATK4 HaplotypeCaller. Mitochondrial DNA (mtDNA) was analyzed separately using a shifted mitochondrial reference genome to account for mtDNA circularity and haploidy, with variant calling performed using Mutect2 in mitochondrial mode. A non-stringent minimum allele frequency threshold of 1% was applied to both nuclear and mitochondrial datasets to exclude singletons. Variants were annotated using snpEff, and Chi-square tests were used to compare variant frequencies between RER-affected and control horses. Results: Whole-genome sequencing depth averaged 21.7 ± 9.3X. After quality filtering, 98.4% of reads passed quality control, with all FastQC scores exceeding 32. Following MAF filtering, 20.8 million nuclear variants were included in statistical analyses. Among these, 44,460 variants (SNPs and indels) differed significantly between RER and control horses, including 385 predicted to have a high biological impact. Mitochondrial sequencing quality was high (Q > 32), with a mean depth of 280.9 ± 35.2X. A total of 434 mtDNA variants were identified at 410 positions, predominantly SNPs. Forty-two mtDNA variants differed significantly between groups, including three predicted to have high biological impact. Discussion & Conclusion: Whole-genome sequencing quality and mtDNA depth were high, ensuring complete coverage of the mitochondrial genome and consistent with expectations for blood-derived samples. Despite limitations related to sample size and annotation resources, this study provides valuable insights into candidate nuclear and mitochondrial variants associated with RER. Further analyses, including segregation studies, validation by Sanger sequencing and large-scale population genotyping will be required to confirm the best candidate variants. Given the exercise-induced nature of RER, mitochondrial DNA represents a biologically relevant target for investigation. These preliminary findings demonstrate the utility of whole-genome sequencing for characterizing mtDNA variability and identifying all putative genetic factors involved in RER susceptibility. Prevalence of equine missing eyes (Microphthalmia and Anophthalmia) with sex skewed inheritance and parent-of-origin effect

V. Asti[1,2], Å. Gelinder Viklund[1], S. Mikko[1]
[1] Swedish University of Agricultural Sciences, Department of Animal Biosciences, Almas Allé 8, 750 07 Uppsala, Sweden, [2] University of Parma, Department of Veterinary Science, Strada del Taglio 8, 43126 Parma, Italy

Eye diseases encompass a wide range of conditions, with two specifically related to abnormal eye development: anophthalmia, the complete absence of the eye, and microphthalmia, defined as an eye axial length 2 standard deviations below the population mean. These conditions have been reported in humans, with prevalence estimated to be between 0.002% and 0.017%, classifying them as rare diseases. While no conclusive genetic causes have been identified, several factors have been suggested to predispose individuals, including maternal age, Vitamin A deficiency, and infections during pregnancy. In horses, these conditions represent a significant portion of ocular diseases (7-14%), although specific prevalence rates have not been reported. The aims of this study were to estimate the prevalence of missing eyes (Microphthalmia and Anophthalmia) in Swedish Warmblood horses (SWB) and to investigate potential factors contributing to the disease. Information on cases has been recorded since 1997; however, systematic recording began in 2017. Thus, to obtain a realistic representation of prevalence, the study population comprised foals born between 2017 and 2023 (21014) along with their parents. Among those, 44 foals, sired by 28 different stallions, were affected. Analyses investigating the overrepresentation of sire lines among affected families, assessing inbreeding and relatedness, and evaluating the effect of age at mating were carried out in R (version 4.5.0). We estimated the prevalence of missing eyes in SWB to be 0.21%, with a higher proportion of affected females (95%) than males, suggesting that autosomal recessive inheritance or classical X-linked inheritance is unlikely and favouring epistatic interactions between at least two loci. The rates of unilateral and bilateral missing eyes were similar, accounting for 54% and 46%, respectively; all unilateral cases involved the left eye. This laterality might result from random developmental processes, potentially influenced by epigenetic regulation or X-inactivation. Among sires, the ones with at least one affected foal were significantly more related to each other (p-value = 1.47 x 10□□) than sires with no affected foals (IBD = 0.011). Obligate carrier sires were significantly overrepresented among the stallions (p = 7.25×10□□), although no single sire showed a large effect alone. Among female obligate carriers, older age at mating increased the risk of having an affected foal from 17% to 80%. A possible explanation for this pattern may involve age-related biological changes affecting female reproductive biology, such as oocyte quality, epigenetic DNA modifications, increased chromosomal variation, or reduced reproductive efficiency. Equine microphthalmia is a complex disease influenced by multiple factors. Based on our calculations, equine microphthalmia is no longer considered a rare disease. This shift is causing economic losses within the horse sector, and breeding associations should take action to control this disease.

Long-read mitochondrial DNA sequencing for genetic variability analysis in endurance horses

S. Dhorne-Pollet[1], N. Pollet[2], M. Filipe Ferreira[1], C. Robert[3], E. Barrey[1], A. Ricard[1,4]
[1] Université Paris-Saclay, INRAE, AgroParisTech, UMR1313-GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [2] Université Paris-Saclay, CNRS, IRD, Evolution, Génomes, Comportement & Ecologie, 12 rue 128, 91198 Gif-sur-Yvette, France, [3] Ecole Nationale vétérinaire d'Alfort, 7 quater Av. du Général de Gaulle, 94700 Maisons-Alfort, France, [4] Institut Français du Cheval et de l'Equitation, Pôle Développement, Innovation et Recherche, 170 avenue du Cadre noir, 49400 Saumur, France

Introduction: The mitochondrial oxidative potential plays a major role in skeletal muscle metabolism and is a key determinant of individual variation in endurance performance. Therefore, mitochondrial DNA (mtDNA) genetic polymorphisms warrant significant attention in studies of endurance in animals. However, research has largely focused on phylogenetics or haplotype diversity, and only a few investigations have analysed the contribution of mtDNA variants to performance traits. Moreover, studies of horse mtDNA are largely limited to small populations or partial genomic regions. To our knowledge, even fewer studies have combined a comprehensive intraspecific mitochondrial pangenome with GWAS for athletic traits. In a previous study of 430 endurance horses using short-read sequencing, mitochondrial GWAS identified 1,268 SNPs, 15 of which were significantly associated with endurance traits (raw p-value < 0.01), including average speed and finishing status. The large number of SNPs and alleles per locus highlighted the need to expand the study to a larger cohort to generate the first large-scale equine mitochondrial pangenome and explore mtDNA variants in greater detail. In addition, the horse genome contains a large nuclear insertion of mtDNA (NUMTS), which can confound variant calling accuracy. This motivated the use of a high-performance long-read sequencing methodology to identify mtDNA variants in more horses. Methods: We selected a new cohort of 300 horses to generate the first large-scale equine mitochondrial pangenome. We used long-read sequencing technologies combining nuclear DNA depletion and mtDNA enrichment via multiple displacement amplification (MDA). We optimized the multiplexing step to ensure full coverage, high depth, and cost-effectiveness. Results: We optimized and streamlined the molecular biology protocols to selectively amplify horse mtDNA and sequence it. From the first 108 samples, we achieved complete coverage of mtDNA in all cases, with a median depth of 457 and a median mapping quality of 59.5. We could call variants confidently across all mtDNA features, including the D-loop. Ongoing analyses include mitochondrial GWAS and comprehensive structural and sequence characterisation. Conclusion: Preliminary sequencing and analytical pipelines are complete, and detailed results will be presented at the congress, demonstrating both technical innovation and biological discovery. This integrated approach will identify mtDNA variants linked to endurance and provide novel insights into mitochondrial function, equine health, and athletic performance.

Systemic Transcriptomic Mirroring: Unveiling the Neuro-Muscular Axis and Non-Invasive Biomarkers for Elite Racing Performance in Horses

J. W. Park[1,6], J. M. Kim[2,6], K. S. Lim[3,6], J. E. Park[4,6], D. Shin[5,6]
[1] Jeonbuk National University, Department of Animal Biotechnology, 567 Baekje-daero, Deokjin-gu, 54896 Jeonju, South Korea, [2] Chung-Ang University, Department of Animal Science and Technology, 4726 Seodong-daero, Daedeok-myeon, 17546 Anseong, South Korea, [3] Kongju National University, Department of Animal Resources Science, Daehak-ro 54, Yesan-eup, Yesan-gun, 32439 Chungnam, South Korea, [4] Jeju National University, Department of Animal Biotechnology, 102 Jejudaehak-ro, 63243 Jeju, South Korea, [5] Jeonbuk National University, Department of Agricultural Convergence Technology, 567 Baekje-daero, Deokjin-gu, 54896 Jeonju, South Korea, [6] Korean Society of Animal Science and Technology, The Korean Society of Animal Big Data Research, #1618, 8-13, Gwangpyeong-ro 56-gil, 06367 Seoul, South Korea

Selecting elite Thoroughbreds currently relies on pedigree and phenotypic evaluation, but the underlying molecular architecture remains partially understood due to the invasiveness of skeletal muscle biopsies. This study aimed to identify systemic genomic signatures of racing excellence by integrating skeletal muscle and peripheral blood transcriptomes from 28 high-depth libraries. Using the Jeju horse (Natural Monument No. 347) as an unselected evolutionary baseline, we characterized the derived bioenergetic specialization in Thoroughbreds. Our analysis revealed a significant “transcriptomic mirroring” effect (R=0.63) between muscle and blood, identifying 89 core performance-associated signatures. Weighted Gene Co-expression Network Analysis (WGCNA) pinpointed a primary module (Darkorange2) driven by a synchronized neuro-muscular signaling axis, with key hubs including MAPK3, PHKA2, SBK3, and VAMP2. In silico source tracking (NNLS) mathematically confirmed that muscle-derived transcripts constitute a distinct reservoir (5–15%) within the circulatory system. Notably, blood-based levels of SBK3 and VAMP2 demonstrated near-perfect diagnostic accuracy (AUC = 0.97–1.00) for distinguishing elite runners. Furthermore, cross-breed meta-validation using an independent Arabian horse cohort confirmed PHKA2 as a universal bioenergetic engine ($p<0.001$), while identifying MAPK3 and VAMP2 as Thoroughbred-specific sprinting signatures. These findings validate peripheral blood as a high-fidelity window into intramuscular status, providing a welfare-friendly genomic framework for precision selection in the equine industry.

Circulating miRNAs and biochemical markers to evaluate heat-stress responses in Sicilian horse breeds

M. Carlentini[1], S. Tumino[1,2], A. Antoci[1], G. Chessari[1], A. Criscione[1], S. Bordonaro[1,2], D. Marletta[1,2]
[1] University of Catania, Di3A, Via Santa Sofia, 95123 Catania, Italy, [2] Centro Interuniversitario A.SI.ZO.CA. CLI, Via Santa Sofia, 95123 Catania, Italy

The two Sicilian horse breeds, Sanfratellano (SAN) and Purosangue Orientale (PSO), represent valuable genetic resources adapted to harsh Mediterranean conditions. The analysis of circulating microRNA (miRNA) and biochemical parameters was conducted to establish functional links between gene regulation and physiological adaptation in heat-stress condition. A total of 15 PSO and 6 SAN were monitored during the thermoneutral TT and heat-stress HS seasons. Overall, 42 serum samples were collected and stored at -80°C until use for analysis on circulating miRNA and 84 serum samples, collected at the beginning and end of experimental tests per season, were used for clinical biochemistry. A Linear Mixed Model (LMM) for repeated measures was used to analyse biochemical parameters collected, including breed, season, and breed-season interaction as fixed effects and Temperature Humidity Index (THI) as a covariate. The subject was treated as a random effect to account for repeated measures and significance was assessed using False Discovery Rate (FDR) adjusted p-values. The QIAseq miRNA library kit was used for library preparation, followed by sequencing on the Illumina NovaSeq X Plus platform in 150-bp single-end mode. After extracting unique molecular identifiers (UMIs) and subsequent trimming, an average of 20.4 million high-quality reads were obtained per sample. About 1.18 million reads mapped to miRNAs. Additional small RNA classes were detected, including tRNAs (about 11.0 million reads), rRNAs (about 1.31 million reads), and other non-coding RNAs. Following DESeq2 normalization, miRNAs with a FDR lower than 0.05 and |log2 fold change| $\geq$ 1 were considered significantly differentially expressed. A significant effect of breed was observed for several biochemical parameters, with the SAN breed exhibiting higher values than PSO for Glutamate-Oxaloacetate Transaminase (GOT) and Gamma-Glutamyl Transferase (GGT), suggesting increased hepatic/oxidative activation and a more marked variation in some electrolytes and minerals (Mg,Ca). PSO generally showed a more stable and less pronounced profile for enzymes indicative of metabolic stress. Notably, GOT, GGT, alkaline phosphatase (ALP), total proteins and electrolytes counts were higher in the HS season than in the TT season, likely reflecting seasonal systemic response to heat load in both breeds. In the breed-season interaction SAN showed a more marked increase in liver enzyme values (GOT, GGT, LDH), Mg and Ca values during HS than in TT season, while in PSO a modest variation was observed indicating a minor biochemical response to heat-stress. Differential expression analyses across HS and TT seasons identified 23 (PSO) and 40 (SAN) differentially expressed miRNAs associated with the regulation of energy metabolism, inflammatory processes and immune response. PSO showed a more targeted modulation of immune-metabolic and stress adaptation pathways than SAN, which reported a more pronounced response. Furthermore, 5 miRNAs shared between breeds with opposite trends (upregulated in PSO and downregulated in SAN), indicating different post-transcriptional regulation of the mechanisms involved in the heat-stress response. This approach, integrating miRNA and biochemical markers, allowed the identification of season-associated genetic modulation patterns potentially linked to heat-stress adaptation mechanisms, showing greater physiological resilience in the HS season of PSO than SAN. This research was funded by “Progetto EquiDiv”-Istituto Incremento Ippico per la Sicilia and PRIN 2022-“ECOS”.

Selective breeding in insects - state of the art and prospects

H. M. Nielsen[1], T. Nygård Kristensen[1,2], G. Gebreyesus[1], H. G. Tariku[1,3], R. M. Zaalberg[1], L. S. Hansen[1]
[1] Aarhus University, Center for Quantitative Genetics and Genomics, C.F. Møllers Alle 3, 8000 Århus, Denmark, [2] Aalborg University, Section for Bioscience and Engineering, Department of Chemistry and Bioscience, Fredrik Bajers Vej 7H, 9220 Ålborg, Denmark, [3] Makerere University, School of Agricultural Sciences, Department of Animal and Range Sciences, P. O. Box, 7062 Kampala, Uganda

Advances in insect selective breeding and quantitative genetics are reshaping the potential for commercial production systems for insects used as food and feed. Recent reviews outline a selective breeding framework adapted to insects, including definition of breeding objectives, standardized phenotyping protocols, mating designs, and estimation of genetic parameters. This framework also emphasizes the necessity of mitigating inbreeding and maintaining genetic diversity in commercial insect populations. Insect species used for food and feed typically have short generation intervals. This provides benefits in terms of fast genetic progress, but it also complicates breeding as little time is available for phenotyping. Studies on insect species, such as the house fly (Musca domestica), the black soldier fly (Hermetia illucens), and the yellow mealworm (Tenebrio molitor), demonstrate the presence of additive genetic variance across relevant production traits such as survival, development time, and larval biomass. High-throughput phenotyping of many individuals simultaneously is critical for estimation of reliable heritabilities, variance components, and genetic correlations in these species, where environmental variance constitutes a large component of the phenotypic variation. Breeding programs must be designed specifically for each species, taking their species-specific reproduction and rearing requirements into consideration. Demonstrated genetic gains in insect populations confirm the feasibility and economic relevance of structured genetic improvement programs in insects. Yet they also reveal that there is room for improvement when it comes to selective breeding strategies and population management. Collectively, these developments establish selective breeding in insect production as an emergent discipline positioned to optimize future insect-based food and feed systems.

Global patterns of genomic variation in ten domesticated Black Soldier Fly (Hermetia illucens) strains

The black soldier fly (BSF, Hermetia illucens) has positioned itself rapidly as a crucial species in sustainable biomass conversion, yet the genetic context underlying the performance differences of domesticated BSF strains remains poorly characterized. To broaden our current understanding of BSF population genomics, we analyzed genome-wide variation across ten laboratory-maintained domesticated populations originating from Europe (n = 4), Africa (n = 3), and Oceania (n = 3). Our aims were to characterize genetic diversity, quantify differentiation, and uncover major population structure patterns across these lineages. For each population, 20 individuals were sequenced using Illumina paired-end 150 bp whole-genome sequencing. Following stringent filtering and SNP discovery against the iHerIll2.2 BSF reference assembly, we quantified intra-population diversity, evaluated levels of genetic differentiation, and inferred evolutionary relationships. Population structure and relatedness were assessed through PCA, admixture modelling, and phylogenomic reconstructions. Additionally, scans for putative selection signals and runs of homozygosity were performed to compare these populations. The comparative analyses reveal substantial heterogeneity in genetic diversity and structure among globally sourced BSF strains, reflecting their distinct geographic origins and domestication trajectories. This work delivers one of the most comprehensive genomic assessments of BSF populations to date and provides a valuable foundation for future efforts in selective breeding, strain management, and optimization of bioconversion performance.

Estimating variance components and breeding values in honeybee populations via spatially aware simulation

N. Pustovrh[3], G. Gorjanc[2], J. Obsteter[1]
[1] Agricultural Insitute of Slovenia, Hacquetova ulica 17, 1000 Ljubljana, Slovenia, [2] The Roslin Institute, University of Edinburgh, Easter Bush Midlothian, EH25 9RG Edinburgh, United Kingdom, [3] University of Ljubljana, Kongresni trg 12, 1000 Ljubljana, Slovenia

Simulations are an essential tool in animal breeding for time- and cost-efficient hypothesis testing. The key feature of breeding programme or population simulators is the temporal component of the simulation – we select the best individuals as the parents of the next generation to advance the improved genetic stock and increase genetic gain. In contrast, the spatial component is usually not considered or enabled by the simulators. Larger managed livestock is in general not able to freely move or mate, hence there might be no need to account for the animals' position in space beyond belonging to a certain management group, such as a herd. However, the spatial component becomes an important factor in the simulation of populations that can move around the space and whose environment cannot be completely controlled. The spatial component has two parts to it. The first one is the spatial genetic component, where relatedness depends on the distance between organisms, and the second is the environmental component, where the environment continuously changes through space. In honeybees, there are also many populations that collect phenotypes, but lack the pedigree information or at least the paternal side. This can be because part of the population is open-mated, but still recorded, or because there is not pedigree keeping. Such populations need to rely on genomic information for relatedness calculation. The aim of this work was thus to evaluate the choice of model for genomic evaluation of variance components and breeding values in an open-mated honeybee population via spatially-aware simulation. We simulated the population with the SIMplyBee R package. The simulation mirrored a yearly cycle of a managed, yet open-mated honeybee population. In the simulation, every colony was assigned a location and spatial mating was implemented by considering mating partners in a 5km radius. We simulated a single phenotype composed by the queen and worker trait. The phenotype was computed as the sum of queen and worker trait genetic effect, non-genetic systematic effect, spatial effect, and a residual. The spatial effect was simulated as a continuous spatial variation with R package INLA. The estimation models included the same components using an alternative Bayesian approach (Integrated Nested Laplace Approximation with Stochastic Partial Differential Equation, INLA-SPDE). The estimation scenarios varied the genotyping strategy by collecting i) only queen genotypes; ii) pooled genotypes of n workers per colony with varying n; and iii) queen and pooled workers genotypes. The models were evaluated by their performance in estimating variance components and breeding values. We used the continuous ranked probability score metric to evaluate the accuracy of estimated variance components by comparing the realised variance to the variance obtained by sampling from the posterior distribution. We estimated the accuracy of breeding values by correlating them with the true genetic value. Our results shed light into the sampling scheme required to reliably estimate quantitative genetic parameters in open-mated honeybee populations and will therefore guide future research as well as breeding efforts.

Integrative multi-omics analysis reveals genetic variants associated with growth traits in the superworm (Zophobas atratus)

A. Sode[1], N. Jeßberger[2], N. T. Grabowski[2], C. Schwennen[3], M. Plötz[2], C. Visscher[3], J. Metzger[1]
[1] Institute of Animal Genomics, Bünteweg 17p, 30599 Hannover, Germany, [2] Institute of Food Quality and Food Safety, Bischofsholer Damm 15, 30173 Hannover, Germany, [3] Institute for Animal Nutrition, Bischofsholer Damm 15, 30173 Hannover, Germany

Abstract: The rising global population and increasing numbers of livestock are expanding the demand for efficient production of protein and other nutrients, creating a need for sustainable alternatives to cover this demand. Edible insects represent a promising future food and feed source due to their high nutritional value, efficient feed conversion, short generation intervals and potentially reducing the carbon footprint. Despite growing interest in insect-based production systems, genomic resources and functional genetic studies remain limited for many commercially relevant species, including the superworm (Zophobas atratus). This research study focuses on the darkling beetle species Z. atratus at the larval stage, aiming to characterize population-level genetic variation and to identify variants associated with growth-related traits, specifically body weight and length. To address this, we applied a multi-omics approach integrating genomics, transcriptomics and 3D epigenomics profiling to advance the functional interpretation of the desired loci and to identify key regulators of developmental pathways during larval growth. In a genome-wide-association-study (GWAS) based on whole-genome sequencing data, we identified SNPs linked to larval body weight and length. Functional prioritization is being achieved by integrating RNA-sequencing and high-throughput chromatin conformation capture (Hi-C) data to assess growth-dependent gene expression (eQTLs) and the spatial chromatin context of GWAS loci within topologically associating domains (TADs). This integrative framework allows the identification of regulatory variants whose genomic position and chromatin modification context suggests a functional impact on growth-related gene expression. In addition, diversity analysis reveals distinct kinship patterns and major genetic clusters within Z. atratus, providing insights into population structure and relatedness. Our work represents the first population-scale and GWAS-based investigation of growth traits in this species. Beyond advancing fundamental insect biology, these insights highlight the translational potential of omics-guided strategies for improving sustainable food and feed systems and addressing global protein demands. This work exemplifies how innovative omics technologies applied to non-traditional model organisms can contribute to translational research with relevance to human and animal health.

On the change of heritability and genetic correlations over time in honeybee breeding

A. Hoppe[1]
[1] Länderinstitut für Bienenkunde Hohen Neuendorf e.V., Friedrich-Engels-Str. 32, 16540 Hohen Neuendorf, Germany

Heritability of a trait within a species is not a fixed biological constant but a population-specific parameter that depends on the genetic architecture and allele frequencies of a defined breeding population at a given time. Accurate estimation of heritability is essential for reliable breeding values estimation and for assessing expected genetic gain. Likewise, precise knowledge of genetic correlations between traits is crucial for the efficiency and predictability of simultaneous selection. As selection alters allele frequencies and genetic variance components, both heritabilities and genetic correlations are expected to change over time.Reliable estimation of genetic parameters requires breeding data of sufficient depth and structure. Broad datasets spanning multiple years increase statistical robustness and reduce sampling variance. Conversely, analyses restricted to shorter time intervals are more sensitive to temporal fluctuations in variance components. This creates an inherent trade-off: extended time horizons support stable parameter estimation, whereas shorter windows allow the detection of dynamic changes in genetic architecture.In this study, we analyse temporal patterns of heritabilities and genetic correlations for key performance and behavioural traits in the A. m. carnica breeding population, including honey yield, gentleness, calmness, swarming inertia, hygienic behaviour (pin test), and Varroa infestation development. The population is characterised by several decades of systematically recorded breeding data (Hoppe et al., 2020, Insects 11:768), enabling estimation of variance components across different temporal scopes and the assessment of their dependence on the selected time span and reference year.Across traits, we identify a consistent biphasic pattern in heritability development. An initial acceleration phase is characterised by increasing heritability, likely reflecting the reduction of environmental variance relative to additive genetic variance and the structuring of the breeding population under directional selection. This is followed by a saturation phase marked by declining heritability, consistent with a reduction in additive genetic variance as favourable alleles approach higher frequencies. Traits with lower initial heritability exhibit a delayed transition into the saturation phase.Genetic correlations show a complementary temporal pattern. In early phases of structured breeding, correlation estimates display comparatively large fluctuations, reflecting unstable covariance structures and sensitivity to sampling and selection effects. Over time, these correlations tend to stabilise and converge toward narrower value ranges, indicating consolidation of the underlying genetic architecture under sustained selection pressure.The results provide a population-genetic interpretation of long-term selection dynamics in the Carnica breeding population. Beyond the specific case studied, the analysis offers methodological guidance for breeding populations with shorter or less comprehensive datasets, particularly regarding the choice of temporal scope for parameter estimation and the interpretation of time-dependent genetic parameters.

Genotype × Environment and the gut microbiome shape Hermetia illucens performance: insights from 14 Lines across three diets

F. Ijdema[1,2], M. Verschaeren[3], L. Broeckx[3], L. Frooninckx[3], S. Van Miert[3], N. Buys[1], R. Meyermans[1], J. De Smet[2]
[1] KU Leuven, Center for Animal Breeding and Genetics, Department of Biosystems, Kasteelpark Arenberg 30, 3001 Leuven, Belgium, [2] KU Leuven, Research group for insect production and processing, Department of Microbial and Molecular Systems, Kleinhoefstraat 4, 2440 Geel, Belgium, [3] Thomas More University of Applied Sciences, Centre of Expertise Sustainable Biomass and Chemistry, Kleinhoefstraat 4, 2440 Geel, Belgium

The black soldier fly (Hermetia illucens) has become an important species for sustainable biomass conversion, yet its performance in rearing systems remains variable. Earlier studies have shown that both substrate and genetic background strongly influence larval growth, feed conversion, and waste reduction. These strain-specific differences are often accompanied by distinct gut microbiome profiles, some of which persist across generations, suggesting that certain microbes may be linked to host lineage. Such patterns point to a more intricate genotype × environment (G×E) interaction than previously assumed, with microbial communities potentially actings as intermediaries connecting substrate conversion, host genetics, and larval performance. To broaden our understanding of these interactions, we expanded our earlier work to eleven geographically diverse BSF populations and three controlled crosses, reared on three contrasting diets commonly used in BSF research and industry. Larval growth was measured daily, and pooled samples were subjected to PacBio long-read microbiome sequencing achieving high taxonomic and functional resolution. Early analyses reveal clear performance differences among strains on the various diets. Even within a single substrate, the microbiomes of different strains retain unique features. These early results suggest that specific bacterial taxa correlate with improved larval growth, hinting at beneficial microbial functions. By combining long-read microbiome sequencing with multi-strain phenotyping, this study aims to identify the microbial and genetic factors that make certain strain–substrate combinations more efficient than others. Ultimately, these insights may support the development of microbiome-aware breeding strategies for industrial BSF production and inform prebiotic treatments to improve substrate conversion. This highlights the importance of considering GxE interactions when selecting or developing strains for specific substrate-reducing applications.

Genetic progress in honeybee population under selection depending on mating design – a simulation study

S. Andonov[1]
[1] Swedish University of Agricultural Sciences, Department of Animal Bioscience, Ulls vag 26, 75007 Uppsala, Sweden

Breeding program of Apis mellifera is fundamental for enhancing traits related to productivity, docility, and disease resistance. A critical component of any breeding scheme is the degree of mating control, which determines both accuracy and genetic progress. This study presents a structured honey bee breeding program employing a dual mating strategy that integrates natural mating at a controlled mating station with a 70% reliability and instrumental insemination for precise pedigree management. Four scenarios were simulated: a baseline relying solely on the mating station (II0), and three scenarios in which 10% (II10), 20% (II20), or 30% (II30) of virgin queens were instrumentally inseminated each generation. Simulations assumed 1,000 colonies over 10 generations, each colony consisting of one queen and 100 worker bees. Queens were mated with 15 drones sourced from the top 10% of colonies. Each generation, 500 virgin queens were mated. The trait of interest had a mean of 0, genetic variance of 0.3, residual variance of 0.7, and no environmental effect. Trait architecture was modelled using 100 QTLs per chromosome (1,600 total QTLs). Results represent the average of 10 iterations per scenario, and genetic progress was evaluated relative to the baseline. Genetic progress increased steadily across all scenarios. As expected, both genetic gain and selection accuracy improved with higher proportions of instrumentally inseminated queens. By generation 10, scenario II30 achieved the largest improvement, reaching 50% greater genetic progress than the baseline, corresponding to 1.89 units. Scenarios II20 and II10 yielded 33% and 15% higher genetic progress than II0, respectively. Accuracy increased slightly until generation 3 and then stabilized, ranging from 0.27 in II0 to 0.44 in II30. In conclusion, the results suggest that combining a moderately reliable mating station with targeted instrumental insemination can optimize the efficiency of the honeybee breeding program. However, because instrumental insemination is costly, an economic evaluation should be performed before determining the optimal proportion of queens inseminated each generation.

Evidence for adaptation to divergent diets in black soldier flies using an experimental evolution set up

M. D. Mogensen[1], M. S. Christiansen[1], L. S. Hansen[2], H. M. Nielsen[2], R. M. Zaalberg[2], T. N. Kristensen[1,2]
[1] Aalborg University, Department of Chemistry and Bioscience, Fredrik Bajers Vej 7H, 9220 Aalborg, Denmark, [2] Aarhus University, Center for Quantitative Genetics and Genomics, C. F. Møllers Allé 3, 8000 Aarhus, Denmark

The Black Soldier Fly (BSF, Hermetia illucens L.), can convert waste-stream products into valuable protein for food and feed. However, waste-stream-based diets pose challenges for the industry, as they often have low nutritional quality and can vary in composition over time. This may have negative effects on key production traits, including growth, development time, and fertility. It may be of interest for the industry to develop BSF-lines tailored to perform under low-quality diets. In this study, we aimed to adapt BSF-larvae to a high-quality diet and a low-quality diet using a low-cost-low-input experimental evolution setup. The idea being that long-term rearing on the two distinct types of diets would lead to local adaptation, i.e. better performance on their "home-base" diet. Six replicate lines were established from a commercial base population. The larvae of three lines were fed with a nutritionally rich diet with the main ingredient being organic alfalfa (ALF-1, ALF-2, ALF-3), and the other three lines with a nutritionally poor diet consisting of organic orange peels (ORA-1, ORA-2, ORA-3). In each generation, 1000-1500 flies were selected at random and mated to create the next generation. When the experiment concluded, the ALF-lines had been kept for 20 generations, and the ORA-lines for 15 generations. After the experiment, all six lines were subsequently reared on chicken feed for two generations. After those two generations, larvae from each line were exposed to two treatments: their own "home-base" diet or the alternative diet (e.g., ALF-1-alf or ALF-1-ora). From each line, for each of the two diet treatments, 50 larvae were selected at random and reared individually on either of the two medium types until adulthood. These larvae were weighed daily until they reached their top weight. When flies hatched, they were sexed, and a random selection of females was submitted to a heat tolerance test. Individual weight data for 563 larvae (249 females, 243 males, 71 unknown) were collected. Of the 563 larvae, 492 pupated and hatched as flies. Overall, female larvae had a higher top weight and reached their top weight later (μ = 158 mg in 12.5 days) than males (μ = 134 mg in 11.3 days). When fed alfalfa, ALF-larvae and ORA-larvae reached a similar top weight (μ = 146.9 gr and 146.2 mg, respectively), but ALF-larvae reached their top weight a bit earlier than ORA-larvae (μ = 7.6 days and 8.2 days, respectively). Larger differences were observed when larvae were fed with orange peels, where the ORA-larvae reached top weight faster but had a much lower top weight (μ = 127 mg in 15.2 days) compared to ALF-larvae (μ = 155 mg in 16.4 days). Finally, the ORA-larvae had a similar heat tolerance across diets and tended to have a higher heat tolerance than ALF-larvae. Yet, the heat tolerance of ALF-larvae tended to increase when they were fed with orange peels. In conclusion, these results show signs of evolutionary adaptation after relatively few generations of rearing on divergent diets. However, there is no support for the hypothesis that performance is higher when lines are tested on the diet they have evolved under. These findings provide promising insights for genetically selecting BSF through a low-cost-low-input selection process.

Determining the Minimal Viable Population Size of the Black Soldier Fly (Hermetia illucens) over Ten Generations of Inbreeding

M. Verschaeren[3], L. Frooninckx[3], L. Broeckx[3], R. Meyermans[1], F. Ijdema[2], N. Buys[1], J. De Smet[2], S. Van Miert[3]
[1] KU Leuven, Department of Biosystems, Kasteelpark Arenberg 30 box 2472, 3001 Arenberg, Belgium, [2] KU Leuven, Department of Microbial and Molecular Systems, Kleinhoefstraat 4, 2440 Geel, Belgium, [3] Thomas More University of Applied Sciences, Centre of Expertise Sustainable Biomass and Chemistry, Kleinhoefstraat 4, 2440 Geel, Belgium

The production of black soldier fly larvae (BSFL, Hermetia illucens) is widely used for organic waste conversion and as a sustainable biomass source, particularly for animal feed. As production systems scale up, maintaining healthy and genetically stable colonies becomes crucial. However, it remains unclear how breeding population size affects long-term strain performance. To address this knowledge gap, breeding populations of 1000, 200, and 20 individuals were established in winter 2025. Each population is maintained for ten generations under standardized rearing conditions, with a 50:50 sex ratio and in triplicate, to systematically compare survival, performance, and genetic stability across population sizes. Prior to the start of the experiment, an optimized breeding protocol was developed for smaller populations. Initial trials showed that even when providing the calculated amount of feed per larva, survival was lower due to factors such as fungal growth. The protocol ensures that even the smallest populations can be reliably maintained while supporting consistent development and survival. This study aims to provide preliminary insights into the relationship between breeding population size, performance, and genetic stability in BSFL. In generations 1, 5, and 10, key traits including egg production, survival, growth, larval mass, pupal emergence and feed conversion efficiency are being monitored. By integrating phenotypic and genomic data, the project aims to determine a minimal viable population size and generate practical guidance for maintaining robust BSFL strains in both research and industrial production systems.

Circular Feed Ingredients in Livestock Systems: Opportunities and Constraints for Circular Agriculture

A. Khimasia[1]
[1] *The Centre for Feed Innovation, Covent Garden, WC2H 9JQ London, United Kingdom*

Improving the circularity of livestock production systems is increasingly recognised as a priority for enhancing resource efficiency, reducing environmental impacts, and strengthening the resilience of agricultural supply chains. Feed production plays a central role in this challenge, as livestock diets rely heavily on a limited number of ingredients, including soybean meal and fishmeal, which are associated with land-use pressures, marine resource constraints, and supply volatility. At the same time, large volumes of nutrient-rich by-products and residues are generated across food processing, agriculture, and other industrial sectors. Circular feed ingredients offer a pathway to valorise these side streams by converting them into inputs for livestock and aquaculture nutrition. Traditional by-products such as brewers' grains and oilseed meals have long demonstrated the role of co-products in animal feed. More recently, technological innovation has expanded the range of residues that can potentially be redirected into feed supply chains. Emerging approaches include microbial fermentation to produce single-cell proteins and oils, enzymatic hydrolysis of animal and plant residues into functional feed ingredients, insect bioconversion of organic side streams, and thermochemical processes that convert biomass into feed additives. The aim of this presentation is to examine the potential role of circular feed ingredients in advancing circular livestock systems. Drawing on recent research conducted by The Centre for Feed Innovation and developments across the feed sector, the presentation will provide an overview of emerging technological pathways that enable the valorisation of underutilised biomass streams. It will discuss how these innovations may contribute to improving nutrient cycling, diversifying feed supply chains, and enhancing resource efficiency within livestock production systems across sectors including poultry, pigs, ruminants, and aquaculture. The presentation will also consider practical constraints influencing the adoption of circular feed ingredients, including regulatory frameworks governing feed safety, feedstock availability and logistics, technological maturity, and production economics. Understanding both the opportunities and limitations of these approaches is essential for identifying realistic pathways toward more circular and resilient livestock nutrition systems.

Food loss and waste to animal feed – an imperative for a circular, sustainable, One Health food system

G. Shurson[1], Z. Dou[2]
[1] University of Minnesota, Animal Science, 1988 Fitch Ave., 55108 St. Paul, MN, United States, [2] University of Pennsylvania, School of Veterinary Medicine, 382 West Street Rd, 19348 Kennett Sq, PA, United States

Food loss and waste (FLW) along entire supply chains from production to post-consumption accounts for 33 to 40% of total food produced for human consumption and is the greatest contributor to the inefficiency of resource use in global food production systems. About 25% of freshwater, 30% of agricultural land area, and 38% of total energy consumption used for food production is wasted due to FLW. About half of the greenhouse gas emissions from the entire global agrifood system are attributed to FLW, which represents 17% of total anthropogenic emissions. Progress toward achieving the Sustainable Development Goal 12.3 of halving global per capita food loss and waste by 2030 has been minimal. Therefore, increased efforts are needed to recover and recycle nutrients in FLW for other productive purposes. After reducing FLW and feeding hungry people, the next highest priority of FLW is to recycle nutrients in animal feed. Very few practices could be more impactful for reducing the environmental footprint in food animal production than repurposing FLW to animal feed in a circular bioeconomy. Recent results from modeling data obtained from more than 90 studies showed that recycling food waste into animal feed was carbon neutral and could result in average emissions mitigation of -1059 kg CO2equiv. per tonne of FLW by avoiding landfill disposal. If equal amounts of FLW currently disposed in landfills was diverted to aerobic composting, anaerobic digestion, and animal feed, GHG emissions in the EU would be reduced by 20 Mt CO2e which would offset 5% of total GHG emissions from agricultural systems. Under this same scenario, greater reductions in GHG emissions could also be achieved in the US (10%) and China (17%). By diverting one third of the FLW away from disposal in landfills, open-dumps, and incineration and using it in animal feed, about 9.4% of cropland, 9.7% of freshwater, 8.3% of energy, 6.3% of synthetic fertilizer, and 13.6% of herbicide and pesticide use attributed to maize and soybean production would be spared in the EU. Using greater amounts of FLW in animal feed would dramatically reduce reliance on imported feed ingredients, enable greater resiliency to feed supply chain disruptions, and substantially reduce the environmental burden of meat, milk, and eggs production. Unfortunately, only about 5% of the more than 58 million tonnes of FLW produced in the EU is used in animal feed, compared with Japan, which recycles about 55% of total FLW into safe, high quality, branded, and certified "Eco-feed". There are many reasons for the limited recycling of FLW to animal feed in most countries including: negative perceptions and historical images of "garbage feeding" to pigs; historical animal disease outbreaks and economic losses associated with feeding uncooked food waste to animals; competition with abundant, consistent supplies of commodity grains and agri-industrial by-products; lack of collection, handling, transport, and processing infrastructure; challenges of managing high moisture content, storage stability, and variability in nutrient content; lack of government and economic incentives; and overly restrictive laws and regulations. However, about 86 to 88% of total global FLW is derived from plants which have very low risk of microbiological feed safety concerns. Recycling FLW into animal feed and diverting potentially high feed safety risk animal-derived FLW sources to biogas production using anaerobic digestion, and soil amendments using aerobic composting can have an immediate impact and substantially improve the sustainability of food animal production.

Qualitative and quantitative analysis of meat by-products in France to enhance circular bioeconomy

V. Landais[1], B. Duflot[1], T. Bonaudo[2], R. Baumont[3]
[1] Institut de l'Elevage, 149 rue de Bercy, 75595 Paris, France, [2] AgroParisTech, UMR TETIS, 500 rue Jean-François Breton, 34093 Montpellier, France, [3] INRAE, UMR Herbivores, Route de Theix, 63122 Saint-Genès-Champanelle, France

Animal by-products are materials of animal origin not intended for human consumption like (leather, wool, feathers, bones, blood, feet, heads, viscera). Materials posing a health risk are destroyed (e.g., coming from animals dead from disease…), while healthy materials are used in many industries (e.g., petfood, aquaculture, textile, organic fertilisers, biofuels, chemistry and medicine as for example heparin production…) and play an important role in a circular bioeconomy. The work carried out by GIS Avenir Élevages aimed to quantify and map the flows of these by-products, across all animal sectors: beef and dairy cattle, ovine, caprine, pork and poultry meat production. This analysis is based on the annual reports of the "Syndicat des Industries Françaises des Coproduits Animaux", supplemented by interviews with industry experts. By-products represent 55.0, 30.5 and 46.5% of annual slaughtered liveweight respectively for ruminants, pigs and poultry. In 2023 (https://terriflux.com/portfolios/IDELE/diagrams.html) the meat industry generated more than 2.0 million tonnes of by-products used as processed animal proteins, animal fats and bones, of which more than 800,000 tonnes came from ruminants. For the beef industry, the transition to negligible Bovine Spongiform Encephalopathy risk status has made it possible to classify more animal by-products as 'healthy'. Leather represented 161,000 tonnes and 441,000 tonnes were used through spreading and composting as fertilizers. Although synthetic substitutes exist for certain animal by-products, their performance and the quantities produced often make them the material of choice. The downward trend in livestock numbers and its predicted acceleration according to various forward-looking scenarios to reduce the carbon footprint of the livestock sector, could lead to supply problems for certain industrial sectors that depend wholly or partly on animal by-products. The socio-economic issues surrounding these products need to be addressed, alongside environmental issues, in order to assess their overall contribution to a circular bioeconomy.

Competitive resources in dairy cattle feeding: effect on yields, efficiency and emissions

M. Berton[1], L. Gallo[1], E. Sturaro[1]
[1] University of Padova, DAFNAE, via dell'Università 16, 35020 Legnaro (PD), Italy

The use of resources (feed, land) competitive with direct human use has been increasingly questioned in terms of appropriateness and food-system level efficiency. Additionally, livestock systems are pursuing more environmentally friendly configurations. The aim was to assess the effect of the inclusion of competitive feed resources in lactating dairy cow's diets on milk energy yield (MEY), net gross energy (GE) provision, and greenhouse gas emissions (GHGe). Data were collected from 336 farms, representative of northern Italy systems. Farm visits were performed to obtain data on farm size, milk yield and quality, animal diets as well as management and structure to compile farm inventory. Daily MEY was computed as MY x GE content (NASEM protocol). Lactating cows' dry matter intake (DMI) was computed based on ratio between net energy requirement and dietary net energy. The GE intake (GEI) was computed as DMI x dietary GE content, considering the whole diet (GEIw), contribution due to concentrates target of land occupation (GEIc) and to human-edible portion of the diet (GEIe). Net provisions were calculated as the difference between MEY and GEIw (NEPw), GEIc (NEPc) or GEIe (NPEe). Life Cycle Assessment was applied to compute GHGe (as 100-y global warming potential, GWP) per kg of fat- and protein-corrected milk (FPCM), considering cradle-to-farm gate boundaries, biophysical milk-meat allocation and IPCC computation protocol. Classes of percentage of GEI covered by GEIc (GEIc_p) and GEIe (GEIe_p) (quintiles, average values of 4(6), 17(19), 24(25), 31(30), and 42(39)%, for quintiles from 1 to 5 of GEIc (GEIe)) were used in two separate mixed models to test their effect on MEY, NEPs and GWP. Quartile of farm size, lactation stage and percentage of specialized breeds as well as use of total mixed rations (yes vs no), housing (tie vs loose stall) and random effect of the dairy system were used as additional effects. Average size was 101 lactating cows (min-max: 3-1009), MY 25.7 kg/cow/d (8.5–44.5) and MEY 78.2 MJ/cow/d (25.3–135.5). Net provision (mean±sd) averaged -345±38 (NEPw), -23±48 (NEPc), -21±37 (NPEe). Mean GWP was 1.48±0.28 kg CO2-eq/kg FPCM. The GEIc_p significantly affected MYE, NPEs and GWP. In particular, MYE and GWP in first quintile were significantly lower (MYE) and higher (GWP) than 3rd-5th quintiles, with intermediate values in 2nd quintile. About NEPs, increasing GEIc_p was associated with a linear increase in NPEw and decrease in NPEc, with values above zero in the first two quintiles (i.e. positive net provision of energy). Same results were found for GEIe_p. In conclusion, diets with GEIc_p close to 17% and GEIe_p to 19% resulted in the best combination of high MYE, low GWP and positive energy net provision when feed origins and types were considered. Moreover, although not completely overlapping, concentrates could be used as proxy of human-edible portion of the diets, allowing faster and easier evaluation of the lactating cows' diets. Acknowledgement: project 'Looking for the agro-environmental friendly dairy farm: innovative approaches and integration of methodologies for an inclusive definition of sustainability in dairy systems', Prot. 2022ME2537, call PRIN 2022, fundend by European Union – NextGenerationEU.

Closing the loop in Mediterranean lamb production: Circular economy benefits of cucumber–straw silage evaluated through in vitro, in vivo, and life cycle assessment

M. Hassan[1], A. Belanche[2], N. Davison[3], M. Romero-Huelva[1], L. G. Smith[3], D. R. Yañez-Ruiz[1]
[1] Estación Experimental del Zaidín, CSIC, Profesor Albareda, 1, 18008 Granada, Spain, [2] Departamento de Producción Animal y Ciencia de los Alimentos, Universidad de Zaragoza, Miguel Servet 177, 50013 Zaragoza, Spain, [3] School of Agriculture, Policy and Development, University of Reading, Earley Gate, RG6 6EU Reading, United Kingdom

Improving efficiency while reducing environmental impacts remains a major challenge for livestock systems in Spain, where viable alternatives to conventional forages are limited. This study evaluated cucumber–straw silage (SIL) as an alternative forage to oat hay (HAY) for lamb production using an integrated approach combining in vitro rumen fermentation, an in vivo commercial farm trial, and a cradle-to-farm-gate life cycle assessment (LCA). In the in vitro batch culture experiment, concentrate was progressively replaced with SIL or HAY at 25, 50, 75, and 100%, and ruminal fermentation characteristics, cumulative gas production, and methane (CH_4) emissions were measured over 144 h. Subsequently, a 12-week in vivo trial was conducted on a commercial farm with 450 lactating Segureña ewes and 610 lambs to assess productive performance and metabolic status. The in vitro experiment followed a factorial design (two forage types × four inclusion levels) within a completely randomized design, while the in vivo experiment was performed using a completely randomized design. Results showed that a 50% inclusion of SIL maintained fermentative activity comparable to HAY, including total gas production and total volatile fatty acid concentrations; however, SIL shifted fermentation toward greater butyrate production (+13.3%; P = 0.001) and reduced CH_4 emissions (−17.3%; interaction P = 0.001), indicating a potentially more favourable rumen fermentation profile. In vivo, SIL supported comparable animal performance to HAY, with no significant differences in lamb ADG (210 vs. 215 g/day; P = 0.382) or ewe body condition (P = 0.954), and blood metabolites remained within physiological ranges, indicating adequate metabolic health. A cradle-to-farm-gate life cycle assessment, following ISO-14044 standards and applying two allocation approaches for cucumber waste, revealed that under a zero-allocation scenario (treating waste as burden-free), SIL reduced greenhouse gas emissions by 18% (9.50 vs. 11.6 kg CO_2-eq per kg liveweight), land occupation by 50%, and water consumption by 70% compared with the HAY-based system. Therefore, SIL potentially presents an effective strategy to valorise horticultural waste while maintaining productivity and improving the environmental performance of Mediterranean lamb systems. Further validation across diverse management conditions and by-product sources is recommended.

Advantages of an ensiled total mixed ration including sugar beet pulp for French dairy farms

A. Roméo[1], R. Delagarde[2], J. Duponchel[1]
[1] Tereos, Rue de Senlis, 77230 Moussy-le-Vieux, France, [2] INRAE, PEGASE, Domaine de la Prise, 35590 Saint-Gilles, France

In the current context, environmental and economic concerns encourage the development of sustainable solutions in dairy farms. Among these solutions, the inclusion of byproducts in total mixed rations (TMR) has gained increasing attention in many countries. In addition, ensiling TMR can reduce labour requirements and simplify feeding practices. Between 2017 and 2024, the benefits of ensiled TMR with sugar beet pulp versus fresh TMR were assessed in France through experimental trials and field surveys, focusing on cow performance and feeding management. First, a preliminary study was conducted with two groups of cows (35 cows per group; 1 Normande, 5 Jersey, 29 Holstein) comparing an ensiled TMR (Pulp'Mix®, Tereos) and a fresh TMR over 6 months. The diet was based on grass silage, maize silage, sugar beet pulp, and distillers dried grains with solubles (DDGS). Cows fed the ensiled TMR showed a numerical improvement in feed efficiency, without any decrease in milk yield. Daily milk fat production tended to increase ($P = 0.09$). These results were reinforced in a study conducted in 2020, with two groups of cows (11 Holstein cows per group) fed an ensiled TMR or a fresh TMR, with the same ingredients (mainly maize silage, sugar beet pulp, baled herbage, DDGS, wheat gluten feed), for 53 days. When expressed per kg of dry matter intake, milk yield and milk fat were higher in cows fed the ensiled TMR ($P < 0.05$) compared to the control group. In addition, methane emissions, measured using a GreenFeed system, were significantly reduced, both per day ($P < 0.05$) and per kg of milk ($P < 0.01$), in the group fed the ensiled TMR. Increase in the efficiency of cows and reduction in methane emissions may be attributed to a shift of some fermentation processes from the rumen to the silo. In particular, the higher lactic acid concentration in the ensiled TMR could enhance the propionic acid production and reduce the methanogenesis. Regarding field surveys, before/after comparisons (i.e. before and after the introduction of the ensiled TMR with sugar beet pulp and various byproducts) were conducted in 2017 in Alsace-Lorraine, in 2018 in Hauts-de-France, and in 2024 in Hauts-de-France. In 2017, 9 dairy farms were evaluated, allowing statistical comparisons. Results showed a significant reduction in feeding costs ($P < 0.05$), as a result of a higher inclusion of wet byproducts. Using an ensiled TMR instead of mixing all ingredients every day resulted in time savings estimated at more than 90 h per year. Similarly, in the 2018 survey, performed in three farms, time savings were evaluated between 90 and 120 h per year. In addition, milk yield was maintained, with an increase in feed efficiency. Feeding costs were reduced. Finally, the 2024 survey conducted in three farms estimated time savings of around 80 h per year. Before/after comparison in one farm showed stable milk and stable fat productions over the year. In conclusion, studies and surveys over the past years demonstrated the advantages of an ensiled total mixed ration based on byproducts, such as sugar beet pulp, in dairy farms. This solution can not only reduce labour requirements but also lower feed costs, and represents a sustainable option through a circular local economy and decreased methane emissions.

Ensiling by-products: destoned olive pomace silage as an on-farm strategy for lamb meat production to reduce food/feed competition and enhance meat quality

F. G. Cella[1], T. Malizzi[1], M. Finocchi[1], E. Senatore[1], A. Silvi[1], A. Ripamonti[1], A. Mantino[1], G. Conte[1], A. Serra[1], M. Mele[1]

[1] University of Pisa, Department of Agriculture, Food and Environment, Via del Borghetto 80, 56123 Pisa, Italy

Tuscany is among the leading Italian regions for olive oil production and sheep farming, two activities that are historically rooted and remain central to the region's agricultural identity and economic value. These sectors generate large amounts of olive pomace (OP) as a by-product (BP) and contribute to a high demand for animal feed. Although OP is recognized as a sustainable feeding resource for ruminants the perishability and seasonal availability limit its widespread use. Drying is commonly adopted to stabilize feed, but for water-rich BP this approach can negatively affect feasibility and sustainability due to high energy requirements. Mixing different BPs and ensiling them represents an on-farm solution to stabilize water-rich BP with low economic and environmental costs. This study evaluated the productive performance and meat quality traits of Appenninica lambs fed diets based on destoned OP silage, wheat bran, and beet pulp combined with distillers' grains (SD) or faba beans (SF), compared with a conventional diet (C) based on maize, barley, soybean, and alfalfa hay. A completely randomized design was applied to 18 lambs (average body weight: 18.8±2.1 kg), equally allotted to three dietary treatments (SD, SF, and C). After the adaptation period, data were collected over four weeks. Dry matter intake (DMI) and water intake (WI) were daily recorded while body weight (BW) was weekly recorded. The offered feed and refusals were analysed for chemical composition to assess nutrients intake. After slaughter, carcass weights were recorded, and meat samples were collected for laboratory analyses. A linear mixed model was applied with diet and week as fixed factors, animal as random factor, and initial BW as a covariate. Model for analysis of meat quality traits included diet as a fixed factor and animal as a random factor. DMI (934±30 g/d) did not differ among treatments. The C diet showed lower aNDF intake ($291\pm12_{b}$) respect to SF ($354\pm12_{a}$) and SD ($332\pm12_{ab}$). Similarly, ADL intake was lower in C ($14\pm1_{b}$) than in SF and SD ($36\pm1_{a}$). Ether extract intake was higher in SF and SD ($64\pm1_{a}$) than in C ($26\pm1_{b}$). Crude protein intake was lowest in C ($103\pm4_{c}$), intermediate in SF ($125\pm4_{b}$), and highest in SD ($164\pm4_{a}$).WI (L/kg DMI) was significantly greater in SF ($4.2\pm0.4_{a}$) than in C ($2.8\pm0.4_{b}$), whereas SD were intermediate ($3.6\pm0.4_{ab}$). No differences were found in final BW (24.6±0.6 kg), average daily gain (201±19 g/d), carcass weight (12.2±0.6 kg) among treatments. Chemical composition of meat did not significantly differ among treatments, except for total lipid content that was higher in SF ($4.1\pm0.4_{a}$) respect to SD ($2.3\pm0.4_{b}$) and C ($3.6 \pm 0.4_{ab}$). No significant differences were observed for meat colour parameters and deoxymyoglobin but oxymyoglobin was highest in C ($78.4\pm2.5_{a}$), followed by SD ($73.5\pm2.7_{ab}$) and SF ($67.0\pm2.7_{b}$). Metmyoglobin was higher in SF ($15.2\pm2.8_{b}$), followed by SD ($9.8\pm2.8_{ab}$) and C ($3.4\pm2.5_{a}$). Unsaturated fatty acids (FA) ($43.9 \pm 1.3_{a}$) and monounsaturated FA ($37.6 \pm 1.5_{a}$) were significantly higher in SF than in C and SD, whereas polyunsaturated FA did not differ among treatments. The ω-6/ω-3 ratio was lowest in SF lambs ($4.6 \pm 0.6_{b}$) compared with C ($6.9 \pm 0.6_{a}$) and SD ($6.9 \pm 0.7_{ab}$). Ensiled OP in combination with other BP can be successfully included in the diet of fattening lambs without any detrimental effect on growth performance if compared to a conventional diet. Overall, using ensiled OP in the lamb diet enhances nutritional quality of meat minimizing food–feed competition.

What intrinsic levers do mixed crop–livestock farmers in Guadeloupe have to improve the agroecological performance of their farms?

N. Mandonnet[1], A. Fanchone[1], M. Eugene[1], E. Laclef[1], C. Latchman[4], G. Pioche[1], F. Stark[2], B. Dumont[3]
[1] INRAE, ASSET, Domaine Duclos, 97170 Petit-Bourg, France, [2] INRAE, SELMET, 2 place Viala, 34000 Montpellier, France, [3] INRAE, Herbivores, Theix, 63122 Saint-Genès-Champanelle, France, [4] GDA ECOBIO, Convenance, 97122 Baie-Mahault, Guadeloupe

Meeting the growing demand of Guadeloupean consumers for healthy, affordable, locally produced food is constrained by limited and shrinking agricultural land, part of which is durably contaminated. This calls for efficient farming systems dedicated to supplying the local market, which currently has a self-sufficiency rate of only about 25%. Family farming represents 80% of farms in the archipelago and produces a wide diversity of products in small quantities, mainly marketed through short supply chains (local markets, direct sales). Crop–livestock integration (CLI) has the potential to enhance the agroecological performance (efficiency, resilience, autonomy) of small tropical family farms. We evaluated the multi-performance of small organic farms in Karukera (Guadeloupe) according to their degree of CLI and diversification (MAKIBIO). With the support of the GDA ECOBIO network of organic farmers, participatory surveys were conducted with 29 farmers across the archipelago between 2024 and 2025. Farms were selected to represent the diversity of local CLI practices. Farm performance was assessed using the STREAM tool developed within the European Agroecology-TRANSECT project and adapted to tropical conditions. Agroecological indicators were derived from ecological network analysis (ENA) and expressed as annual nitrogen flows. The field phase was conducted using a participatory approach: half a day was devoted to a task chosen by the farmer before carrying out questionnaires and observations. The involvement of 5 to 6 researchers over an extended time fostered trust, common language and improved understanding of farm organization. The surveyed farms averaged 9 ha of area (over 40% ≤6 ha) and employed 1.98 workers on average. The Shannon index of cultivated plant biodiversity ranged from 0.002 to 2.57 (mean 1.24), while the Shannon index of livestock biodiversity (corrected for tropical livestock units) ranged from 0 to 1.44. Internal nitrogen circularity (internal flows/total flows) ranged from 8% to 83%, reflecting a wide range of CLI practices. However, no direct relationship was found between ENA-based agroecological performance and biodiversity indices or nitrogen circularity. The type of livestock enterprise had a stronger influence on nitrogen-use efficiency than the degree of crop–livestock integration. Intensive organic monogastric systems rely on high inputs but achieve high productivity, whereas grazing ruminant systems require fewer inputs and generate greater within-system circularity. Farm resilience increased strongly with the balance of flows between farm compartments ($R^2 = 70.11$; $p < 0.001$). To a lesser extent, resilience, efficiency and autonomy increased with the number of farm compartments and their interconnections. These results highlight that resilience largely depends on the farmer's systemic vision of the farm. In this tropical context, the independence between resilience and nitrogen-use efficiency appears to result from recycling processes associated with increasing agroecosystem complexity. In the medium term, the collective aims to digitalize the STREAM tool to monitor small farms over time and support farmer-led data collection for decision-making.

Energy-Plus Dairy Farming – Evaluating the Decarbonization Potential of Integrated Biogas and Photovoltaic Systems in Northern German Milk Production

J. Drews[1], J. Koerte[2], S. Krueger[2], P. Sanftleben[1]
[1] Mecklenburg-Vorpommern Research Centre for Agriculture and Fisheries, Institute of Livestock Farming, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [2] RinderAllianz GmbH, Am Bullenberg 1, 17348 Woldegk, Germany

The transition towards a low-carbon agriculture requires dairy farms to evolve from pure food producers into integrated energy hubs. While livestock farming is traditionally associated with high greenhouse gas (GHG) emissions, the strategic implementation of large-scale renewable energy systems – specifically biogas and photovoltaics (PV) – offers a transformative pathway to offset these impacts through the circular economy and avoided burdens. This study investigates the environmental performance of nine intensive dairy farms in Northern Germany, focusing on the mitigation potential of high-capacity renewable energy integration. The research quantifies how on-farm energy generation affects the global warming potential (GWP), acidification (AP), and eutrophication (EP) of 1 kg of milk. Individual farm data from the calendar year 2024 or the financial year 2023/24 were used. Cradle-to-farm gate life cycle assessments (LCA) were conducted respectively. The functional unit was defined as 1 kg energy-corrected milk. Economic allocation of 86:12:2 (milk, culled cows, calves produced) was applied. Four technical scenarios were compared: (0) integrated PV and biogas (1) biogas only, (2) PV only, and (3) a baseline reference without renewable energy systems. The integrated energy system (Scenario 0) achieved a 27% reduction of GWP compared to the baseline. The biogas plant was identified as the primary mitigation driver, accounting for 44% of total GWP savings. This is attributed to the "double-dividend" of biogas: the prevention of methane (CH_4) leakages from manure storage and the subsequent generation of carbon-neutral electricity. While PV systems provided a significant further reduction (approximately 15% of total savings), their impact was strictly limited to electricity substitution. Changes in AP and EP were marginal (1–2%), primarily driven by the reduction of fossil-fuel combustion in the national grid. The study demonstrates that large-scale energy integration can pivot Northern German dairy farms into "Energy-Plus" operations. The findings highlight that the synergy between manure-based biogas and solar energy is essential for reaching decarbonization targets in the livestock sector. This research provides a robust framework for policymakers and farmers to evaluate the dual role of agriculture in food security and renewable energy transitions.

Effects of nitrogen fertilization, biorefinery processing and season on nitrogen fractions in grasses

M. Gomes[1], N. Hansen[1], M. Weisbjerg[1], S. Jensen[1]
[1] Aahus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark

This study aimed to evaluate how grass species, nitrogen fertilization level, cut number, biorefinery processing, and alkaline treatment during biorefinery affect total N concentration (total N) and the proportion of neutral detergent insoluble nitrogen (NDIN) relative to total N (NDIN-P) in grasses and pulp/press-cake. Treatments included three grasses (perennial ryegrass and festulolium [festuca and lolium type]), three levels of fertilization (300, 450, and 600 kg N ha^{-1} $year^{-1}$), and four fractions (original plant, pulp pressed once [pulp 1], pulp pressed twice with water [pulp control], and pulp pressed twice with NaOH [pulp alkaline]). All treatment combinations were evaluated across five cuts in 2024 (May 14, June 11, July 9, August 12, and September 23). The complete random design resulted in 180 samples (3 species × 3 N fertilization levels × 4 fractions × 5 cuts). Following the first pressing, pulp was mixed with either deionized water (Milli-Q) or a 0.6% NaOH solution, kept overnight at room temperature and pressed again (pulp control and pulp alkaline, respectively). Fractions were freeze-dried for analysis of neutral detergent fiber (NDF, Fibertec) and total N (Dumas). Nitrogen was determined in the NDF residues to calculate NDIN-P. Statistical analyses were performed in R using linear mixed-effects models (lmer) including Species, N fertilization level, Cut, Processing, and their two-way interactions as fixed effects. Species x N fertilization level x Cut was included as a random effect in the model. Pairwise comparisons were performed using Tukey-adjusted tests. Interactions were observed for total N between N fertilization × Processing ($P<0.01$) and Cut × Processing ($P<0.01$), and for NDIN-P between Species × N fertilization ($P<0.01$), Species × Processing ($P<0.01$), N fertilization × Processing ($P<0.01$), and Cut × Processing ($P=0.01$). Within processing, interactions with level of fertilization were detected only in the original plant, where total N increased with N fertilization rate (from 1.88% of DM at 300 kg N ha^{-1} to 2.81% of DM at 600 kg N ha^{-1}). NDIN-P was higher at 300 and 450 kg N ha^{-1} (≈45% of N) compared to 600 kg N ha^{-1} (35.8% of N), with no differences observed among processed pulps. In general, total N concentration decreased with increasing processing intensity in all cuts and N fertilization rates, with pulp 1 and pulp control consistently showing intermediate and similar values. The tendency for NDIN-P was the opposite, increasing with increasing processing intensity (74.4% of N on pulp alkaline vs. 42.0% of N on original plant). Increasing fertilization correlated positively with total N, mainly by increasing the soluble fraction. The biorefinery process efficiently extracts N, and the alkaline treatment further removes N. Festulolium festuca type showed a higher NDIN-P (64.3% of N) than Ryegrass and Festulolium lolium type at 600 kg N ha^{-1} only. Within Processing, NDIN-P was higher in Ryegrass in the original plant (49.1% of N) and in Festulolium fescue type in pulp 1 (62.6% of N). Interactions with Cut were observed only in the original plant material, where total N was higher in cuts 2 and 3 (≈2.8% of DM) than in cuts 1, 4, and 5 (≈2.0% of DM). Cut 2 also had a lower NDIN-P (30.3% of N) compared to cuts 1, 3, 4, and 5 (≈45% of DM). The lower total N content in Cut 1 relative to Cut 2 and 3 was unexpected and might be due to lower fertilization level or later-than-intended harvest, potentially reducing soluble components. In conclusion, cut and N fertilization primarily affected the soluble N fraction. As the season progressed, total N decreased, due to a decreased content of soluble N.

Greenhouse gas emissions of grass-based dairy systems: insights from nutrient cycle assessments of Dutch dairy farms

G. Bonekamp[1], L. De Jong[1], N. Van Eekeren[1], J. Pijlman[1]
[1] Louis Bolk Institute, Kosterijland 3-5, 3981AJ Bunnik, Netherlands

Grasslands contribute to many ecosystem services and play a crucial role in achieving (inter)national sustainability goals for e.g. biodiversity, water quality and carbon sequestration. Besides that, these grasslands offer non-human edible feed resources which ruminants can convert into high quality human edible food. However, the utilization of grass by ruminants contributes to emissions of greenhouse gasses (GHG), nitrate and ammonia, which have negative environmental impacts. This study, therefore, addresses how milk (and meat) production from Dutch grasslands can be optimized for low GHG emissions while simultaneously considering other sustainability indicators, including ammonia emissions, soil nitrogen surplus and protein self-sufficiency. We selected 18 conventional dairy farms (9 on clay and 9 on sandy soil) with a high, medium, or low proportion of total grass (fresh grass, grass silage and hay) in the cow's diet. We quantified technical and environmental performances of 2023 and 2024 of these farms using the Annual Nutrient Cycle Assessment (ANCA) tool. In ANCA, GHG emissions are quantified via a life cycle assessment approach. At these farms, total grass in the diets varied from 39 to 78% on clay and from 28 to 62% on sand. Diets with a low proportion of grass contained more maize silage and byproducts, while the proportion of concentrates was relatively similar between the different diets (20-30%). With increasing percentages of grass in the diet, annual milk production per cow decreased from about 11,000 to 8,100 kg fat protein corrected milk (FPCM) on clay and from 10,400 to 9,500 kg FPCM on sand. Total GHG emissions per kg FPCM varied and increased slightly with more grass in the diet (4.3g CO2-eq kg FCPM^{-1} per percentage point increase in dietary grass proportion, hereafter %$^{-1}$), while GHG emissions per hectare decreased with more grass in the diet (-0.25t CO2-eq ha^{-1} %$^{-1}$). On average, 46% of the GHG emissions originated from rumen fermentation, increasing slightly with higher percentages of grass in the diet (2.1g CO2-eq kg FCPM^{-1} %$^{-1}$). 25% of the GHG emissions originated from external inputs, on average decreasing with more grass in the diet (-1.1g CO2-eq kg FCPM^{-1} %$^{-1}$). The rest of the GHG emissions originated from on farm feed production, increasing slightly with more grass in the diet (3.9g CO2-eq kg FCPM^{-1} %$^{-1}$), from energy use and from the barn and manure storage, both decreasing slightly with more grass in the diet (-0.3g CO2-eq kg FCPM^{-1} %$^{-1}$ and -0.3g CO2-eq kg FCPM^{-1} %$^{-1}$, respectively). These results indicate that increasing the dietary grass proportion shifts the relative contribution of GHG emission sources, suggesting trade-offs between enteric, on-farm and external emission components. High proportions of grass in the diet were associated with higher protein self-sufficiency (0,69% %$^{-1}$), while ammonia emissions decreased slightly (-0,54 kg NH3 ha^{-1} %$^{-1}$) and no consistent relationship was observed with soil nitrogen surplus. The observed patterns indicate that higher dietary proportions of grass can be associated with improved performances of several sustainability indicators at farm level. Furthermore, the observed variation between farms indicates that there is room to optimize sustainability indicators across a range of dietary grass proportions. This suggests that that a relatively high proportion of grass in dairy cow diets does not necessarily result in higher GHG emissions per kg FPCM, while more grass-based systems can contribute to more ecosystem services and substantially reduce feed–food competition of milk and meat production.

It's not always as simple as it seems: lessons from genetic susceptibility to prion and lentivirus infections in sheep

G. Lühken[1], M. Serena Beato[2], K. Elisabetardottir[3], P. König[4], C. Fast[5], E. Grochowska[6], V. Beringue[7], S. Thorgeirsdottir[8]

[1] Justus-Liebig-Universität Gießen, Ludwigstr. 21, 35390 Giessen, Germany, [2] Italian Reference Centre for Ruminanti retroviruses, Via G. Salvemini 1, 06126 Perugia, Italy, [3] Hvammshlíð, Blönduós, 541 Blönduós, Iceland, [4] Institute of Diagnostic Virology, Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Südufer 10, 17493 Greifswald – Insel Riems, Germany, [5] Institute of Novel and Emerging Infectious Diseases, Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Südufer 10, 17493 Greifswald – Insel Riems, Germany, [6] Collegium Medicum, Nicolaus Copernicus University, Faculty of Health Sciences, Łukasiewicza 1, 85821 Bydgoszcz, Poland, [7] 7Université Paris-Saclay, INRAE, INRAE domaine de Vilvert bâtiment n°440, 78350 Jouy-en-Josas, France, [8] Institute for Experimental Pathology at Keldur, University of Iceland, Keldnavegur 3, 112 Reykjavík, Iceland

Classical scrapie and small ruminant lentivirus (SRLV) infections in sheep are among the few infectious diseases in which a single genetic variant can play a decisive role in determining host susceptibility. For classical scrapie, selection for the amino acid arginine (R) at codon 171 of the prion protein (PrP) was a milestone in the control and eradication of this disease from many sheep populations. Likewise, the prevalence of SRLV infection was shown to be significantly lower in sheep homozygous for lysine (K) at codon 35 of the transmembrane protein 154 (TMEM154). Despite these clear associations, breeding for lower susceptibility to both diseases is not always straightforward. A major limitation is the low frequency or absence of the protective allele in the target population. In Iceland, unsuccessful efforts have been underway for almost 50 years to eradicate scrapie in sheep. However, a survey in 1999 dashed hopes for a breeding solution, because no sheep carrying the R171 allele were identified in the Icelandic sheep population. In search of an alternative, we conducted a case-control study including 4,782 samples, of which 360 originated from scrapie-positive sheep, from 20 scrapie-affected Icelandic flocks. The results suggest that alternative PrP variants at codons 137, 138, 151 and 154 are associated with lower susceptibility than the wild type. The threonine (T) variant at codon 137 proved particularly promising, as it was not detected in any scrapie-positive sheep. Moreover, it behaved similarly to R171, acting as a strong molecular barrier to prion conversion in the protein misfolding cyclic amplification (PMCA) assay. After genotyping almost 30,000 Icelandic sheep, only a few R171 carriers were found. Therefore, T137, C151 and H154 are now considered protective alleles in Iceland. For SRLV susceptibility, the protective TMEM154 K35 allele also occurs at low frequency, particularly in susceptible breeds. In addition, a frameshift mutation in exon 1 showed a protective effect in German Pomeranian Coarsewool sheep. However, in some breeds, such as German Merinoland sheep, no significant association of TMEM154 E35K with SRLV susceptibility was observed despite sufficiently high allele frequencies. Similar to ovine scrapie, where susceptibility to atypical forms is not governed by the same PrP variants as in classical scrapie, the protective effect of TMEM154 variants may depend on the genotype of the circulating SRLV. Recently, SRLV genotype B2 was detected together with A5 in a Merinoland flock, and both genotypes infected sheep with TMEM154 genotype KK. Thus, viral genetic variation alone does not explain the missing protective effect. In summary, these examples emphasize the importance of considering additional genetic variation in both the host and the pathogen.

Dissecting the genetic architecture of somatic cell score in Cyprus Chios ewes: Heritability, genetic correlations with milk traits and GWAS analysis results using 50K SNP DNA microarray data

S. Panayidou[1], T. Christofi[1], G. Hadjipavlou[1]
[1] Agricultural Research Institute, P.O. Box 22016, 1516 Lefkosia, Cyprus

Somatic cell score (SCS) is an important indicator of udder health and subclinical mastitis in dairy sheep, and high SCS significantly impacts milk quality. Data for about 900 Cyprus Chios ewes with parities 1 to 6 were analyzed in this study. Genetic analyses showed moderate heritability for SCS ($h^2 = 0.31 \pm 0.03$) and high repeatability ($r = 0.66 \pm 0.008$). Genetic correlation analyses revealed that SCS was strongly and negatively associated with lactose content at both the genetic and phenotypic levels ($rg = -0.49 \pm 0.07$, $p = 3.95 \times 10^{-12}$; $rp = -0.37 \pm 0.02$, $p = 7.21 \times 10^{-74)}$. Total milk yield also exhibited a negative association with SCS at the genetic level ($rg = -0.29 \pm 0.08$, $p = 4.48 \times 10^{-4}$) and at the phenotypic level ($rp = -0.16 \pm 0.02$, $p = 3.40 \times 10^{-12}$), reflecting a strong antagonism between udder health and milk production. Furthermore, this study investigated further the genetic architecture of SCS in Cyprus Chios sheep using a combination of linear and binomial GWAS models and 50K SNP microarray genotypes for 721 Cyprus Chios ewes. While binomial scans under strict Bonferroni correction identified high-confidence hits on chromosome 10 within the Basic Immunoglobulin-Like Variable Motif Containing (BIVM) gene and a Chromosome 6 hotspot involving non-coding RNAs, linear models were refined using a multi-marker backward elimination procedure (Multi-Locus Mixed Models). This approach identified 11 independent SNPs explaining 55.42% of the total genetic variance for SCS. Functional annotation of these regions revealed a large set of genes associated with milk quality and mammary health. Significant findings include the gene CCSER1, encoding a protein that is a crucial regulator of milk content and udder shape, and CEP112, previously linked to mammary morphology traits. The NRG3 gene, which encodes a cell-cell signaling protein and has been connected to mammary gland conformation and reproductive performance, was also identified in our analysis. In addition, an important mediator of the NF-kB inflammatory pathway was identified. These results demonstrate how a multi-marker refinement approach effectively captures complex genetic signals and link for the first time genetic pathways involved in structural mammary characteristics, milk composition, and immune-related signaling to mastitis resistance in commercial dairy sheep, such as the Cyprus Chios breed.

Genetic selection as a sustainable strategy against gastrointestinal nematodes in Flemish Texel sheep

A. Genin[1], R. Meyermans[1], W. Gorssen[1], K. Hooyberghs[1,2], E. Uchenna Nwosu[1], N. Buys[1], S. Janssens[1]
[1] Center for Animal Breeding and Genetics, Department of Biosystems, Kasteelpark Arenberg 30, 3001 Leuven, Belgium, [2] Unit of Animal Genomics, GIGA and Faculty of Veterinary Medicine, Avenue de l'Hôpital 11, 4000 Liège, Belgium

Gastrointestinal nematodes, particularly Haemonchus contortus, pose an increasing threat to sheep production, compromising animal welfare and causing substantial economic losses. Across Europe, the cost of gastrointestinal nematode infections is estimated to €443 million annually in sheep and goats, with approximately 80% attributable to production losses and 20% to treatment expenses. The situation is further exacerbated by the emergence of anthelmintic resistance and by additional stressors such as the 2024 Bluetongue virus outbreak. In this study, 2,300 lambs, primarily from Texel flocks, were phenotyped between 2017 and 2025 in Flanders (Belgium). Owners participated voluntarily in the study, and the sampling aimed to include farms with pedigree links. Recorded traits included body weight, FAMACHA® score (anaemia indicator), body condition score (muscle and fat reserves), DAG score (extent of faecal soiling) and log-transformed faecal egg count (log(FEC)). The pedigree used in the genetic analyses included information tracing back five generations, including a total of 7,855 animals. A multi-trait animal model was fitted to estimate genetic parameters and breeding values using the BLUPF90 software. To account for non-heritable sources of variation, the model included breed, dam's age (6 classes), litter size at birth, sex, farm effect (defined as breeder + recording date) and lamb age fitted as both linear and quadratic covariates. Average standardized weight at sampling was 34.44 ± 7.65 kg at 140.65 ± 30.80 days of age. Heritability (h_2) estimates differed markedly among traits. Body weight ($h^2 = 0.40 \pm 0.05$) and DAG score ($h^2 = 0.19 \pm 0.04$) were moderately heritable, whereas FAMACHA ($h^2 = 0.05 \pm 0.02$) and log(FEC) ($h^2 = 0.07 \pm 0.02$) had low heritability. Moreover, favourable genetic correlations (rg) were observed: genetically heavier lambs tended to show lower parasite burdens (rg=-0.26 ± 0.15) and reduced anaemia indicators (rg=-0.15 ± 0.31). These findings demonstrate that progress in parasite resistance is associated with improved growth performance. A clear litter-size effect on body weight remained visible at sampling age, with lambs born as singles averaging +3.67 ± 0.31 kg, and those from triplet litters averaging -2.21 ± 0.39 kg, relative to twins. Predicted genetic gain expressed relative to the average age and weight of the lambs in the dataset, indicates that selecting the top 15% of animals could increase lamb weight by 2.67 kg while simultaneously reducing FEC by 12% within a single generation. The EBVs are particularly valuable for lowly heritable traits such as FEC and FAMACHA, where individual phenotypes provide limited information. Several improvements of the scheme are envisaged: genomic data has the potential to enhance selection accuracy, especially in young animals lacking own performance records. Secondly, a cost-effective and scalable phenotyping method would allow for sampling more animals and lead to stronger genetic gain. Finally, knowledge of the individual nemabiome and the parasite communities will refine the breeding values across farms. Overall, this study in a limited number of flocks demonstrates the potential of reducing parasite burden using selection and as such provides a realistic pathway towards more resilient, productive and sustainable sheep systems in Flanders.

Genetic correlations between dairy and maternal traits in the Lacaune dairy sheep breed

F. Tortereau[1], E. Langlais[1], C. Allain[2], J. Raoul[1,3]
[1] GenPhySE, INRAE,Université de Toulouse, ENVT, 24 Chemin de Borde Rouge – Auzeville Tolosane - CS 52627, 31326 Castanet-Tolosan, France, [2] La Fae Experimental Farm, La Fage, 12250 Saint Jean Saint Paul, France, [3] Institut de l'élevage, 24 Chemin de Borde Rouge – Auzeville Tolosane - CS 52627, 31326 Castanet-Tolosan, France

In ruminants, there is a growing interest in producing meat from dairy herds. In France, lamb production from dairy ewes account for 23% of the national lamb production and crosses with meat sheep breeds are common to produce lambs with improved meat traits. Improving reproductive (i.e. prolificacy) and lamb meat traits in dairy herds might be relevant. However, the genetic potential of French dairy sheep breeds to produce lambs has never been evaluated. In this study we analysed data from more than 11,000 lambings and lactations and 13,000 lambs in the Lacaune dairy sheep breed, collected at the INRAE La Fage experimental farm. The objective was to estimate the heritability of prolificacy and early growth traits and their genetic correlations with the main selected dairy traits (milk yield, fat and protein yields). Prolificacy was modelled as dairy traits, with a direct genetic effect and a permanent environmental effect of the ewe, while early growth traits (measured on lambs) were modelled with direct and maternal genetic effects and a permanent environmental effect of the dam. The heritabilities for dairy traits, close to expected values, are moderate to high (25%, 56% and 65% for milk yield, fat yield and protein yield, respectively). The heritability of prolificacy reaches 9%, and birth weight is heritable both at the direct and maternal genetic components levels (27% and 20%, respectively). The direct heritability of body weight at 30 days of age (BW30) is higher than the heritability of the maternal genetic component (26% and 8%, respectively). For both studied body weights, negative genetic correlations were estimated between direct and maternal components (-0.28 and -0.12 for birth weight and BW30, respectively). Prolificacy is not genetically correlated with dairy traits (genetic correlations below 0.06). Milk yield is moderately positively genetically correlated with birth weight and BW30 direct and maternal components (genetic correlations ranging from 0.22 to 0.44). Genetic correlations between milk yield and maternal components of birth weight and BW30 decrease as days in milk increase (from 0.34 to 0.11 at 42 and 167 days in milk, respectively for birth weight; from 0.62 to 0.24 at 42 and 167 days in milk, respectively for BW30). Fat yield is only significantly genetically correlated with the direct genetic effect of BW30 (-0.19). Protein yield is moderately negatively correlated with direct genetic effects of both lamb traits (-0.36 and -0.19 for birth weight and weaning weight, respectively) and is moderately positively correlated with the maternal genetic effect of birth weight (+0.19). Traits related to lamb production are thus heritable in the Lacaune dairy sheep breed and are mostly positively correlated with dairy traits, which is favourable for their improvement in dairy sheep breeding programmes.

Genetic correlations between leather pinhole defect and selected traits in Lacaune dairy sheep

H. Largant[1], L. Drouilhet[1], F. Woloszyn[1], F. Plisson-Petit[1], S. Lucas[2], J. C. Duchêne[3], D. Allain[1], H. Larroque[1]
[1] GenPhySE, Université de Toulouse, INRAE, ENVT, 24 chemin de Borde Rouge, 31326 Castanet-Tolosan, France, [2] OVI-TEST, 5 rue de la Prade, 12850 Onet Le Chateau, France, [3] ALRIC Tannerie, 11 rue de la Saunerie, 12100 Millau, France

Pinhole defect consists of small holes on the grain surface of a dewooled pelt, which negatively impacts the quality of lamb leather. This defect is increasingly found on Lacaune lamb skins, which are usually recognized for their suitability for processing into high quality leather, intended for the luxury industry. The occurrence of the defect often leads to the downgrading of the skins, affecting their market value. However, the valorization of livestock by-products is considered as a way of improving the sustainability of current sheep breeding systems. A first study involving around 1,400 Lacaune lambs, genotyped using the Illumina OvineSNP50 BeadChip and phenotyped for pinhole revealed a high heritability for this defect (0.59 ± 0.07), and a high genetic correlation with a wool trait, the predicted core bulk, that could be measured on live animals. To assess the impact of a selection on pinhole defect, genetic correlations between pinhole and traits currently included in the breed's total merit index were estimated. Phenotypes measured during the routine genetic evaluation for milk traits (milk yield, fat content, protein content, fat yield and protein yield), udder morphological traits (teat angle, anteroposterior teat position , udder depth and udder cleft), and lactation somatic cells score were used for around 8,000 ewes, which were full or half-siblings of the lambs phenotyped for pinhole. Genetic correlations between pinhole and milk quantity and quality traits appeared to be quite low and in a favorable sense, meaning that reducing the prevalence of the defect would not compromise milk traits. However genetic correlations with udder traits were higher and in an unfavorable direction, a better mammary conformation being associated with an increase of the defect. Further insights should be obtained by measuring leather phenotypes on more lambs coming from dams of the open nucleus flocks. More generally, our results may open up new prospects in other dairy sheep breeds for improving wool and leather quality, in order to obtain a better valorization of these farming by-products.

Genomic insights into health resilience and environmental adaptation in Portuguese and Angolan small ruminants

A. Amaral[1,2]
[1] University of Évora, Mediterranean Institute for Agriculture, Environment and Development & Global Change and Sustainability Institute, Pólo da Mitra, Edifício de Fitotecnia, Apartado 94, 7006-554 Évora, Portugal, [2] Centre for Interdisciplinary Research in Animal Health, Faculty of Veterinary Medicine, University of Lisbon, Avenida da Universidade Técnica, 1300-477 Lisboa, Portugal

Local small ruminant populations represent valuable reservoirs of genetic diversity shaped by natural and artificial selection under diverse production systems. Understanding the genomic basis of resilience to disease and adaptation to harsh environments is essential for sustainable breeding and conservation strategies. In this study, we integrated genome-wide analyses from European and African small ruminant populations to investigate genetic mechanisms associated with health and environmental adaptation. First, a genome-wide association study (GWAS) was conducted in Portuguese Merino sheep naturally exposed to coccidial infection to identify loci associated with parasite resilience. Using high-density SNP genotypes (~531K markers), several significant genomic regions were detected, including variants located within or near genes encoding for Claudin and Rab proteins, highlighting biological pathways related to epithelial barrier integrity, vesicle trafficking and immune signalling involved in host–parasite interactions. Second, high-coverage whole-genome sequencing (≈30×) was performed in 49 sheep and 42 goats sampled across multiple provinces and ecological regions of Angola, representing populations adapted to extensive pastoral systems and challenging climatic conditions. Preliminary selection scan analyses identified candidate genes under selection, related to growth hormone regulation, maternal processes involved in parturition and neuromuscular junction development, suggesting genomic adaptation associated with growth, reproductive performance, and structural resilience in these populations. Together, these results demonstrate how genomic analyses across contrasting environments can uncover complementary mechanisms underlying health resilience and environmental adaptation in small ruminants. The integration of GWAS and high-coverage whole-genome sequencing provides valuable resources to support breeding strategies and the conservation of locally adapted livestock populations.

From zero to hero – the spread of a new breed throughout a sheep industry using the Texel in Britain as an example

G. Pollott[1]
[1] *RVC, PPS, Royal College Street, NW1 0TU London, United Kingdom*

Britain has traditionally had an extensive sheep industry spread throughout the farming sectors from mountain down to mixed lowland systems. Innovative farmers have always looked to improve profitability and sustainability of their enterprises by introducing new ideas and methods. In the case of the British sheep industry, one such innovation was the introduction of foreign breeds – in this particular case the Texel from The Netherlands and France. There were no known flocks of Texels in Britain until their introduction in early 1970s as a maternal breed playing a part in the stratified crossbreeding structure endemic in Britain. Regular surveys of the breeding structure of the British sheep industry over the last 50 years have highlighted the growth of the Texel breed in the country. The latest survey carried out in 2020 showed just how far the breed had spread throughout the various sectors of the British sheep industry. Although originally thought of as a maternal breed, on initial importation, the breed soon demonstrated a higher carcase lean content in subsequent carcase evaluations. This resulted in its widespread adoption as a sire of lambs for meat production. Thus by 2020 about 27% of the ewes in Britain were mated to Texel rams and their genes accounted for the largest breed contribution to lamb carcase meat. Whereas the Texel found its place on British farms as a terminal sire it was also discovered that the breed had suitable maternal qualities, the main reason for its original importation. By 2020 the breed contributed to over 2 million crossbred ewes mostly used as the mothers of lambs for meat production. Thus, from a starting point of zero in 1970 the breed has spread throughout the British sheep industry to contribute to both the paternal and maternal side of lamb production. Not surprisingly this has led to a reduction in the use of local breeds in these roles over this period (1970 to 2020). On the paternal (Terminal Sire) side the Suffolk breed has gone from over 50% of the national ram flock in 1970 down to about 9% in 2020. Whereas the Suffolk did not play such an important role in the maternal component of British sheep, nevertheless its role on the maternal side has declined too. Interestingly, the various breed surveys carried out over the last 50 years have highlighted over 26 imported breeds in Britain and another 16 synthetic produced locally; none of these other breeds or synthetics have achieved the same level penetration of the British sheep industry as the Texel. This dramatic uptake of a new breed over 50 years is a reflection of its qualities both as a contributor to higher lean proportion carcases and more efficient mothering abilities of the ewes. Clearly decisions in the early days of importation were based on objective measurement of the characteristics of a new breed and extensive highlighting of the advantages of using such a breed in the appropriate sectors of the industry.

Genomic insights into the genetic diversity of the Slovak Askanian merino sheep

A. Halvoník[1], N. Moravčíková[1], K. Pálešová[1], I. Pavlík[2], J. Tomka[2], L. Vostrý[3], H. Vostrá-Vydrová[3], R. Kasarda[1]
[1] Slovak University of Agriculture in Nitra, Faculty of Agrobiology and Food Resources, Institute of Nutrition and Genomics, Tr. A. Hlinku 2, 94976 Nitra, Slovakia, [2] NAFC – Research Institute for Animal Production Nitra, Hlohovecká 2, 95141 Lužianky, Slovakia, [3] Czech University of Life Sciences Prague, Faculty of Agrobiology, Food and Natural Resources, Kamýcká 129, 16500 Prague, Czech Republic

The Merino sheep is a globally recognized fine-wool population that has given rise to numerous Merino and Merino-derived breeds. The Askanian Merino is one such breed, established between 1925 and 1934 at Askania Nova in Ukraine and historically maintained in Eastern and Central Europe. However, in recent decades, changes in the wool industry and an overall decrease in the number of sheep in Slovakia have led to a dramatic decline in its population size. Currently, the Slovak Askanian Merino population is confined to only a few hundred animals. Therefore, this study aimed to characterize the genomic diversity of the Slovak Askanian Merino population using SNP data. After standard quality control, the dataset comprised 48,419 autosomal SNPs and 506 individuals, representing the entire active population of the Slovak Askanian Merino. Genetic diversity was assessed using the inbreeding coefficient based on homozygous-by-descent segments (FHBD) and the effective population size (Ne) estimated based on the relationship between linkage disequilibrium patterns and Ne. The Slovak Askanian Merino showed a total FHBD of 2.5%, while the most pronounced length category of the HBD segments contributing to overall inbreeding exceeded 16 Mb. These long HBD segments reflect recent common ancestry within the population. A difference in inbreeding was observed between sexes, with FHBD reaching 2.5% in ewes and 5.3% in rams. The higher FHBD observed in rams likely reflects the limited number of breeding males in the current population. This increases the probability of mating among related individuals and contributes to higher realized inbreeding in rams. The contemporary Ne was estimated at 78 individuals, while historical Ne estimates showed a decreasing trend over recent generations. The observed trends in Ne and FHBD are consistent with demographic changes in the analysed population and indicate a recent reduction in genetic diversity. These results suggest that targeted genetic diversity management is necessary to prevent further erosion of this unique animal genetic resource. This research was supported by the Ministry of Education, Research, Development and Youth of the Slovak Republic (grant no. 1/0316/25) and the Slovak Research and Development Agency (grant no. APVV-20-0161).

Genomic diversity and population structure of the endangered Thuringian goat breed

A. W. Omar[1], P. Korkuć[1,2], E. Strucken[1], G. B. Neumann[1,2], A. Martinez[3], S. Carolan[4], G. A. Brockmann[1], S. A. Rahmatalla[1,5]

[1] Humboldt Universität zu Berlin, Unter den Linden 6, 10099 Berlin, Germany, [2] Leibniz Institute for Zoo and Wildlife Research, Alfred-Kowalke-Straße 17, 10315 Berlin, Germany, [3] University of Cordoba, ceiA3., 14071 Cordoba, Spain, [4] Old Irish Goat Centre, Mulranny, F28X213 Mayo, Ireland, [5] University of Khartoum, Shambat, 13314 Khartoum North, Sudan

The Thuringian goat is an endangered dairy breed from Germany that was developed in the 20th century through crossbreeding between local goats in Thuringia and the Swiss Toggenburg goats. It is valued for its high milk yield, fertility, hardiness, and adaptability to cold, mountainous, and harsh environments. This study aimed to assess the genetic diversity of the Thuringian goat and examine its genetic relationships with other European breeds, especially its historical ancestor, the Toggenburg goat, as well as to identify genomic regions under positive selection. Genetic analyses were conducted using SNP chip data from 1,233 animals representing 36 European breeds across 43 populations. After quality control, 47,040 SNPs were retained for downstream analyses. Genetic diversity was assessed using observed and expected heterozygosity and nucleotide diversity, while inbreeding was estimated from excess homozygosity. Relationships between Thuringian goats and other European breeds were analysed using FST, phylogenetic analysis, and PCA, and selection signatures were identified from RoH islands. The analyzed Thuringian goat population exhibited the lowest genetic diversity among all breeds, characterized by the lowest heterozygosity (36.61%), the lowest nucleotide diversity (6.37×10^{-6}), and a high inbreeding level (FHom = 18.2%). The Thuringian goat showed moderate genetic differentiation from the investigated European breeds, with FST values ranging from 0.104 with Alpine (Italy) and Saanen (France) to 0.126 with Malaguena (Spain), while Toggenburg populations showed FST values of 0.128 and 0.133 for the Swiss and Tanzanian populations, respectively. Principal component analysis (PCA) revealed that Thuringian goats clustered closely with Alpine (Italy), Saanen (France), and Toggenburg (Switzerland), whereas the Toggenburg population from Tanzania exhibited greater divergence. RoH analysis showed higher homozygosity in short regions (<1 Mb; FRoH = 4.33%) and lower homozygosity in longer regions (>4 Mb; FRoH = 3.22%). This pattern indicates mainly historical inbreeding in the Thuringian goat, whereas recent conservation efforts may have mitigated recent inbreeding. Genes located within RoH islands in Thuringian goats were mainly associated with mastitis and mammary innate immunity, lipid metabolism and oxidative homeostasis, immune and cellular regulation, fertility and reproduction, stress response, development, bone growth, and neurodevelopment. The low genetic diversity and high inbreeding observed in the Thuringian goat underline the need for targeted breeding and conservation efforts. Expanding the genetic base, strengthening breeder networks, and limiting further inbreeding will be crucial to safeguard the long-term viability and genetic integrity of this endangered breed.

From pedigree to genomics, studying genetic diversity and selection signatures in the Cornigliese sheep breed

V. Asti[1], M. Ablondi[1], M. S. Ferrari[2], A. Negro[4], S. Grande[3], M. Malacarne[1], A. Summer[1], A. Sabbioni[1]
[1] University of Parma, Department of Veterinary Science, Str. del Taglio, 10, 43126 Parma, Italy, [2] University of Padova, Department of Agronomy, Food, Natural Resources, Animals and Environment, Vle dell'Università, 16, 35020 Legnaro, Italy, [3] Italian Sheep and Goat Breeders Association, Viale Palmiro Togliatti, 00155 Roma, Italy, [4] University of Florence, Department of Agriculture, Food, Environment and Forestry, Piazzale delle Cascine, 18, 50144 Firenze, Italy

Sheep are among the most widespread species in the Mediterranean region and play a central role in traditional farming systems. According to the FAO, over 60% of Italian sheep breeds are classified as having an unknown risk status, and about 28% are considered endangered. Among these endangered breeds, the Cornigliese sheep is a local breed facing a population decline. The small population size and limited pedigree information make it challenging to control inbreeding and manage genetic diversity in this breed. Therefore, implementing effective conservation strategies is essential for ensuring the breed's long-term survival. The present study aims to investigate genetic diversity and selection patterns in the Cornigliese sheep breed using an integrated approach based on pedigree and genomic data. We used pedigree information from 5,784 animals and genomic data from 293 individuals genotyped with the Illumina® OvineSNP50v2 BeadChip. An additional 42 individuals from the Bergamasca breed were genotyped with the same SNP chip. All analyses related to pedigree completeness and genetic variability were performed using ENDOG (v4.8), while genotype data were analyzed in PLINK (v1.9) and R (v4.5.0). Pedigree-based inbreeding in Cornigliese sheep is notably low (2%). However, due to low pedigree completeness (CGE = 1.03), the reliability of these values is limited. In contrast, genomic inbreeding showed a higher level of inbreeding (10%), consistent with values reported for other Italian local breeds. Meanwhile, Bergamasca sheep exhibited lower genomic inbreeding (6%), consistent with their much larger population size. Our analysis also supports the historical and geographical connections between the two breeds examined. Population structure analyses revealed a close clustering of Cornigliese and Bergamasca sheep, reflecting their historical exchanges. ROH islands, shared by at least 70% of individuals within specific farms, were identified as candidate SNPs under directional selection. Selection-signature analysis identified several ROH islands, primarily on chromosomes 2, 6, and 9, where genes and quantitative trait loci (QTLs) associated with growth, carcass, milk, and wool traits are located. On chromosome 2, the TFPI gene was identified in the flanking region of an ROH island. TFPI is a plausible candidate target for selection related to growth and productive performance, as it has previously been associated with body weight in meat-oriented breeds across several species, including horses and cattle. The ROH island detected on chromosome 6 overlaps with a genomic region previously linked to wool quality in other sheep breeds, such as Mérinos, which historically contributed to the development of the Cornigliese breed through crossbreeding. In addition, within the ROH island on chromosome 9, the UBXN2B gene emerges as a promising candidate due to its reported association with carcass weight and intramuscular fat deposition. Overall, these findings reveal genomic regions influenced by both historical and recent selection, offering important insights to inform conservation programs and future genomic selection strategies for this endangered breed.

Predicting Feed Efficiency from Multi-Omics Data in Lambs Fed Two Consecutive Diets

Q. Le Graverand[1], C. Bellanger[1], C. Marie-Etancelin[1], J. L. Weisbecker[1], N. Marty-Grasset[1], M. L. Chemit[1], F. Tortereau[1]

[1] GenPhySE, Université de Toulouse, INRAE, ENVT, 24 Chemin de Borde-Rouge-Auzeville CS 52627, 31326 Castanet-Tolosan, France

In sheep farming, improving feed efficiency can lower the carbon footprint, limit the feed-food competition and strengthen farmers' economic sustainability. However, few breeding companies can record individual feed intake, which is essential to estimate feed efficiency. Previous studies have identified feed efficiency proxies, such as plasma metabolites or rumen microorganisms. Nonetheless, it remains unclear whether proxies are robust across environments. Here, the goal was to assess whether feed efficiency proxies are generalizable across different years, diets and growing periods. Since 2015, Romane meat lambs have been divergently selected for residual feed intake at the INRAE P3R unit (https://doi.org/10.15454/1.5483259352597417E12). Between 2018 and 2022, 290 male lambs were raised under two different diets. First, lambs were accustomed to a 100% concentrate diet and were phenotyped in spring (17 to 23 weeks of age). Later, the same animals were fed a mixed diet (66% hay, 33% concentrate) and were phenotyped either in summer (29 to 35 weeks of age) or in fall (37 to 43 weeks of age). Under each diet, the collected phenotypes included body weight at the beginning and end of the 6-week period, as well as back ultrasound to measure muscle depth and backfat thickness. Daily intakes of concentrate and forage were recorded to compute the average daily energy intake (ADEIC under a concentrate diet, ADEIM under a mixed diet). From the previous phenotypes, residual energy intake (REIC or REIM) was calculated separately for each diet. Lambs were genotyped with a 54K SNP chip. After each 6-week period, the rumen microbiota was sequenced (16S V4-V5 regions), and the plasma metabolome was obtained using NMR spectroscopy. Partial least-squares models were used to assess the predictive ability of pedigree, genotypes, microbiota and metabolomic data separately. The prediction accuracies of REI and ADEI were computed by randomly subsampling the datasets 100 times and averaging the Pearson correlation (r) between the predicted and true phenotypes. Models were developed for each diet and also across diets, using proxies measured under one diet to predict phenotypes under the other. Whatever the diet, the best proxies for REI were the pedigree and the genotypes ($r = 0.56$ for REIC and 0.32 for REIM), followed by plasma NMR spectra ($r = 0.42$ and 0.26), and rumen microbiota ($r = 0.16$ and 0.19). When samples were collected under one diet, no reliable proxies could be identified to predict REI under the other diet. Whatever the diet, ADEI was better predicted by fixed effects and body weight ($r = 0.88$ for ADEIC and 0.78 for ADEIM). ADEI could be moderately predicted by omics data ($0.58 \leq r \leq 0.69$ for ADEIC, against $0.47 \leq r \leq 0.65$ for ADEIM). When ADEI was measured under one diet, proxies collected under the other diet could still moderately predict it. For example, ADEIM was partially predicted by the rumen microbiota composition under the concentrate diet ($r = 0.64$). Similarly, ADEIC was moderately predicted by the rumen microbiota under the mixed diet ($r = 0.69$). However, models selected different proxies depending on the diet. Finally, the prediction distributions suggest that microbiota data and NMR spectra mostly capture the environmental variations of energy intake, such as the year of rearing. Our results confirm that feed efficiency and energy intake proxies are context-specific: proxies could not be generalized across diets or environments. Thus, integrating new omics data into breeding programs would require collecting omics data routinely: each year and under each farming system.

Estimation of genetic parameters for meat traits using replacement ewe lambs.

J. Raoul[1,2], H. Geniès[3], C. Burg[3], M. Arnal[1,2], F. Tortereau[1]
[1] GenPhySE, Université de Toulouse, INRAE, ENVT, campus INRAE, 31326 Castanet Tolosan, France, [2] Institut de l'élevage, campus INRAE, 31326 Castanet Tolosan, France, [3] Ovi-Test, 5 rue de la Prade, 12850 Onet-le-Château, France

In the Lacaune meat sheep breeding program, run by the breeding society Ovi-Test, elite artificial insemination rams are evaluated based on the maternal abilities of their daughters in nucleus flocks. Concurrently, these elite rams are also evaluated for meat traits based on the phenotypes of their progeny in dairy ewe flocks. Ongoing developments within the Lacaune meat sheep breeding program, particularly the prospective transition from traditional to genomic selection, offer the opportunity to reorganize meat trait evaluation, potentially restricting phenotyping to nucleus flocks only. Ovi-Test has implemented a protocol for recording meat trait data on replacement ewe lambs. Since 2024, 1,421 ewe lambs from 16 flocks have been phenotyped on-farm for meat traits at approximately 110 days of age (mean = 108 days). Measurements included ultrasound scanning for fat (mean = 4.6 mm) and muscle depth (mean = 23.3 mm), muscle development scoring (five elementary scores rated from 1 to 10), and post weaning growth (mean = 168 g/day). Uni-trait genetic evaluations revealed heritability estimates close to those used in official evaluations. Estimated heritabilities for growth rate, fat depth, and muscle depth were 0.278, 0.274, and 0.375, respectively. Multi-trait models confirmed these estimates. Preliminary estimates of genetic correlations suggest an unfavourable genetic correlation between fat and muscle depth, however, the accuracy of these estimates is low and additional data are required to achieve sufficient precision. These initial results indicate that selection for meat traits, assessed through phenotyping of replacement ewe lambs, is feasible. Reproductive performance data from these ewe lambs as well as the pre-weaning growth of their progeny will enable a first estimation of genetic correlations between meat and maternal traits in the Lacaune meat breed.

Enhancing the sustainability of Latvian sheep breeding through genomic selection for relative growth rate and Kleiber ratio

N. Paramonova[1], M. Martins[1], S. Plavina[1], D. Malakovska[1], N. Krasnevska[1], J. Paramonovs[1], D. Kairisa[2], I. Trapina[1]
[1] Genomics and Bioinformatics Centre, Department of Pharmaceutical Sciences, Faculty of Medicine and Life Sciences, The University of Latvia, Jelgavas 1, LV-1004 Riga, Latvia, [2] Department of Animal Sciences, Faculty of Agriculture and Food Technology, Latvian University of Life Sciences and Technologies, Liela Street 2, LV-3001 Jelgava, Latvia

The function of breeders of sheep breeds is not only to produce economically valuable lamb meat, but also to improve the breed, especially in the case of national breeds. One indicator of breed improvement, which also contributes to breeders' income, is feed conversion relative to live weight gain, or breeding lambs with high feed efficiency. Marker-assisted selection (MAS) related to feed utilisation has been developed for commercial breeds, but it is not yet applicable to national breeds. The aim of the study was to identify molecular markers from the GeneSeek® Genomic Profiler™ Ovine 50K (Lansing, MI, USA), that are related to feed efficiency indicators: relative growth rate (RGR) and Kleiber ratio (KR) in Latvian sheep breeds, especially in the national breed. DNA genotyping data from 261 controlled fattening lambs of eight common breeds, including 135 (51.72%) of the national breed Latvian Dark-headed (LT), were used. The computed average RGR and KR for the 60-day period (from day 90 to 150) for all lambs were 0.40±0.12 % per day and 18.84±2.52, respectively; whereas for the LT breed, they were 0.36±0.08 % per day and 19.80±2.27, respectively. In the genome-wide association study (GWAS) analysis for association with RGR, 1876 SNPs were identified with $P < 0.01$ and 3709 SNPs with $P < 0.05$ across all breeds and 504 SNPs were identified with $p<0.01$ and 2014 SNPs with $p<0.05$ for the LT breed only. For association with KR, 2277 SNPs were identified with $P < 0.01$ and 3976 SNPs with $P < 0.05$ across all breeds and 526 SNPs were identified with $P < 0.01$ and 2053 SNPs with $P < 0.05$ for the LT breed only. GWAS results showed 4130 common loci for RGR and KR across all breeds, and 1472 loci for the LT breed only. Machine learning methods were employed to integrate lamb birth rates and GWAS-significant loci to identify the most effective predictors of the lamb RGR or KR prior to the fattening phase. The resulting MAS prediction would facilitate the identification of potential breeding candidates before they mature. The study revealed the potential of MAS to enhance national breeding efforts in Latvia, especially for the LT breed, thereby improving breed development and competitiveness while maintaining national value. Acknowledgements: Funded by UL Faculty of Medicine and Life Sciences internal student grant FUD2025/195, and by the Latvian Council of Science, Latvia, projects LZP-2021/1-0489 and LZP-2024/1-0092.

Genetic determinism of leather pinhole defect in Lacaune dairy sheep

H. Largant[1], H. Larroque[1], M. C. Cadiergues[5], C. Allain[2], M. Lamarque[2], F. Woloszyn[1], F. Plisson-Petit[1], K. Feve[1], S. Lucas[3], J. C. Duchêne[4], D. Allain[1], S. Fabre[1], L. Drouilhet[1]

Lacaune lamb skins are renowned for their exceptional suitability for high-quality leather production, catering to the luxury industry. However, over the past few decades in France, the quality of this leather has declined significantly, primarily due to the increasing prevalence of a skin defect known as pinhole. This defect manifests as small holes in the grain surface of the dewooled pelt. To unravel the genetic determinism of this defect, 1,400 Lacaune lambs were genotyped using the Illumina OvineSNP50 BeadChip and phenotyped for the pinhole defect. A genome wide association study revealed a region located on OAR3 that influences this trait. Haplotypes surrounding the most significant SNP were reconstructed and evaluated using analysis of variance, leading to the identification of haplotypes associated with a less pronounced skin defect. Through the whole genome sequencing of 14 animals and the analysis of polymorphisms located within a 5 Mb region surrounding the most significant SNP, three candidate causal mutations were identified in keratin genes KRT1, KRT8 and KRT74. These mutations are non-conservative resulting in changes in the protein-coding sequences. To investigate the potential effects of these candidate mutations, controlled matings were conducted on an experimental farm to produce lambs homozygous for either the wild-type or the mutated alleles at the three loci. Skin biopsies were collected at 2 months of age from these lambs. After slaughter at the end of the fattening period, skins were tanned and visually assessed by experienced tanners for the presence of pinhole. Histological examination and gene expression analyses of the biopsy samples are currently being conducted to elucidate the molecular mechanisms underlying the presence of skin defects. This study brings to light the first evidence of genetic markers that can be used for the sorting of lambs with high potential for skin quality.

Effect of Aloe vera Supplementation in a Tris-Based Cryoextender on the Post-Thaw Quality of Box-Frozen Goat Spermatozoa

A. G. Onal[1], Y. Z. Guzey[2]
[1] Cukurova University, Animal Science, Sarıçam, 01330 Adana, Turkey, [2] Hatay Mustafa Kemal University, Animal Science, Serinyol, 31060 Hatay, Turkey

Goat semen cryopreservation is an important reproductive biotechnological tool for sperm conservation. However, freezing–thawing can impair sperm function and structure. Cold shock, osmotic imbalance, and oxidative stress are major limitations for the successful cryoprervation for frozen semen in goats. Therefore, improving the composition of semen extenders is of considerable practical interest. Aloe vera, known for its antioxidant and protective bioactive components, may help reduce cryoinjuries, but there is limited evidence regarding its use in goat semen cryopreservation. This study aimed to evaluate the effect of Aloe vera supplementation in a Tris-based extender on the post-thaw quality of box-frozen goat spermatozoa. Semen samples were collected from three sexually mature Saanen bucks using an electroejaculator. Fresh semen was assessed before cryopreservation to establish baseline values. Post-thaw sperm kinetics were evaluated using the iSperm portable Computer-Assisted Sperm Analysis (CASA) system (Aidmics Biotechnology). Total motility and progressive motility were numerically lower in the Aloe vera group than in the control group (47.50 ± 4.79% vs 60.50 ± 2.40% and 43.25 ± 4.04% vs 56.25 ± 2.43%, respectively). Similarly, the number of live spermatozoa was lower in the Aloe vera group than in the control group (44.50 ± 3.30 vs 56.75 ± 3.20), whereas the number of dead spermatozoa was higher (72.75 ± 3.64 vs 58.75 ± 2.72). However, paired statistical comparisons showed that these differences were not statistically significant ($P > 0.05$). In conclusion, Aloe vera supplementation to the tested Tris-based extender did not improve the post-thaw quality of box-frozen goat spermatozoa under the present experimental conditions.

Genetic background of feed efficiency residual traits for sustainable breeding of sheep breeds raised in Latvia.

I. Trapina[1], M. Martins[1], S. Plavina[1], D. Malakovsa[1], N. Krasnevska[1], J. Paramonovs[1], D. Kairisa[2], N. Paramonova[1]
[1] Genomics and Bioinformatics Centre, Department of Pharmaceutical Sciences, Faculty of Medicine and Life Sciences, The University of Latvia, Jelgavas str 1, LV-1004 Riga, Latvia, [2] Department of Animal Sciences, Faculty of Agriculture and Food Technology, Latvian University of Life Sciences and Technologies, Liela str 2, LV-3001 Jelgava, Latvia

Sheep breeders' responsibilities extend beyond just producing economically viable lamb meat. They also involve improving breed quality, especially for indigenous populations. One of the key indicators of breed improvement that can also increase breeders' income is feed efficiency relative to live weight gain, particularly through selecting lambs with higher feed efficiency. Marker-assisted selection (MAS) related to feed utilisation has already been developed for commercial breeds; however, it has not yet been adapted for national breeds in Latvia. The aim of this study was to identify molecular markers associated with residual traits of feed efficiency, specifically residual feed intake (RFI), residual weight gain (RWG), and residual intake and body weight gain (RIG) in sheep breeds that are raised and selected in Latvia, with a particular emphasis on the national breed, the Latvian Dark-headed (LT). Genotyping data collected using the GeneSeek® Genomic Profiler™ Ovine 50K (Lansing, MI, USA) were analysed from 261 performance-tested fattening lambs from eight common breeds, including 135 animals (51.72%) from the national Latvian Dark-headed breed. Across all lambs, the RFI and RWG values calculated for the 60-day period (from day 90 to 150) ranged from -0.16 to 0.14 (SD 0.04) kg per day and from -0.45 to 0.52 (SD 0.16) kg per day, respectively. For the LT breed, these values ranged from -0.11 to 0.11 (SD 0.04) kg per day. The ranges of RIG were from -5.51 to 3.44 (SD 1.65) across all lambs and from -4.50 to 3.46 (SD 1.62) in the LT group. The genome-wide association study (GWAS) results for RFI found 1,095 SNPs with a significance level of less than 0.01 and 3,068 SNPs with a significance level of less than 0.05 across all breeds; in the LT breed alone, there were 559 SNPs ($P < 0.01$) and 1,986 SNPs ($P < 0.05$). The analysis identified 2,524 SNPs with $P < 0.01$ and 4,058 SNPs with $P <0.05$ for RWG across all breeds; the LT population specifically exhibited 533 SNPs ($P < 0.01$) and 2,189 SNPs ($P < 0.05$). GWAS analyses found 1,118 loci linked to both RFI and RWG across all breeds, and 335 loci in the LT breed. For RIG, 1,539 SNPs ($P < 0.01$) and 3,305 SNPs ($P < 0.05$) were identified across all breeds; specifically, within the LT breed, 533 SNPs ($P < 0.01$) and 1,999 SNPs ($P < 0.05$) were identified. Of all the SNPs associated with RIG, 1,094 loci were also associated with RFI and RWG in the entire sample group, and 331 SNPs were found within the LT breed. Machine learning methods were used to combine lamb birth data with important genetic markers to identify the best indicators of RFI, RWG, or RIG before the fattening phase. The resulting MAS-based predictions would enable the identification of promising breeding candidates before they reach maturity. Overall, the study demonstrates the potential of MAS to strengthen national breeding programmes in Latvia, particularly for the Latvian Dark-headed breed by supporting genetic improvement, increasing competitiveness, and preserving national genetic resources. Acknowledgements: Funded by the UL Faculty of Medicine and Life Sciences internal student grant FUD2025/195 and by the Latvian Council of Science, Latvia, projects LZP-2021/1-0489 and LZP-2024/1-0092.

Mapping Growth and Carcass Traits in Sheep for Sustainable, Low Emission Meat Production.

S. R. Chacko Kaitholil[1,2], M. H. Mooney[1], A. Aubry[2], F. I. Rezwan[3], M. Shirali[1,2]
[1] Queen's University, Belfast, School of Biological Sciences, 19 Chlorine Gardens, BT9 5DL Belfast, United Kingdom, [2] Agri-food and Biosciences Institute, Large Park, BT26 6DR Hillsborough, United Kingdom, [3] Aberystwyth University, Department of Computer Sciences, Penglais, SY23 3FL Aberystwyth, United Kingdom

Sheep body weights, especially pre-weaning (pre-WW, 8 weeks), post-weaning (post-WW, 20 weeks) and carcass weight (CW), are key indicators of early development, feed efficiency, and market readiness. Improving these traits enhances productivity while also reducing emissions per kilogram of meat, as animals that grow fast require less feed and emit less. This study aimed to identify single nucleotide polymorphisms (SNPs) associated with body weight and carcass traits by utilizing single-step genome wide association study (ss-GWAS) and regional heritability mapping (RHM) methods. A high-quality dataset of 1,348 sheep with pre- and post-WW and 289 with CW, alongside 43,823 SNPs, was analysed. Both methods employed a mixed linear model with litter size, age at pre- and post-weaning, and age at slaughter as fixed effects. Borderline suggestive signals ($P < 2.3\times10^{-5}$) emerged for pre-WW including two SNPs on chromosome 3 and one SNP each on chromosome 4 and 20. One SNP on chromosome 17 surpassed suggestive significance for CW ($P < 2.2\times10^{-5}$). RHM analysis yielded multiple suggestive regions on chromosome 3 for pre-WW ($P < 0.005$), and chromosome 17 for CW ($P < 0.0002$). No significant SNPs were identified for post-WW from either method. Gene annotation within ±50 kb region of the SNPs identified 34 genes for pre-WW with five (DNAI7, IRAG2, ENSOARG00020084804, ENSOARG00020092445, ENSOARG00020065109) overlapped between ssGWAS and RHM. For CW, both ss GWAS and RHM highlighted MAML3 as an overlapping gene. Functional annotation of the overlapped genes from both methods indicated pre-WW genes were linked to ciliary movement and sensory perception, whereas CW genes were associated with gluconeogenesis, hepatic lipogenesis, and intramuscular fatty acid deposition. This study has demonstrated that the integration of ss-GWAS with RHM reveals single SNP and regional effects for sheep body weight and carcass traits, identifying genes that can support breeding of animals with greater efficiency, lower emissions, and improved carcass quality.

Genome-wide signatures of selection and genomic divergence in three autochthonous sheep breeds from Epirus, Greece

A. Kominakis[1], D. Gelia[2], D. Pappas[3], M. Goliomytis[1]
[1] Agricultural University of Athens, Department of Animal Science, Iera Odos 75, 11855 Athens, Greece, [2] Association of Pastoral Farmers of Epirus, Ethnikis Antistaseos Street 5, 45221 Ioannina, Greece, [3] Ioannina Center for Animal Genetic Resources, Panepistimiou Street, Terma, 45110 Katsika Ioannina, Greece

Indigenous sheep breeds represent valuable genetic resources shaped by long-term adaptation to local environments and by human-driven selection for production and health-related traits. Understanding the genomic basis of divergence among such breeds can provide insights into both evolutionary processes and breeding history. In this study, we investigated genome-wide signatures of selection and genomic differentiation among three autochthonous sheep breeds from Epirus, Greece: Kalarrytiko, Katsika, and Oreino. Genome-wide allele frequency data from 53,274 SNPs and approximately 100 animals per breed were used to detect lineage-specific divergence. Breed-specific differentiation was quantified using the population branch statistic (PBS), while absolute allele frequency differences ($|\Delta p|$) were calculated between each focal breed and the mean allele frequency of the remaining breeds. To reduce stochastic variation at individual loci, both statistics were summarized across non-overlapping windows of ten SNPs. Candidate regions were identified using a stringent empirical threshold corresponding to the top 0.1% of the genome-wide distributions for both PBS and $|\Delta p|$, and adjacent significant windows were merged to define contiguous selection sweeps. Candidate genes were defined as genes whose genomic coordinates overlapped the detected sweep regions according to the Oar_v4.0 reference genome annotation. Several genomic regions showed signals of breed-specific genomic differentiation. A candidate region detected in the Kalarrytiko breed overlapped the LCORL–NCAPG locus on chromosome 6. This region showed elevated $|\Delta p|$ values and clear allele-frequency divergence relative to the other breeds. The LCORL–NCAPG locus has been widely associated with body size and growth traits in livestock, suggesting that variation in this region may contribute to phenotypic differentiation among Epirus sheep breeds. Another candidate region detected in the Oreino breed overlapped the prion gene cluster (PRNP, PRND, PRNT). The PRNP gene (OAR13) encodes the prion protein and is a major determinant of genetic susceptibility to scrapie in sheep. The differentiation signal was concentrated in a narrow cluster of highly divergent SNPs, indicating localized divergence at the PRNP locus. Given that Kalarrytiko and Katsika have been selected for scrapie resistance, whereas Oreino has not, this pattern likely reflects divergence generated by selection in the former two breeds rather than positive selection acting specifically in Oreino. Additional genes overlapping sweep regions included CBS, CRYAA, NDUFV3, PKNOX1, SIK1, U2AF1, RASSF2, SLC23A2, and TMEM230, which are involved in diverse metabolic, regulatory, and cellular processes. Although the functional roles of these genes in sheep production traits remain to be clarified, their presence within differentiated genomic regions suggests potential involvement in breed-specific adaptation. Overall, the results highlight genomic regions shaped by both artificial selection for disease resistance and selection related to growth and physiological processes, providing new insights into the genomic architecture and evolutionary differentiation of indigenous sheep breeds from Epirus, Greece.

Variation in host transcriptomic responses in three SRLV-associated tissues in relation to sheep serological SRLV infection status, TMEM154 E35K polymorphism and breed

E. Grochowska[1], O. O. Adeniyi[2], M. Ibrahim[1], K. Pokrzywka[1], P. Guz[3], G. Lühken[2]
[1] Nicolaus Copernicus University, Collegium Medicum, Faculty of Health Sciences, Łukasiewicza 1, 85821 Bydgoszcz, Poland, [2] Justus Liebig University, Institute of Animal Breeding and Genetics, Ludwigstrasse 21, 35390 Gießen, Germany, [3] Department of Animal Biotechnology and Genetics, Bydgoszcz University of Science and Technology, Mazowiecka 28, 85084 Bydgoszcz, Poland

Small ruminant lentiviruses (SRLV) are prevalent pathogens in sheep populations. The TMEM154 E35K polymorphism is associated with SRLV infection risk; sheep carrying the KK genotype can exhibit reduced susceptibility compared to those with EK or EE genotypes. The influence of this polymorphism on the susceptibility of the host varies according to sheep breed and SRLV genotype. This study aimed to analyze transcriptome differences in three tissues targeted by SRLV−spleen (S), lung (L), medulla oblongata (M) from sheep with opposite serological SRLV infection status and different TMEM154 E35K genotypes, belonging to two sheep breeds. Merinoland (ML) and East Friesian Milk (EFM) sheep ewes (≥ 3 years old) were serologically tested for SRLV and genotyped for the TMEM154 E35K variant, resulting in 3 groups: (1) SRLV-positive, TMEM154 EK (posEK); (2) SRLV-positive, TMEM154 KK (posKK); and (3) SRLV-negative, TMEM154 KK (negKK). After RNA sequencing, differentially expressed genes (DEGs) and enrichment analyses were performed. The analyses revealed breed- and tissue-specific transcriptional patterns. In ML sheep, the highest number of DEGs was observed in M (258) and S (265) tissues between posEK and posKK sheep. These DEGs included genes linked to chemokine-mediated signaling pathway and inflammatory response. In S tissue, specific DEGs (EIF2AK2, RC3H2, and RIGI), which play roles in activating antiviral response mechanisms, were enriched in the double-stranded RNA binding term. All of the above-reported GO terms were significant, except the inflammatory response term (FDR = 0.07 after Benjamini–Hochberg (BH) correction). The L tissue showed few DEGs (30) between these groups. Low numbers of DEGs were found across the three tissues in the remaining group comparisons. In EFM sheep, the highest number of DEGs (71) was observed between posKK and negKK sheep in L tissue. These DEGs were enriched for several GO terms, including type I TGF-β receptor binding term. In this tissue, 47 DEGs were found between posEK and posKK sheep, with several genes enriched in extracellular space and inflammatory response terms. In the S tissue, 37 DEGs were observed between posEK and negKK sheep, including three DEGs enriched in defense response to virus term. Moreover, 28 genes were differently expressed between posEK and posKK groups, including 2 genes enriched in the antibacterial humoral response term in S tissue. The above-reported GO terms in EFM sheep reached nominal significance ($p < 0.05$). However, after BH correction, only the extracellular space term remained significant (FDR < 0.05). Few DEGs were found in M tissue (15) between posKK and negKK groups. In conclusion, ML sheep exhibited more pronounced responses in the central nervous system and spleen, whereas EFM sheep demonstrated stronger transcriptional modulation in lung. These tissue differences as well as the differences in DEG numbers and genes between same TMEM154 genotype comparisons in both breeds are in concordance with both the previously observed different SRLV susceptibility and the differences in association of the TMEM154 genotype KK with serological SRLV infection status in the two breeds. Metabolic stress reshapes intracellular signalling in ovine hypothalamic KNDy neurons

D. Zięba[1], E. Ocłoń[2]
[1] University of Agriculture in Krakow, Animal Biotechnology, Al. Mickiewicza 21, 31-120 Kraków, Poland, [2] University of Agriculture in Krakow, Department of Infectious Diseases and Public Health, Al. Mickiewicza 21, 31-120 Kraków, Poland

Energy balance is a key determinant of reproductive physiology in mammals through hypothalamic mechanisms linking metabolic cues with neuroendocrine regulation. Nutrient availability and circulating metabolic signals are integrated by hypothalamic neurons to coordinate reproductive activity with the energetic status of the organism. Among hypothalamic neuronal populations, KNDy neurons located in the arcuate nucleus play a central role in regulating gonadotropin-releasing hormone (GnRH) secretion and reproductive axis activity. Disturbances in lipid metabolism can influence hypothalamic signaling processes involved in this regulatory network. Elevated circulating fatty acids during metabolic imbalance may disrupt intracellular signaling within hypothalamic neuronal networks. Lipid oversupply can alter neuronal metabolism, promote oxidative stress and modify signaling pathways essential for proper hypothalamic function. However, the molecular pathways connecting lipid-induced metabolic stress with hypothalamic signaling remain insufficiently characterized. Experiments were conducted using the immortalized ovine KNDy neuronal cell line FRI273 derived from the fetal sheep mediobasal hypothalamus and kindly provided by Dr. Patrick Chappell (Oregon State University). Cells were cultured in high-glucose Dulbecco's modified Eagle's medium supplemented with 10% FBS and exposed to palmitate (5 mM) for 24 h to induce metabolic stress. Proteomic and phosphoproteomic profiling was performed using multiplexed TMTpro LC-MS/MS. Data analysis was carried out using MaxQuant and Perseus against the UniProt Ovis aries reference proteome. Among the quantified proteins, approximately 15% showed significant abundance changes ($q < 0.05$). Several enzymes involved in neuronal metabolism were increased, including hexokinase-2 (FC 1.08), fructose-bisphosphate aldolase (FC 1.28) and HMG-CoA synthase (FC 2.77). Proteins associated with redox regulation were also elevated, including NAD(P)H dehydrogenase [quinone] 1 (FC 1.19) and heme oxygenase-1 (FC 1.17). Phosphoproteomic analysis identified 4,086 phosphosites, with 18% showing significant changes ($q < 0.05$). Notable phosphorylation changes were detected in proteins involved in neuronal signaling and membrane trafficking, including the GABA receptor alpha-3 subunit (FC −1.14), dynamin-1 (FC −1.22) and clathrin heavy chain (FC −1.23). These results show that metabolic stress affects proteins associated with neuronal metabolism, redox homeostasis and synaptic signaling in ovine hypothalamic neurons. Increased abundance of metabolic and redox-related proteins suggests activation of adaptive metabolic and antioxidant responses to lipid overload. In parallel, altered phosphorylation of proteins regulating membrane trafficking and cytoskeletal organization indicates remodeling of intracellular signaling processes involved in neuronal regulation. Such phosphorylation-dependent changes may influence receptor trafficking and synaptic responsiveness within hypothalamic networks. Together, these findings indicate coordinated metabolic and signaling adaptations of hypothalamic neurons exposed to lipid-induced metabolic stress. Understanding these responses may help explain how metabolic imbalance affects hypothalamic mechanisms regulating reproductive physiology in mammals, including livestock species. This research was financially supported by the National Science Centre, Poland (Grant No. UMO-2023/51/B/NZ9/00651).

Association of C18 fatty acids, including the shift-t10, with the rumen microbiome in lambs

C. Manuel[1,2,3], S. Moradi[2,3], O. Guerreiro[4], E. Jerónimo[4], S. Alves[2,3], R. Bessa[2,3], D. M. Soares[2,3]
[1] University Zambeze, Alfredo Lawley, 0000 Beira, Mozambique, [2] Centre for Interdisciplinary Research in Animal Health Medicine, Avenida da Universidade técnica, 1300-477 Lisbon, Portugal, [3] Associate Laboratory for Animal and Veterinary Sciences, , Avenida da Universidade técnica, 1300-477 Lisbon, Portugal, [4] Centre for Agricultural and Agri-Food Biotechnology of Alentejo, Campus IPBeja, 7800-295 Beja, Portugal

The rumen microbiota, particularly bacteria, play a crucial role in the biohydrogenation of dietary polyunsaturated fatty acids. This complex process leads to the formation of various intermediates, including trans and conjugated fatty acids, as well as saturated fatty acids, as end products. A phenomenon known as the ”trans-10 shift” occurs when the production of trans-10 biohydrogenation intermediates increases at the expense of trans-11. This shift is believed to be linked to changes in the rumen microbial population. However, there is limited information about the specific microbes responsible for this alteration. This work aims to explore the relationship between C18 fatty acids, particularly the main trans isomers, the 18:0 as the end product, and the trans-10 shift (ratio 18:1t10/18:1t11), and the rumen microbiome composition in lambs. Approximately 150 rumen content samples, previously collected and phenotyped for fatty acid composition, were selected based on high or low trans-10 shifts for 16S rRNA gene sequencing, to identify and classify rumen microorganisms, particularly bacteria, and correlate these findings with C18 fatty acids. Total DNA was extracted from freeze-dried rumen contents using a Qiagen QIAmp DNA Stool Mini Kit (Qiagen Inc., Valencia, CA, USA), according to the manufacturer’s instructions. DNA amplification, library preparation, and sequencing were performed by the MR DNA™ commercial service (Shallowater, TX, USA). Data was analysed using the software R. First, microbial species data were Centred Log-Ratio (CLR) transformed before analysis. Associations between microbial species and fatty acids were evaluated using Spearman correlations followed by Benjamini–Hochberg False Discovery Rate (FDR) correction. Associations with FDR < 0.05 were considered significant. The rumen microorganisms included 97.2% bacteria and 2.7% archaea. Among the composition of bacteria at the phylum level, the most abundant community in the lamb’s rumen was Bacillota (27.6%), Bacteroidota (16.4%), Fibrobacteres (14.7%), Proteobacteria (12.6%), and Bacteroidetes (7.3%). Significant associations were observed between bacterial species and fatty acids related to ruminal biohydrogenation, especially 18:1t10 (802 significant associations) and shift-t10 (761 significant associations). Even 18:1t11 and 18:0 showed 506 and 202 significant associations, respectively. Concerning those associated with 18:1t10, the top 10 included Prevotella lacticifex, Anaerotruncus rubiinfantis, and Butyrivibrio fibrisolvens, some of which are already known bacteria involved in the biohydrogenation of unsaturated fatty acids. These results support the idea that coordinated changes in microbial community composition accompany a shift in biohydrogenation pathways. Integration of these results with genotyping data is ongoing to identify genomic variants linked to resistance to the trans-10 shift. Financial support was provided by PTDC/CAL-ZOO/29654/2017 and UIDB/152816/2022 research projects, UIDB/00276/2020, and LA/P/0059/2020 – AL4Animals.

Assessing the population structure in a recently established hair sheep population using pedigree data

A. M. Deidewig[1], E. Jonas[1,2], B. Hüttenmann[3], E. Tholen[1]
[1] Institut für Tierwissenschaften, Universität Bonn, Abt. Haustiergenetik, Endenicher Allee 15, 53115 Bonn, Germany, [2] Förderverein Bioökonomie Forschung e.V. (FBF e.V.), Adenauerallee 174, 53113 Bonn, Germany, [3] Nolana Netzwerk, kontakt@nolana-schafe.de, 56745 Weibern, Germany

Sheep breeding in Germany is characterised by a small number of large-scale farms and many smallholders. While smaller farms mainly keep sheep often as a hobby, larger farms rely on a high turnover of lambs and low production costs. This also includes fewer management expenses, such as shearing or treatment costs. In 1998, a group of German sheep breeders and farmers crossed Merino ewes with a Wiltshire Horn ram to create a new breed of sheep. The aim of the breeding programme was to produce a robust, polled hair sheep that did not require shearing, but which showed good carcass characteristics. Already after a few generations, most lambs showed preferable traits, especially self-shedding of hair. Further on the mating scheme included Barbados Blackbelly, Berrichon du Cher, Cameroon and Dorper rams for additional improvement. Following the successful development of a robust hair sheep, the population was divided into two distinct breeds based on appearance: the meat-focused Nolana sheep and the Brown sheep, which is better suited to landscape conservation. While these breeds are relatively young, the limited initial population size may increase the risk of inbreeding. This study aimed therefore to determine the population structure of Nolana sheep and establish the risk of inbreeding within and across farms. Pedigree data from more than 17,000 Nolana sheep were investigated using the OptiSel package in R (version 2024.12.0 + 467). With an effective population size exceeding 50, this breed is, by definition, not at risk. Furthermore, there is a growing interest in the breed, accompanied by an increase in population size. The average inbreeding coefficient was low (F = 3.9%), though an increase was observed on some farms. Inbreeding coefficients were similar in ewes and rams. Most of the Nolana sheep investigated had an inbreeding coefficient below 1%, with nearly half of the population showing no inbreeding. While an increase of the inbreeding coefficient was observed until 2010, recent years showed a decline again. An average kinship coefficient between pKin = 1 % and 3 % was observed. The analysis of the genetic contribution showed the larger contribution of Wiltshire Horn and Dorper rams, and smaller contribution of Cameroon and Barbados Blackbelly rams. The farm-based analyses showed larger management differences based on the introduction of other breeds, this especially contributed to the aim for an improved carcass quality. Based on the population size and inbreeding, this study indicates that the Nolana breed is currently not at risk. Genomic analysis could help to improve our understanding of the population structure and breeding programme.

Rethinking phytate utilisation in poultry: Endogenous phytate degradation and influencing factors

M. Rodehutscord[1]
[1] *University of Hohenheim, Institute of Animal Science, Emil-Wolff-Str. 10, 70599 Stuttgart, Germany*

Phytate-bound phosphorus (P) in plant feedstuffs was long considered unavailable to poultry. This concept shaped feeding strategies, P evaluation assays, and development of exogenous enzymes. However, poultry possess an endogenous capacity to degrade inositol-hexakisphosphate (InsP6), releasing P and myo-inositol (MI). This contribution summarises recent findings on endogenous InsP6 degradation in growing birds and laying hens. In broiler chickens, endogenous InsP6 degradation can exceed 70% and responds strongly to dietary mineral P and calcium (Ca). Mineral P, and particularly excess Ca, reduces InsP6-P digestibility. Therefore, P digestibility values of individual feedstuffs are not additive in mixed diets. In broilers, changes in InsP6 degradation are consistently associated with alterations in ileal and plasma MI and P digestibility. In young turkeys, lower degradation than in broilers was observed when species-specific diets were fed. When both species received the same diet, mucosal phytase activity, InsP6 degradation, and P digestibility did not differ at 3 weeks of age, indicating similar intrinsic capacities. At 6 weeks, turkeys showed higher enzyme activity. MI responses differed markedly between species, suggesting species-specific MI metabolism. In laying hens, the interdisciplinary Research Unit "P-Fowl" (https://p-fowl.uni-hohenheim.de/en) found that Ca in feed and intestinal lumen is a stronger regulator of endogenous InsP6 degradation than dietary mineral P. Complete renunciation of mineral P only modestly stimulated degradation under high-Ca conditions. This contrasts with broilers and turkeys. A marked physiological shift occurs at the onset of laying. The transition from pre-lay (~19 weeks) to active lay (~24 weeks) represented a comprehensive systemic adaptation of mineral metabolism. After onset of lay, mucosal phytase activity and InsP6 degradation increased, accompanied by changes in intestinal gene expression, endocrine regulation, plasma mineral profiles, transporter abundance, and medullary bone. Genetic background introduces further variability. Lohmann Brown (LB) and Lohmann Selected Leghorn (LSL) hens showed distinct metabolic strategies in the P-Fowl studies. LB exhibited higher mucosal enzyme activity, higher intestinal InsP-related gene expression, higher plasma phosphate and MI, and greater ileal MI flow and disappearance. LSL but not LB showed increased intestinal sodium-dependent phosphate transporter (NaPi-IIb) protein expression at onset of lay. With graded MI supplementation, LB upregulated NaPi-IIb, whereas LSL downregulated it, without major plasma P changes. MI is not merely a degradation end-product but a metabolically active molecule linking InsP6 hydrolysis to intracellular phosphate sensing and energy homeostasis via inositol phosphates and pyrophosphates. LB appear to have a metabolic strategy with enhanced MI turnover and phosphate transport, associated with higher egg MI concentration. LB showed greater quantitative genetic variation in P metabolism-related traits. Heritability of InsP6 degradation and plasma MI was found only in LB. Overall, poultry show high endogenous potential for InsP6 degradation but marked differences in adaptation. In growing birds, mineral P supplementation is a primary cause of reduced endogenous degradation, whereas in laying hens, high Ca supply predominates. This complexity challenges P evaluation systems. Endogenous InsP6 degradation is central to a system spanning the intestine, bone, endocrine axes, and involving the animal genome, transcriptome, and metabolome.

Dynamics of endocrine and transcriptional profiles in phosphorus and calcium metabolism at onset of egg laying

H. Reyer[1], M. Oster[1], N. Trakooljul[1], S. Ponsuksili[1], V. Sommerfeld[2], M. Rodehutscord[2], K. Wimmers[1]
[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee, 18196 Dummerstorf, Germany, [2] University of Hohenheim, Emil-Wolff-Strasse 10, 70599 Hohenheim, Germany

During sexual maturation in female chickens, endocrine factors such as estradiol, PTH and vitamin D regulate the transition from haematopoietic to medullary bone and coordinate calcium (Ca) and phosphorus (P) homeostasis. Medullary bone forms within the cavities of long bones and serves as a mobilizable Ca source for eggshell mineralization. Adaptive changes in renal reabsorption and systemic mineral metabolism maintain mineral homeostasis at high daily Ca turnover at onset of egg laying. During maturation, laying hens need to manage sharply elevated Ca demands for eggshell formation while forming medullary bone, preserving skeletal integrity and mineral homeostasis. In this study, Lohmann Selected Leghorn (LSL) and Lohmann Brown (LB) were fed sequential developer, pre-layer, and layer diets according to current recommendations. Plasma, kidney, and femur samples were collected from weeks 16-24, covering the pullet stage to onset of lay. Plasma metabolites and gene expression of medullary bone and kidney were analysed. The temporal profile during the study period showed an increase in serum β-CTX-1 in weeks 17 to 21, which was attributable to early matrix degradation, an increase in estradiol in weeks 20 to 21, and the onset of Ca and P accumulation in the medullary bone in weeks 22 to 23. Renal expression of genes involved in active mineral transport (SLC34A1, TRPV6) was low in immature birds until ~20 weeks of age and an upregulation towards week 23. Genes involved in tight junction formation (CLDN10, OCLN) were lowered in mRNA abundance in immature pullets, with lowest values around week 20. Expression of receptors of endocrine regulators (PTH2R, VDR) suggested reduced renal sensitivity to PTH and vitamin D3 in response to high Ca intake along sexual maturation, which might promote hypercalciuria and phosphaturia in the period prior onset of egg laying. Around week 20/21 of life, endocrine cues triggered renal adjustments maintaining hypercalcemia to initiate eggshell formation. Along maturation, the corresponding gene expression profiles in medullary bone indicated synchronized regulation of vascular, metabolic, and osteogenic pathways, with the overall remodelling process commencing earlier in LSL than in LB hens. Deconvolution of bulk mRNA sequencing data estimated medullary bone cell composition. Erythroid lineage cells constituted about 85% within the bone cavity, whereas mesenchymal cells, including osteoblasts, accounted for only 0.33%. During maturation, macrophage and lymphatic cell populations expanded at the expense of erythroid cells. Osteoblasts were absent in both strains at week 19 but were detectable by week 24, with higher proportions in LSL than LB. Overall, successful medullary bone formation and mineral metabolism in the kidneys occurred in a cascade-like sequence in both LB and LSL laying hen strains. Analyses identified key genes and pathways for genetic or nutritional interventions aimed at maintaining efficient mineral turnover and mineral use efficiency throughout the laying period. Funding: This work was supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – Project number 322916021 and was part of the Research Unit FOR 2601: Inositol phosphates and myo–inositol in the domestic fowl: Exploring the interface of genetics, physiology, microbiome, and nutrition.

Strain-Specific Molecular, Immune, Physiological, and Microbiome Shifts Along the Gut–Bone–Kidney Axis Under Mineral Phosphorus Depletion in Laying Hens

S. Ponsuksili[1], H. Reyer[1], M. Oster[1], Y. A. Abitew[1], N. Trakooljul[1], F. Hadlich[1], S. Schmucker[2], V. Stefanski[2], Y. H. Chien[2], A. Camarinha-Silva[2], V. Sommerfeld[2], M. Rodehutscord[2], K. Wimmers[1,3]

[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [2] University of Hohenheim, Institute of Animal Science, 70599 Stuttgart, Germany, [3] University Rostock, Faculty of Agricultural and Environmental Sciences, 18059 Rostock, Germany

The maturation of laying hens offers a powerful model to study how phosphorus (P) homeostasis is regulated along the gut–bone–kidney axis. Under low P supply, endocrine factors such as vitamin D□ increase intestinal mineral absorption and renal mineral reabsorption. Moreover, the turn-over of minerals in the medullary bone needs to be ensured for eggshell formation. The aim of this study was to integrate multi-omics data to uncover production-stage-dependent molecular and physiological changes along the gut-bone-kidney axis in two laying hen strains fed diets with or without mineral P supplementation. Briefly, 80 laying hens (40 Lohman Brown (LB), 40 Lohman Selected Leghorn (LSL)) were used in a family-balanced 2×2×2 factorial design testing strain, diet (P+ supplied with +1 g/kg non-phytate P vs. P− without mineral P), and age (19 vs. 24 weeks (wk)). We collected plasma, jejunal mucosa, kidney, medullary femur bone, duodenal digesta, and excreta, and measured immune traits in blood, spleen, and cecal tonsils. After standard quality control and data-type-specific normalization/transformation, we applied the DIABLO framework in mixOmics (block sPLS-DA) to integrate the datasets (biochemistry of gut and blood, microbiota, immune traits, bone and body phenotypes, epigenetic layers (miRNA, ATAC-seq), and mRNA-seq from gut/bone/kidney) and identify multi-omic biosignatures discriminating strain and dietary P at 19 and 24 weeks across three latent components. Component 1 mainly captured the age (24 vs 19 wk), separating 24-wk from 19-wk hens across strains and diets. The wk 24 hens showed higher mRNA signals across bone (VLDLR/GREB1L), gut (SLC30A10/EPHA4/KCNK17), and kidney (ASIC4/HSD17B2), a shift toward innate and mucosal immunity, intensified mineral handling (plasma Ca/estradiol), higher gut myo-inositol and excreta P, enriched Lactobacillaceae ASVs (Amplicon Sequence Variants), and altered femur traits. In contrast, week 19 hens displayed higher abundance of certain miRNAs, stronger blood T-cell/lymphocyte signatures, elevated plasma β-CTX, T3, inorganic P, higher excreta Ca, and increased jejunal promoter accessibility at immune/remodeling loci. Component 2 reflected a strong strain axis, linking LSL to jejunal CHST14/HCK expression, open lncRNA/rRNA promoter regions and miR-7460-3p, Lactobacillus/Limosilactobacillus enrichment, and T-cell–related immunity. In contrast, LB showed higher kidney MYL1/CD200L/PRDM8 and bone MHC-Y–related expression, higher Lacticaseibacillus/Helicobacter abundances, higher plasma calcidiol, higher plasma IgA and heterophils, greater intestinal InsP6/ileal myo-inositol with increased P excretion, and larger femurs and immune organs. Component 3 captured the dietary P effect (P− vs P+; clearer at 19 than 24 week), with coordinated shifts in gut/kidney/bone transcripts (ECHDC3/CLDN14/PASSS2), miRNAs/ATAC changes, Lactobacillaceae enrichment (mainly Ligilactobacillus ASVs), innate/mucosal markers (plasma monocytes/heterophils and IgA) and matching changes in gut chemistry, mineral-endocrine markers (Pi, PTH/Mg) and bone/body traits. Overall, the integrative framework distilled multidimensional datasets into interpretable biosignatures to separate the effects of age, strain, and diet across multiple data blocks simultaneously.

Quantitative genetic insights into calcium and phosphorus metabolism at the peak of egg laying of two commercial laying hen strains

Phosphorus (P) and calcium (Ca) are essential minerals for laying hens. Phosphorus is primarily bound as phytate in plant feedstuffs and P availability is therefore dependent on the enzymatic activity of phytase. Due to the high Ca intake of laying hens, intestinal phytate hydrolysis is limited, thereby reducing the availability of P. As P and Ca metabolisms are complex and interdependent, the present study investigated traits of P and Ca metabolism in two commercial laying hen strains at the phenotypic and quantitative genetic level. By using phenotypes obtained from different tissues relevant to these metabolic pathways, as well as important performance traits, a comprehensive picture of P and Ca metabolism was generated to get in-depth insights into the role of genetics. The experimental population comprised 200 Lohman Selected Leghorn (LSL) and 200 Lohman Brown (LB) hens that descended from 10 unrelated roosters per strain. Genotyping was performed using 60K SNP chips. All hens were hatched and reared under the same standardized conditions. During experimental periods in the subsequent laying phase, the hens were kept in individual metabolic units and fed the same P-reduced diet, aiming at a low P supply. Sampling was conducted across four consecutive cohorts at 27, 31, 35, and 39 weeks of age, respectively. Depending on the cohort to which they belonged, the animals were 29, 33, 37, and 41 weeks old at excreta sampling and 30, 34, 38, and 42 weeks old at slaughter. An even distribution of the strains and offspring per rooster across cohorts was ensured. Excreta, eggs, blood plasma, and ileal digesta were sampled, either in live animals after a habituation phase or at slaughter. Laying performance, feed intake, and body weight were continuously measured. Traits of P and Ca metabolism were derived from the samples, including concentrations and retention of P and Ca, as well as myo-inositol concentrations. Population genetic analyses of the two strains revealed large differences between LSL and LB; hence all subsequent analyses were conducted separately for each strain. Mixed linear models were applied to assess additive genetic variation and calculate heritability for each trait. Correlations between traits were calculated from phenotypes that were pre-corrected for systematic effects. Most of the traits differed between the strains at the phenotypic and quantitative genetic levels. Whereas the heritability of P and Ca concentration in excreta, plasma and ileal digesta as well as their retention in the excreta was small to moderate (0.03 to 0.27), heritability of myo-inositol concentration was significant in eggs ($h^2 = 0.69$ in LSL, $h^2 = 0.55$ in LB), blood plasma ($h^2 = 0.43$ in LSL, $h^2 = 0.36$ in LB), and ileal digesta ($h^2 = 0.60$ in LB). The correlation showed that the general relationship between traits might be comparable across the strains. Overall, the study provides insight into the genetic determination of traits reflecting phytate degradation and P and Ca utilization in commercial layers at peak lay.

Omics-based covariance matrices in prediction models: a case study phosphorus efficiency and poultry

V. P. Haas[1,2], J. Bennewitz[1], M. P. L. Calus[2]
[1] University of Hohenheim, Institute of Animal Science, Garbenstraße 13, 70599 Stuttgart, Germany, [2] Wageningen University & Research, Animal Breeding and Genomics, Droevendaalsesteeg 1, 6700 AH Wageningen, Netherlands

A central aspect of quantitative genetics is the prediction of complex quantitative traits. Since the use of SNPs has greatly improved breeding value estimation, new omics-based technologies are now available that are inexpensive, guarantee high output, and ideally bridge the gap between animal DNA and the phenotypic expression of quantitative traits. Today, studies increasingly use specific transcriptome or microbial data, often derived from target tissues or specific sections of the gastrointestinal tract. Typically, classical covariance matrices are used in best linear unbiased prediction (BLUP) models incorporating transcriptomic or microbial data as explanatory variables; here is an matrix containing the z-standardized molecular feature values, where is the number of animals and the numbers of molecular features (e.g., microbial taxa abundances or transcript expression levels). In this context, there is often discussion about using covariance matrices that better reflect the biological structure of the data, i.e., covariance matrices that are calculated based on distances, dissimilarities, or ordinations rather than simple similarities. This is expected to result in a better representation of reality and is predicted to lead to higher proportions of explained phenotypic variance and greater accuracy in trait predictions. To verify whether we can truly gain added value by using alternative omics-based covariance matrices, we tested different methods for calculating covariance matrices on a data set of a Japanese quail F2 cross phenotyped for phosphorus efficiency and related efficiency traits. The birds were genotyped, and ileum miRNA gene expression and ileum microbiota composition were classified. The data set contained 760 quail with 4k SNP genotypes, known microbial composition with 1,188 OTUs, and trait records and 481 quail with additional 77 miRNA gene transcript abundances. We tested different dissimilarity (e.g., Euclidean distance, Jaccard distance) and ordination measurements (e.g., redundancy analysis, multidimensional scaling) to build a similarity matrix and compared it with the classical covariance matrix. These matrices were compared using several BLUP models containing the microbial information (MBLUP), the transcriptomic information (TBLUP), and models containing genomic plus microbial or transcriptomic information in one model (GMBLUP and GTBLUP). At first glance, it appears that we can explain up to 30% more phenotypic variance for microbial and up to 19% more for transcriptional data using alternative covariance matrices compared to the classical matrix. However, these explained variances turn out to be merely artifacts when considering phenotypic trait predictions, the significance tests for them, and the mean square errors of the phenotypic predictions. No added value for phenotypic trait predictions was found when using alternative covariance matrices that utilized either microbial or transcriptional data. Depending on the method used, the accuracies of trait predictions are at a similar level or even significantly lower, despite considerably greater explained variance. For this reason, we consider the use of alternative covariance matrices, which are intended to better reflect the biological structure of molecular features, to be unjustified.

The importance of minerals and vitamins for poultry health

C. Visscher[1,2]
[1] University of Veterinary Medicine Hannover, Institute for Animal Nutrition, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] University of Veterinary Medicine Hannover, Science for innovative and sustainable poultry farming, Bünteweg 13, 30559 Hannover, Germany

The importance of vitamins and trace elements in immune defence has long been the focus of scientific research, with the consequences of inadequate or inappropriate intake being widely discussed topics. This keynote presentation will illustrate the importance of these nutrients using a few examples from poultry farming. Certain micronutrients work synergistically to support the various components of the immune system, such as physical barriers, cellular responses and antibody production. Insufficient or deficient levels of these micronutrients negatively affect the body's defences, impairing its ability to fight infections. A number of trace elements influence the functions, processes and mechanisms of the immune system. Therefore, an inadequate supply also leads to reduced resistance to infections. In this context, selenium, copper and zinc are of particular interest and have been frequently studied. The prime antioxidant components in poultry feed are vitamin E, selenium and carotenoids. The synergistic effect of selenium and vitamin E on immune system function is well documented and widely recognised. While both nutrients perform independent functions in the body, they both play a vital role in the antioxidant system. Selenium is an essential component of the glutathione peroxidase enzyme family. Vitamin E is a vital fat-soluble antioxidant that protects against lipid peroxidation caused by free radicals. Copper is involved in both humoral and cell-mediated immunity. Its role in the immune system is linked to the function of the antioxidant system, as it is an essential component of both copper-zinc dismutase and ceruloplasmin, defending living organisms against reactive oxygen species. However, copper acts as a pro-oxidant when it is unbound. For example, Zn contributes to the maintenance of immune function, growth performance and skeletal development in broiler chickens. Severe zinc deficiency significantly impairs immune system function in animals. However, a slight zinc deficiency has no effect on immune system function. Vitamins are essential nutrients required for optimum general health and physiological functions, such as development, growth, maintenance and reproduction. Most birds cannot synthesise vitamins and must therefore obtain them from their feed. However, feed alone is not sufficient to cover vitamin requirements. Vitamin-supplemented diets play an important role in disease treatment and prevention. For instance, vitamin E is a biological antioxidant that improves the growth performance and the physiological and immunological status of broiler chickens by reducing lipid peroxidation and neutralising free radicals in skeletal muscle and plasma. Vitamin D3 is important for bone growth and plays a critical role in biological pathways such as immune function, calcium homeostasis, and cellular proliferation and differentiation. Vitamin A is necessary for visual development, growth, reproductive physiology and maintaining the integrity of epithelia and the skeleton. It also supports an optimum immune response, thus diminishing susceptibility to infection. Trace elements and vitamins are therefore crucial nutritional components for poultry. Issues of stability (e.g. vitamin A) and formulation (e.g. organically bound trace elements) are of particular interest in this context.

Impact of feeding diets without mineral P supplement on the immune system of two laying hen strains

N. Wallauch[1], S. Schmucker[1], T. Hofmann[1], V. Sommerfeld[1], M. Hasselmann[1], K. Huber[1], M. Rodehutscord[1], V. Stefanski[1]

[1] Institute of Animal Science, University of Hohenheim, Garbenstraße 17, 70599 Stuttgart, Germany

Phosphorus (P) is an essential nutrient for tissue development, cell function and biochemical signaling pathways. An adequate P availability is also a fundamental prerequisite for an efficient and well-regulated immune system. In the context of sustainable animal husbandry, reducing mineral P in feed is becoming increasingly important. Recent studies indicate that mineral P supplementation in poultry diets can be substantially reduced, as poultry can utilize much of the phytate-bound-P in plant feedstuffs when mineral P levels are kept low. Moreover, research shows that reducing mineral P in laying hen diets does not adversely affect the immune system (Hofmann et al., 2021, doi: 10.3390/ani11010129). Therefore, the objective of this research was to investigate the effects of a complete renunciation of dietary mineral P on the peripheral and gut-associated immune system of two laying hen strains. The current study is part of interdisciplinary research project P-FOWL, which investigates the influence of inositol phosphates and myo-inositol at the interfaces of genetics, physiology, microbiome, and nutrition in domestic chickens (https://p-fowl.uni-hohenheim.de/). The experiment described here was based on a 2 × 2 × 2 factorial design (P × laying hen strain × week of life). Feed rations were either enriched with 1 g/kg mineral P (P+) or contained no mineral P supplement (P-) and were fed for a total of 4 weeks (wk). Lohmann Brown Classic (LB) and Lohmann LSL Classic (LSL) hens were sampled at the age of 19 or 24 wk to additionally investigate the impact of the onset of egg laying. Absolute numbers of leukocyte subsets in blood, spleen and cecal tonsils (CT) were measured using flow cytometry. Antibody concentrations in blood plasma and bile were analyzed by ELISA. Mitogen-induced splenocyte proliferation was detected using a lymphocyte proliferation assay and gene expression of pro- and anti-inflammatory cytokines were analyzed by qRT-PCR in the spleen and CT. Statistical analysis was performed using SAS 9.4 software using a linear mixed model. Statistical significance was set at $P < 0.05$. The complete renunciation of dietary mineral P affected the systemic and gut-associated immune system of LB and LSL hens. The results show that the cytokine gene expression and the distribution of immune cell populations were influenced by the absence of mineral P supplementation in the feed. In the CT, the cytokine profile of hens fed the P- diet was characterized by high expression of IL-2 and IL-10 and by higher proportions of NK cells and $CD4^{+}CD25^{high}$ T cells. The latter are described to represent regulatory T cells, which increased proportion corresponds to higher expression of IL-10. Together, this could indicate an increased immunoregulatory activity and anti-inflammatory immune status in the hens fed P- diets. Besides, the P- diet led to lower immune cell counts in the blood, including total leukocytes, total T cells and $CD4^{+}$ T cells. In this context, a targeted regulation of the activation of pro-inflammatory T cells in the CT could be a possible cause for the decline in immune cell populations in the blood when fed the P- diet. Overall, our findings suggest that the renunciation of mineral P supplementation modifies immune regulation within the gut-associated immune system and fosters an anti-inflammatory condition. The immunological changes associated with renunciation of mineral P supplementation cannot yet be conclusively evaluated as beneficial or detrimental; further studies, including infection trials and prolonged withdrawal of dietary mineral P, are required.

Impact of myo-inositol feeding and mineral phosphorus supply on insulin signaling in liver and adipose tissue of two high-performing laying hen strains at different production stages

L. Ruda[1], Á. Szentgyörgyi[1], V. Sommerfeld[2], K. Huber[1], M. Rodehutscord[2]
[1] University of Hohenheim Institute of Animal Science, Functional Anatomy, Fruwirthstr. 35, 70599 Stuttgart, Germany, [2] University of Hohenheim Institute of Animal Science, Animal Nutrition, Emil Wolff Str. 10, 70599 Stuttgart, Germany

As in other species, insulin plays a major role in energy and protein homeostasis of chicken, too. Insulin action might change throughout the production cycle of laying hens due to the changing nutrient and metabolic demands. Myo-inositol (MI) is discussed to modulate insulin signaling cascade (ISC), at least in broilers. For various cellular signaling processes depend on phosphate, dietary supply of mineral phosphorus (P) might also affect ISC. However, P utilization and MI metabolism differ between certain layer strains suggesting variations in ISC response to dietary MI or P. Thus, the present study aimed to assess the impact of different concentrations of MI or omission of mineral P in the diet on hepatic and adipose ISC of Lohmann Brown (LB) and Lohmann Selected Leghorn (LSL) hens at certain stages of production cycle. The study involved two trials. Trial 1 comprised 40 LB and 40 LSL hens, divided into four feeding groups supplied with 0 (control), 1, 2 or 3 g of MI per kg feed. After 4 weeks (wks), hens were slaughtered at 30 wks of age (laying peak). Trial 2 comprised 40 LB and 40 LSL hens that were fed either 0 (P_-) or 1 g/kg (P_+) of mineral P 4 wks prior to slaughter. Half of these hens were either slaughtered at 19 wks (before onset of egg laying) or at 24 wks of age (laying phase). Protein abundance of phosphoinositide 3-kinase (PI3K), mammalian target of rapamycin (mTOR), insulin receptor β (INSR), protein kinase B (PKB), adenosin monophosphate activated kinase (AMPK) and their phosphorylated forms (pmTOR, pINSR, pPKB and pAMPK) was assessed in liver and abdominal adipose tissue by Western Blot. Statistical analysis used a general linear mixed model with the fixed factors strain and diet for Trial 1 and strain, diet and production stage for Trial 2. In Trial 1, the most prominent effect was exerted by strain with higher abundance of hepatic INSR, pINSR, pmTOR, pAMPK and adipose pmTOR in LB than LSL. In both tissues effects of strain and diet mainly interacted. For example, in MI-supplemented groups AMPK in LB was higher expressed than in the control group whereas in LSL it was lower than in the control group. In Trial 2 production stage exerted the most prominent effect in both tissues. Hepatic INSR, pINSR, PI3K and AMPK were higher expressed at wk 19 than wk 24. This difference was more distinct in LSL compared to LB. Further LSL hens had higher expressions of pPKB in adipose tissue at wk 24 than LB hens at that age. As in Trial 1, effects of diet and strain mainly interacted, leading partially to opposite effects in LB and LSL associated with mineral P supply. For example, LB P_+ hens showed lower abundance of PI3K and AMPK in liver than LB P_- hens, but in LSL P_+ hens abundance of PI3K and AMPK was higher than in LB P_- hens. hens The present study implies that strain and production stage might have a stronger impact on insulin signaling in laying hens than MI feeding or omission of dietary mineral P. Results from Trial 1 suggest enhanced activation of insulin signaling in favor of protein synthesis in LB hens at laying peak. Differences in ISC between hens before and after onset of egg laying might reflect nutrient partitioning in support of egg production. However, interactions of diet and strain may indicate that differences in terms of P and MI metabolism also subsequently affect ISC dependent metabolism.

Risk assessment of environmental samples on the prevalence of antibiotic-resistant microorganisms in broiler fattening systems

T. M. Liegsalz[1], M. Savin-Hoffmeyer[2], U. Blum[3], C. Heinemann[4], J. Steinhoff-Wagner[1]
[1] Technical University of Munich, Liese-Beckmann-Str. 2, 85354 Freising, Germany, [2] University Hospital Bonn, Venusberg-Campus 1, 53127 Bonn, Germany, [3] Bavarian State Institute for Forests and Forestry, Hans Carl-von-Carlowitz-Platz 1, 85354 Freising, Germany, [4] University Bonn, Katzenburgweg 7-9, 53115 Bonn, Germany

While the prevalence of antibiotic-resistant microorganisms in the environment poses a risk for human and veterinary medicine, broiler fattening systems might act as a risk factor due to the stagnating high amount of antibiotics used. However, due to potential co-selection of antibiotics and heavy metals via co- and cross-resistance, supplementation of heavy metals as trace elements in amounts above broilers' requirements might increase those risks. Therefore, a risk assessment was conducted to evaluate the effects of the nutritional composition of environmental samples on the occurrence of antibiotic-resistant microorganisms. Environmental samples of broiler farm-related inputs (feed, unused bedding material, water), system-integrated factors (dust) and outputs (litter as bedding and broilers' excreta) were collected during the last week of fattening of 14 commercial, German broiler farms. Feed, bedding and manure were analysed for their nutritional composition (dry matter, crude ash, crude protein, metabolic nitrogen, crude fat, fibre), while elements were measured in all samples. Additionally, the presence of methicillin-resistant Staphylococcus aureus (MRSA) and species with resistance to extended-spectrum beta-lactams was microbiologically detected, further identified via MALDI-TOF MS and tested for antibiotic susceptibility. The accumulation of nutrients and elements was statistically evaluated using an ART model, with sample type as a fixed factor and farm ID as a block structure. Risk assessment was then conducted via Firth's penelized logistic regression, in addition to Pearson's correlation. Both nutrients and elements showed significant accumulation from inputs (feed, bedding, water) to dust, serving as a system-integrated factor, and to litter as an output. Furthermore, especially trace elements in feed (e.g. Cu, Fe, Zn) showed concentrations up to 5 times (for Cu) or 3.5 times (for Fe and Zn) above the recommended levels for broiler nutrition. Additionally, considering Pearson's correlations, relationships between trace elements within one sample type and between different sample types could be detected. In particular, correlations between feed, litter, and dust illustrate the effect of a general supplementation above broilers' requirements. The risk assessment indicated a higher risk for antibiotic-resistant microorganisms when bedding or litter showed high concentrations of crude protein (e.g., for the occurrence of multidrug-resistant microorganisms (MDR) in general or Enterobacteriaceae, $p = 0.008$) or metabolic nitrogen (relative to total nitrogen) (e.g. for the occurrence of MDR in general or Enterobacteriaceae, $p = 0.062$ or $p = 0.043$, respectively). Fibre components in bedding and litter seemed to reduce those risks (e.g., neutral detergent fibre in litter for Enterobacteriaceae, $p = 0.029$). Nutritional factors in feed had a minor effect on the occurrence of antibiotic-resistant microorganisms. Overall, the composition of environmental factors, such as bedding and thus litter, appears to be mainly influential for the appearance of antibiotic-resistant microorganisms. Therefore, when evaluating or choosing bedding materials, one should primarily focus on high fibre concentrations. This work (Model- and Demonstration Project for animal welfare) is financially supported by the Federal Ministry ofFood and Agriculture, granted by the Federal Office for Agriculture and Food.

Effect of varying dietary methionine plus cysteine concentrations on growth performance of slow-growing broiler chickens at different ages

P. Hofmann[1], A. Lemme[2], F. Ahrens[1]
[1] Bavarian State Research Center for Agriculture, Institute for Animal Husbandry, Animal Nutrition and Feed Management, Mainbernheimer Str. 101, 97318 Kitzingen, Germany, [2] Evonik Nutrition & Care GmbH, Rodenbacher Chaussee 4, 63457 Hanau, Germany

Slow-growing broiler chickens are increasingly used in alternative production systems in Europe. Due to their lower growth rate, required dietary methionine (Met) plus Cysteine (Cys) concentrations for optimal growth performance may differ from those of fast-growing broiler chicken strains. This study evaluated the effects of varying dietary Met+Cys concentrations on growth performance of male slow-growing Ranger Classic broiler chickens. Two dose–response trials were conducted for feeding phases Grower 1 (PG1, day 7-18) and Grower 2 (PG2, day 18-35) using male Ranger Classic broiler chickens in a randomized block design with six dietary Met+Cys concentrations and five pens per treatment (40 birds/pen). In each phase, the basal diets contained 2.7 g Met/kg and 3.1 g Cys/kg. Graded levels of DL-Met (g/kg diet) were added to the other diets to achieve higher dietary Met+Cys concentrations: PG1: 0.4–2.9; PG2 0.4–3.1. All other nutrients met recommendations to ensure Met+Cys as the first-limiting amino acids. Birds were housed in floor pens and had ad libitum access to feed and water. Body weight and feed intake were recorded to calculate average daily gain (ADG) and feed conversion ratio (FCR). Data were analyzed by one-way ANOVA ($p \leq 0.05$). Further, nutrient–response relationships between daily Met+Cys intake and ADG or FCR were modeled using an interpretable single-neuron machine-learning approach (Ahmadi and Rodehutscord, 2025). Optimal intake was defined as 95% of maximal ADG and 105% of minimal FCR. Dietary Met+Cys concentrations corresponding to these intakes were modelled from the relationship of Met+Cys intake and dietary concentration. Analyzed diets confirmed calculated nutrient concentrations. ADG increased and FCR decreased nonlinearly with increasing dietary Met+Cys, reaching plateaus at 6.6 and 6.9 g Met+Cys/kg for PG1 and PG2, respectively. Maximal ADG was 36.8 g/bird (PG1) and 70.8 g/bird (PG2), and minimal FCR was 1.41 kg/kg (PG1) and 1.57 kg/kg (PG2). Model fit was high for both ADG (PG1 and PG2: $R^2 = 0.96$) and FCR (PG1: $R^2 = 0.92$; PG2: $R^2 = 0.88$). In PG1, optimal daily Met+Cys intake ranged from 341 (ADG) to 310 (FCR) mg/bird, corresponding to dietary Met+Cys concentrations of 6.81 and 6.40 g/kg. In PG2, optimal daily Met+Cys intake ranged from 735 (ADG) to 670 (FCR) mg/bird, corresponding to dietary Met+Cys concentrations of 6.60 and 6.26 g/kg. These optimal dietary Met+Cys concentrations are substantially lower than those recommended for fast-growing broiler chickens that can be found to range between 10.0 and 8.2 g Met+Cys/kg from starter to finisher diets (on a digestible amino acid basis, Aviagen, 2022). Although the use of slow-growing broiler chickens is generally associated with lower resource efficiency, the present findings indicate that optimizing dietary Met+Cys supply to strain-specific requirements may improve amino acid utilization efficiency, reduce nitrogen excretion, and thereby enhance the sustainability of such production systems. Random forest prediction of nitrogen utilization efficiency in broiler chickens with growth performance and dietary nutrient concentrations

W. Dou[1], T. M. Lange[1], W. Siegert[1]
[1] University of Göttingen, Department of Animal Sciences, Kellnerweg 6, 37077 Göttingen, Germany

As the experimental determination of nitrogen utilization efficiency (NUE; percent of N accretion per N intake) is restricted, an accurate statistical method to predict NUE is needed. Compared to linear models, the random forest algorithm has recently been suggested to predict NUE in ruminants (doi 10.1016/j.anifeedsci.2023.115670). Therefore, this contribution evaluated the use of growth performance and diet characteristics to predict NUE of broiler chickens using a random forest algorithm. It was hypothesized that adding dietary amino acids (AA) concentrations as predictors increases the predictability compared to models without AA. A dataset of 528 data lines was initially extracted from 90 peer-reviewed nutrient balance studies from 2016 to 2024 after filtering out data lines where growth performance was reduced by interventions. The AA profile was recalculated from feeding ingredients using the INRAE database for all data lines to avoid missing values. Studies where ingredients were not available in the database were excluded. The final dataset consisted of 371 data lines with no missing values. Five groups of predictors were defined. General accessible predictors (GAP) included dietary crude protein, metabolizable energy, age, feed intake, and weight gain. Further four groups of predictors were GAP plus AA, herein denoted in the three-letter code: first-limiting AA (Gl: Met, Lys, Thr, Trp, Val, Ile), essential AA (Ge: Lys, Thr, Met, Cys, Trp, Ile, Val, Leu, Phe, His, Arg), nonessential AA (Gne: Tyr, Ala, Asp, Glu, Gly, Ser, Pro, Gly equivalent), and all AA (Ga). The five predictor groups were GAP and GAP plus each group of AA, and the dependent variable was NUE. Two Monte-Carlo cross-validation simulations were implemented with the split methods: (I) random split; (II) split by trial to avoid shared trial information between the sets. The number of trees was firstly determined as 1000 by the R package "optRF", and random forest models were computed by the "ranger" package. Both simulations went through 1000 iterations, where models were trained with the training data (70%) and applied to the testing data (30%) for prediction. The goodness-of-fit between predicted and observed NUE was evaluated by root mean squared error (RMSE), mean average error (MAE), and R^2. The concordance to 45° line was indicated by concordance correlation coefficient (CCC). The indicators from 1000 iterations were collected for descriptive analysis. In random split, the inclusion of AA as predictors improved goodness-of-fit and concordance (GAP: RMSE = 5.4, MAE = 3.6; Ga: RMSE = 4.7, MAE = 3.1; GAP: R^2 = 0.58, CCC = 0.70; Ga: R^2 = 0.69, CCC = 0.79). Performances of other AA combinations were similar, e.g., RMSE: Ge = 4.73, Gne = 4.73, Gl = 4.83; CCC: Ge = 0.79, Gne = 0.78, Gl = 0.77. Goodness-of-fit greatly decreased as reduced performances for all models when the data were split by trial compared to random split, e.g., GAP RMSE: 9.35 vs. 5.42, respectively; Ga RMSE: 8.54 vs. 4.66, respectively. These results showed that trial-level information was essential for higher prediction accuracy. Compared to the model without AA, the inclusion of AA improved goodness-of-fit and concordance of the NUE prediction. This effect was influenced by the number of amino acids, but not related to the physiological importance of the AA.

Metagenomic analysis reveals strain-specific ileal microbiome responses to low-phosphorus diets in laying hens

Y. H. Chien[1,2], T. Yergaliyev[1,2], J. Seifert[1,2], A. Camarinha-Silva[1,2]
[1] University of Hohenheim, Institute of Animal Science, Emil-Wolff-Str. 8, 70599 Stuttgart, Germany, [2] Hohenheim Center for Livestock Microbiome Research, Leonore-Blosser-Reisen Weg 3, 70599 Stuttgart, Germany

Improving phosphorus (P) utilization in poultry is critical due to the depletion of global mineral phosphate reserves. While the gut microbiome may contribute to phytate degradation, the interacting effects of host genetics and dietary P restriction on microbial composition remain underexplored. This study investigated the ileal microbiome of two high-yielding laying hen strains (Lohmann Brown Classic, LB; Lohmann LSL Classic, LSL) under low-P supplementation to identify strain-specific microbial and functional adaptations. A total of 400 hens were fed low-P diets, while 40 hens received a P-adequate control diet. After three weeks, ileal digesta were analyzed using shotgun metagenomics. LB hens fed a low-P diet showed significantly higher Shannon diversity than LSL hens fed either a low-P diet or an adequate-P diet. PCoA based on a weighted variant of Bray-Curtis distance metrics showed a significant difference in the bacterial communities of ileal microbiota between two strains, indicating a strong host genetic effect on the ileal microbiota. Differential abundant species analysis showed that the low-P diet shifted the differentially abundant species between LB and LSL hens. At the species level, Ligilactobacillus salivarius and Enterococcus cecorum were more abundant in LB hens, whereas Limosilactobacillus vaginalis and Lactobacillus amylovorus were enriched in LSL hens. Correlation analysis demonstrated that in LB hens, L. salivarius and E. cecorum correlated positively with plasma P concentrations. Conversely, in LSL hens, Limosilactobacillus reuteri and Limosilactobacillus oris correlated positively with plasma P, Ca, and myo-inositol concentrations. Functional profiling using the KEGG database showed that four pathways related to phosphorus metabolism (ABC transporters, mineral absorption, endocrine and other factor-regulated calcium reabsorption, and calcium signaling pathway) were significantly enriched in LSL hens, and three KEGG pathways (phosphotransferase system, inositol phosphate metabolism, and phosphatidylinositol signaling system) were abundant in LB hens. Furthermore, the low-P diet modulated taxa associated with phosphate transport and phytate hydrolysis (including L. salivarius and E. cecorum) in LB hens, while genes encoding phosphonate transport were more abundant in LSL hens. These functional shifts indicated distinct strain-dependent strategies in phosphate transport and inositol-related metabolism under restriction, highlighting the microbiome as a potential target for improving phosphorus efficiency in layer production.

Defatted and dehydrated avocado seed meal improves feed conversion ratio in broiler chickens at 21 days of age

R. Vianna Nunes[1], T. Gabrieli[1], N. Rohloff Junior[1], T. Dos Santos Andrade[1], M. L. Dos Reis Maia[1], N. Borsatto[1], M. E. Gonsatti Costa Curta[1], E. M. Henz[1], G. Natha Comin[1], P. Cesar Pozza[2]

[1] State University of Western Paraná, Animal Science, Pernambuco street, 85960-208 Marechal Candido Rondon, Brazil, [2] State University of Maringá, Animal Science, Colombo avenue, 87020-900 Maringa, Brazil

Alternative feed ingredients in broiler diets require the definition of safe inclusion levels. Avocado seed contains fibrous fractions and phenolic compounds; however, information regarding its use in broiler diets remains limited. This study evaluated the effects of dietary inclusion of defatted and dehydrated avocado seed meal on performance and blood biochemistry in broiler chickens. A total of 720 one-day-old male chicks (Ross AP95) were distributed in a completely randomized design with five inclusion levels (0.0, 1.5, 3.0, 4.5, and 6.0%), eight replicates, and 18 birds per experimental unit. Diets were based on corn and soybean meal, and during the experimental period (1 to 21 days), birds had ad libitum access to feed and water. At 21 days of age, feed intake, body weight gain, and feed conversion ratio were evaluated, and one bird per experimental unit was randomly selected for blood collection from the brachial vein to determine serum concentrations of albumin, aspartate aminotransferase, cholesterol, creatinine, alkaline phosphatase, glucose, total protein, and triglycerides. Data were subjected to tests of residual normality and homogeneity of variances, followed by analysis of variance. When a significant effect was observed, polynomial regression analyses were performed. All analyses were conducted adopting a significance level of 5%. No differences ($P > 0.05$) were observed in feed intake, body weight gain and blood biochemistry at 21 days of age. However, feed conversion ratio was influenced by the inclusion levels of defatted and dehydrated avocado seed meal, presenting linear and quadratic effects ($P = 0.001$), with a better fit to the quadratic model ($R^2 = 0.94$). The optimal point estimated by the model was obtained at 2.1% inclusion of the ingredient, corresponding to a feed conversion ratio of 1.344 g/g. This result may be associated with the presence of phenolic compounds and the fibrous fraction of avocado seed, which may favor digestion and nutrient utilization in broiler chickens. It is concluded that defatted and dehydrated avocado seed meal can be included in broiler diets up to the level of 2.1%, promoting improved feed efficiency without compromising performance or the blood biochemical profile of the birds.

Paraprobiotics and metabolic stress in peak-laying hens: implications for yolk lipid stability

D. Rippel[1], C. Nueangjamnong[1]
[1] Chulalongkorn, Animal Husbandry, Henri-Dunant Road, Pathumwan, 10330 Bangkok, Thailand

Commercial laying hens have been selected for high productivity, which consequently intensified the metabolic pressure on the liver. During peak, elevated hepatic lipogenesis and yolk precursor synthesis may result in susceptibility to liver lipid accumulation and oxidative stress, thus affecting the production performance, health, and may contribute to the reduction of yolk stability. Evidence that oxidative stress due to the higher metabolic demand may impair bile acid homeostasis, hepatic stress, and progressive reproductive decline, with accelerating ovarian aging and shorter clutch in the later phase. Environmental stressors present in intensive poultry systems can further exacerbate this physiological vulnerability. Therefore, nutritional strategies that can improve hens' resilience during this critical period can improve the efficiency of production and the quality of eggs. Probiotics of Lactobacillus spp. have been widely used to promote gut health through microbiota modulation, resulting in improved performance and health of the host. However, the use of live microorganisms raises concerns regarding the potential transfer of antimicrobial resistance genes through conjugative plasmids and transposons. Paraprobiotics are defined as inactivated microbial cells or their structural components that retain biologically active molecules capable of conferring health benefits to the host (e.g., peptidoglycans, lipoteichoic acids, wall teichoic acids, and exopolysaccharides). These structures can interact with pattern recognition receptors in the intestinal epithelium, triggering intracellular signaling pathways such as nuclear factor kappa B and mitogen-activated protein kinase, thereby modulating inflammatory responses and enhancing antioxidant defense. Increasing evidence across species suggests potential effects on host lipid metabolism and oxidative balance. Overall, paraprobiotics represent a promising, safe, and stable nutritional strategy to mitigate oxidative damage and metabolic stress in modern laying hens under intensive production, with potential impact on egg quality and consequent effects on reproductive characteristics in the later laying phase.

Modulation of systemic metabolic phenotype and growth performance in broiler chickens following in ovo administration of myo-inositol

N. Shomina[1], V. Sommerfeld[1], M. Rodehutscord[1], K. Huber[1]
[1] University of Hohenheim, Institute of Animal Science, Fruwirthstr. 35, 70599 Stuttgart, Germany

Myo-inositol (MI) is a bioactive metabolite involved in phosphoinositide signalling, glucose metabolism, and insulin sensitivity [1] and directly modulates cellular energy sensing via AMP-activated protein kinase [2]. Given the central role of these pathways in metabolic regulation, MI may represent a candidate for metabolic programming in broiler chickens to support post-hatch development; however, this concept was not investigated in poultry. Therefore, the aim of the present study was to determine whether increasing MI availability during late embryogenesis leads to lasting modifications in growth performance, plasma metabolomic profiles, and hepatic AMPK- and insulin-related signalling pathways in broiler chickens. We hypothesized that in ovo MI administration would induce sustained alterations in systemic metabolic phenotype, accompanied by modest improvements in growth performance. A total of 480 Ross 308 broiler eggs were incubated under standard conditions, and on embryonic day 17, 440 viable eggs were allocated to 4 groups. Two MI-injected groups received intra-amniotic injections of MI (1 mL, 12 or 24 µmol MI) and two no-MI groups comprised a saline-injected positive control (1 mL, 0.9% NaCl) and a non-injected negative control. After hatch, 384 chicks were placed in 32 floor pens (12 birds per pen; 8 pens per group) and reared under identical nutritional and environmental conditions until day 35. Growth performance was monitored throughout the trial. At day 35, one bird per pen was sampled for blood and tissue collection. Plasma metabolomic profiling was conducted by Biocrates Life Sciences AG using AbsoluteIDQ™ p180 kit. Hepatic expression of insulin- and energy-related signalling proteins (INSR, p-INSR, PI3K, Akt/PKB, p-PKB, mTOR, p-mTOR, AMPK, p-AMPK) were quantified by Western blot and normalized to β-actin. MI concentrations in plasma, liver, kidney and breast muscle were quantified enzymatically, and expression of inositol monophosphatase 1 (IMPase 1) in liver and muscle and myo-inositol oxygenase (MIOX) in kidney was determined by ELISA. Statistical analyses were performed using Proc MIXED in SAS (version 9.4) with planned contrasts comparing MI-injected and no-MI groups. Plasma metabolomics revealed that MI-injected birds had higher concentrations of C2 and C9 acylcarnitines, threonine, sarcosine, and several phosphatidylcholine and sphingomyelin species. This pattern suggested altered mitochondrial substrate handling and acetyl-CoA buffering, modifications in amino acid and one-carbon metabolism, and remodelling of membrane lipid composition. Serotonin and the serotonin/tryptophan ratio were lower in MI-injected groups, indicating altered peripheral serotonergic regulation. In liver, Western blot analysis showed lower expression of p-INSR, p-AMPK and mTOR in MI-injected groups compared with no-MI ones, while INSR, PKB, p-PKB, PI3K, and p-mTOR did not differ. MI concentrations in plasma and tissues, and expression of IMPase 1 and MIOX, were unchanged. MI-injected birds showed lower average daily gain throughout rearing, with unchanged feed conversion ratio and improved survival during the first three weeks. In ovo MI administration induced persistent modulation of selected plasma metabolites and hepatic signalling proteins in broilers, supporting our hypothesis of altered systemic metabolic phenotype. Despite unchanged growth performance, improved early survival suggests functional relevance of the observed metabolic modulation and justifies further investigation. [1] Gonzalez-Uarquin et al. 2020. How Artificial Intelligence Could Transform Pig Farming in the Next Decade

M. Marcon[1], M. Nouri[1]
[1] IFIP, Institut du Porc, 9 boulevard du Trieux, 35740 Pacé, France

Pig farming is facing multiple and sometimes contradictory challenges: improving competitiveness while maintaining high product quality, complying with increasingly demanding regulations, and responding to growing societal expectations regarding animal welfare and antibiotic reduction. At the same time, producers must deal with strong market volatility and rising production costs. These challenges create a strong need for new technological solutions capable of supporting farmers in their daily decision-making. Artificial intelligence (AI), combined with the rapid development of Internet of Things (IoT) technologies, opens new perspectives for the next decade. Sensors, cameras, microphones and connected equipment can continuously monitor animal behaviour, feed intake, body weight, environmental conditions and health indicators. By integrating these large data streams, AI systems can transform raw information into real-time decision-support tools for farmers. Several promising applications are already emerging. Precision feeding systems could dynamically adapt feed composition or ration levels according to animal performance, feed prices or production objectives, helping to reduce feed costs and environmental impacts while improving efficiency. Computer vision technologies may allow automatic counting of animals, estimation of body weight or behavioural monitoring. Health monitoring systems based on sound analysis or activity tracking could detect early signs of disease before clinical symptoms appear. Artificial intelligence could also improve the management of livestock buildings. AI-based systems may detect anomalies in ventilation or ambient conditions and trigger alerts before problems arise. By integrating weather forecasts, intelligent control systems could anticipate sudden temperature variations and automatically adjust ventilation or heating parameters. In the context of climate change, feeding strategies and environmental management could also be adapted during heat stress periods to maintain animal performance and welfare. Beyond the farm itself, AI could support stronger integration between farms and the rest of the value chain. By connecting farm data with producer organisations, feed suppliers or slaughterhouses, digital systems could enable real-time techno-economic analysis of production. Such integration would allow farmers to anticipate feed orders, optimise stock management and adjust production strategies according to market demand or slaughterhouse specifications. More advanced systems may ultimately rely on digital twins of farms: virtual models continuously updated with real-time data that allow simulation of different management scenarios. These tools could support farmers in exploring alternative strategies. Generative AI may also simplify data recording and advisory processes. Farmers could describe their observations verbally while walking through the barn, while AI systems automatically transcribe and structure this information into farm databases. Based on data, intelligent systems could generate semi-automated action plans or management recommendations. The role of agricultural research is also evolving. Researchers are no longer only producers of knowledge but increasingly integrators of data, designers of digital infrastructures and facilitators of collaboration between farmers, technology providers and industry stakeholders. Combining animal science, engineering, data science and economics will be essential to transform technological potential into reliable and usable solutions. Over the next decade, the successful integration of AI in pig farming will therefore depend not only on technological progress but also on the capacity of research communities to co-design these systems together with farmers and industry partners.

How AI Is Reshaping the Role of the Pig Researcher

P. J. De Temmerman[1], J. Maselyne[1], M. Aluwé[2]
[1] ILVO (Flanders Research Institute for Agriculture, Fisheries and Food), Technology and Food Science, Burg. Van Gansberghelaan 115, 9820 Merelbeke-Melle, Belgium, [2] ILVO (Flanders Research Institute for Agriculture, Fisheries and Food), Animal Science, Burg. Van Gansberghelaan 119, 9820 Merelbeke-Melle, Belgium

Since the public release of ChatGPT three years ago, artificial intelligence (AI) has become increasingly integrated into pig research workflows. What began as an optional tool for early adopters has rapidly evolved into standard infrastructure for writing, analysis and scientific communication. AI-assisted drafting is now becoming more widely accepted, and many institutions require disclosure of how AI contributed to research outputs. Across the research process, AI has expanded from a writing assistant to a multipurpose tool. General chatbots and domain-specific systems support brainstorming, structuring information, learning new methods, coding tasks, documentation, data analysis and statistics. They also assist with preparing abstracts, organizing ideas, planning studies and drafting manuscript sections. These tools increasingly shape how pig researchers structure and execute their work. AI is also contributing to changes in experimental approaches. Models can process video, audio and sensor data to monitor behaviour, health and welfare. Current applications include detecting respiratory problems, estimating body weight, quantifying activity and identifying behavioural changes in pig pens. In pig research settings, AI supports automated behavioural annotation pipelines, scoring of posture and activity, and the fusion of multi-sensor signals into interpretable welfare indicators. In addition AI can support the transition from raw data to scientific output. Tools can assist in organizing multi modal data sources, extract relevant findings, highlight patterns, and create visual summaries that support communication with colleagues, stakeholders, and farmers. Tailored systems can also translate behavioral or sensor signals into accessible outputs, such as farm-specific dashboards or chatbots that provide situation-dependent advice. The increasing use of AI may require introducing methodological and ethical considerations. Hallucinations, misinterpretations of biological signals and errors in summarization pose risks for research quality. Furthermore, researchers must also be able to distinguish between general AI outputs based on public knowledge and context-specific analyses derived from private or confidential datasets. Setting requirements for online models, protected environments and local computation, depending on data sensitivity, reproducibility and the need for traceable model behaviour. Overall, AI is not replacing but reshaping the role of pig researchers. Domain expertise remains essential for formulating hypotheses, designing experiments, interpreting biological signals and ensuring ethical oversight. In data-rich production environments, the researcher increasingly acts as an integrator who combines biological knowledge with computational tools. This presentation provides participants an overview of how AI can be integrated across all stages of the research process from idea generation and experimental design to behavioural monitoring, data analysis and communication. Examples will illustrate how tailored models, sensor-based pipelines and farm-specific tools can support research and applied decision-making. The presentation will highlight current limitations, risks such as hallucinations, and opportunities for collaboration in developing accurate, context-specific AI solutions.

Contributions of physiological sensors and AI-assisted videos to the study of physiological and behavioural adaptative mechanisms in growing pigs facing a heat wave

C. Xavier[1], D. Renaudeau[1], L. Bonneau De Beaufort[2], C. Largouët[2], S. Brajon[1], F. Gondret[1]
[1] PEGASE, INRAE, Institut Agro, 16 Le Clos, 35590 Saint-Gilles, France, [2] Institut Agro, Univ Rennes 1, CNRS, INRIA, IRISA, 65 rue de St Brieuc, 35000 Rennes, France

Heat stress (HS) is a growing concern due to global warming, especially for livestock species with limited thermoregulatory capacities such as pigs. Several physiological and behavioural mechanisms are triggered to facilitate pig's adaptation to elevated temperature, which is however generally associated to reduced growth performance. Moreover, there is a wide individual variation in how quickly and effectively pigs may adapt to heat. The aim of this study was to describe the real-time diurnal and nocturnal variations in some physiological and behavioural indicators in growing pigs facing a heatwave. Twelve crossbred (Large White × Landrace) × Piétrain) male pigs were reared in individual indoor pens, with an ambient temperature set to 22°C for 18 days (thermoneutral conditions: [TN]), and then at 32°C for the subsequent 6 days (heat stress challenge [HS]). All pigs were fitted with an indwelled venous catheter, and time-series blood samples were collected every hour at one day during TN and at one day during HS, in order to study the circadian variations of plasma glucose levels. Salivary cortisol levels were measured at two days during TN and each day of HS. Continuous monitoring of core temperature (Tcore) were obtained from sensors (Anipill, France) implanted intramuscularly. A continuous glucose monitoring (CGM) system (Dexcom G6, Dexcom Clarity, US) was inserted subcutaneously the day before HS, and rest during the following 6 days. Measurements were wirelessly transmitted to dedicated recorders. Pigs were fed ad libitum thanks to automated electronic feeders. Pens were video recorded by infrared cameras. We developed AI-based assisted classification of pig behaviours using a convolutional neural network (YOLOv11) and a minute frequency sampling rate, to extract the following behavioural traits (frequency of occurrence): visit to the drinker, head in the feeder, lying down, standing up, sitting, moving, sniffing or nosing the littermate in the neighbouring pen. Data were analysed byANOVA to assess the effects of the period (TN, HS) and circadian rhythm (nocturnal, diurnal). This reveals that salivary cortisol levels were superimposed on the circadian rhythm and, on average, were greater in HS than in TN (0.97 + 0.80 vs. 0.68 + 0.63 ng/mL, $P < 0.001$). On average, Tcore was higher under HS than under TN (39.6 + 0.8 vs. 39.1 + 0.4°C, $P< 0.001$), which indicates perturbations of thermoregulatory mechanisms. There was no difference in mean Tcore between diurnal and nocturnal periods. Daily mean plasma glucose concentrations were similar between TN and HS. The CGM data reveal a large inter-individual variability in metric for peaks and nadirs of glucose levels, in nocturnal as well as in diurnal times. Glycemic excursions and Tcore dynamics were generally synchronized in the HS period. The AI-assisted video classifications revealed behavioural shifts between HS and TN periods, with more frequent visits to drinkers, less frequent visits to feeders, more sitting and reduced social interactions ($P < 0.001$). Data from the automatic feeder confirmed that pigs under HS had a lower feed intake ($P < 0.02$) and shorter duration of meal ingestion ($P = 0.01$) than pigs under TN. In conclusion, sensor-based monitoring systems are helpful to detect (a) synchronic deviations of physiology under heat stress in growing pigs, whereas AI-assisted videos may be reliably used to detect warning signals of health and welfare deviations. This work was funded by the French National Research Agency under the project Wait4 (ANR-22-PEAE-0008).

Heat stress in weaned piglets - respiratory rate in relation to animal behaviour and temperature-humidity index

C. Meyer[1,2], I. Traulsen[2], N. Kemper[1], P. Heseker[1], A. Langehennig-Peristenidou[1], N. Dirksen[3], J. Probst[1]
[1] University of Veterinary Medicine Hannover, Foundation, Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] Christian-Albrecht-University of Kiel, Institute for Animal Breeding and Husbandry, Behavioural Informatics in Livestock Husbandry, Hermann-Rodewald-Straße 6, 24118 Kiel, Germany, [3] Chamber of Agriculture Lower Saxony, Mars-la-Tour-Str. 6, 26121 Oldenburg, Germany

Pigs possess limited thermoregulation mechanisms, increasing the risk of heat stress with high outdoor temperatures and limited heat dissipation in closed housing systems. Sensor systems are a promising approach for continuous monitoring and, thus, early detection of heat stress. Previously, a temperature-humidity index (THI) formula for fattening pigs was developed, which indicates an alarm situation above a heat stress threshold value of 75 (De Prekel et al. 2024). Heat stress in weaned piglets has hardly been object to research yet. It affects individual animals differently. Therefore, aim of this study was to examine animal-related parameters of heat stress in this animal group in a first step. The respiratory rate (RR) of weaned piglets (n=144) was analysed in relation to THI values and behaviour. Therefore, data were collected over a summer period of 39 days in a conventional compartment with six pens. Each pen (2.5 x 5.5 m) was equipped with climate sensors (DOL 114, dol-sensors A/S, Aarhus, Denmark) and a video camera (Axis M3206-LVE, Axis Communications AB, Lund, Sweden, top-down-view, 1,920 x 1,080px, 20 frames/s), which captured the entire pen. The mean daily THI was calculated from the assessed climate data according to De Prekel et al. (2024). Two four-day periods were selected in the data set, characterised by a mean daily THI below the threshold-value of 75 for two days before the threshold-value was exceeded for two consecutive days. Period 1 was from day 17 to day 20 of rearing, and period 2 was from day 29 to day 32 of rearing. For these two test periods, RR was visually determined in videos of a random sample of eight animals per day (n=384). Four animals were examined in the morning (8:00 a.m. to 11:59 a.m.) and four animals in the afternoon (12:00 p.m. to 3:59 p.m.). The animals were marked with coloured ear tags to distinguish them from one another. Breaths were counted for 30 seconds and breaths per minute were calculated subsequently. In addition, a half-hourly scan sampling assessed the number of animals in the manure area (MA), the number of animals lying lateral (LL), and the number of animals lying without physical contact (BC) in the entire pen. A weak positive and significant correlation between MA and RR ($\rho=0.17$; $p<0.001$) was detected, as well as between LL and RR ($\rho=0.11$; $p<0.001$). THI and RR also showed a weak positive and significant correlation ($\rho=0.12$; $p<0.001$). Between BC and RR there was a moderate positive, significant correlation ($\rho=0.30$; $p<0.001$). Respiratory rate reflected the behaviour and THI well. These first results indicate the potential of sensor-based detection of heat stress in weaned piglets. In addition to animal behaviour, the inclusion of RR as a physiological parameter is essential for the development of a climate-based early warning system. Detecting and preventing heat stress at an early stage represents a major contribution to animal welfare and health. The project was supported by funds of the Federal Ministry of Agriculture, Food and Regional Identity (BMLEH) based on a decision of the Parliament of the Federal Republic of Germany via the Federal Office for Agriculture and Food (BLE) under the strategy for digitalisation in agriculture, grant number 28DE109E18.

Effects of Temperature-Humidity Index on reproductive and productive performance in Spanish commercial sow farms

S. Sanjuán[1], X. Díaz De Otálora[2], R. Arnau[1], J. M. Calabuig[1], M. Rodríguez[3], E. Quintana[3], G. Montalvo[3], F. Estellés[2]
[1] Universitat Politècnica de València, Instituto de Matemática Pura y Aplicada, Camino de Vera s/n, 46022 Valencia, Spain, [2] Universitat Politècnica de València, Instituto de Ciencia y Tecnología Animal, Camino de Vera s/n, 46022 Valencia, Spain, [3] Animal Data Analytics, S.L., C/Dámaso Alonso, 14, 40006 Segovia, Spain

Heat stress is a major constraint for reproductive efficiency in intensive pig systems, yet its impact under commercial conditions remains insufficiently quantified. This study evaluated the short- and medium-term impact of climate (through temperature–humidity index, THI) on key reproductive and productive indicators using long-term commercial field data combined with explainable artificial intelligence modelling. Monthly production records from 50 commercial pig farms in Spain were analysed over a 10-year period. Data were extracted from standardized herd performance monitoring systems and included services, farrowing, piglet losses and farm inventory indicators. Meteorological data, including outdoor ambient temperature and relative humidity, were obtained from weather stations located near each farm and used to compute monthly average THI values. Machine learning models (Neural Networks) were developed incorporating both contemporaneous THI and lagged THI values up to five months prior to the observed outcome. This design enabled evaluation of climatic conditions during biologically relevant stages such as insemination, early gestation and late gestation. Model interpretation was performed using SHAP (Shapley Additive Explanations) to quantify variable importance, identify critical lag periods and estimate response thresholds while accounting for farm-level effects. Delayed THI effects were consistently stronger than immediate effects. For farrowing rate, THI recorded three to four months before parturition, corresponding to the insemination and early gestation period, exerted the greatest negative impact. An effective THI threshold around 58–60 was identified, above which farrowing rate declined progressively and repeat rate increased. In contrast, piglet losses were more strongly associated with THI during late gestation, with elevated heat load preceding farrowing increasing both total mortality and early neonatal losses. Farm-specific embeddings revealed substantial heterogeneity in climatic sensitivity, indicating that management, housing design or genetic background modulate heat stress resilience. These findings demonstrate biologically coherent delayed effects of heat stress on reproductive performance and piglet survival under commercial conditions. The integration of long-term field data with explainable artificial intelligence provides a robust framework to identify critical vulnerability windows and support targeted climate-adaptation strategies in pig production systems. Results highlight the importance of incorporating temporal climate dynamics into reproductive management decisions at both farm and system levels across diverse production contexts nationally.

Development of a continuous MIR-based nutritional stress score using an experimental challenge in dairy goats

C. Brosse[1,2], J. Pires[2], M. Calmels[3], M. Bonnet[2], T. Fassier[4], N. Friggens[5], R. Rupp[1]
[1] INRAE, GenPhySE, 24 chemin de Borde-Rouge Auzeville-Tolosane, 31326 Castanet-Tolosan, France, [2] INRAE UCA, UMRH, Rte de Theix, 63122 Saint-Genès-Champanelle, France, [3] Seenovia, 126 rue de Beauge, 72000 Le Mans, France, [4] INRAE, P3R, Domaine de Bourges, 18390 Osmoy, France, [5] INRAE, PEGASE, 65 rue de Saint-Brieuc, 35042 Rennes, France

The aim of this study was to use mid-infrared (MIR) spectra to detect nutritional stress and to construct a continuous nutritional stress score. First, we assessed whether milk spectral profiles were affected by an experimentally induced acute nutritional stress. For this purpose, MIR milk spectra were collected before and after a 2-day nutritional challenge consisting of a straw-only diet. The study involved two INRAE experimental farms (Bourges and Paris) and 377 goats. At Bourges (n = 241), challenges were conducted in March (early lactation) and June (mid lactation). At Paris (n = 136), challenges were conducted in March (early lactation) and September (late lactation). The first objective was to classify milk samples as pre- or post-challenge by training the model on one farm and predicting on the other farm. With external farm validation, the elastic net model based on spectra achieved a 1% classification error rate, whereas a binomial model based on milk yield, fat content, and protein content resulted in a 13% error rate. Then, to construct a continuous score, each MIR wavenumber was adjusted for days in milk using a linear model with 5-day DIM classes fitted on routine records from the Bourges farm (15 to 300 DIM, 11 568 MIR records). The estimated DIM effect was used to correct the challenge spectra before training an elastic net model to discriminate between pre-challenge and post-challenge samples. This elastic net model was applied to routine MIR of milk recording data from the Bourges farm (DIM-adjusted) between 15 and 300 days in milk to estimate the probability of being classified as equivalent to day 2 (post-challenge), therefore indicating a state of spontaneous nutritional stress. The data comprised 11 568 MIR spectra from 883 goats over 7 years. The predicted probability was defined as the STRESS_SCORE, ranging from 0 to 1. Among 11 568 MIR routine records, 80 samples had a STRESS_SCORE greater than 0.5. To assess biological coherence, correlations were computed between STRESS_SCORE and predicted contents of milk metabolites and fatty acids using routine MIR of milk recording data from the Bourges farm. The score showed a positive correlation with milk C18:1 cis-9 (r = 0.42 overall; range: 0.33 to 0.57 across lactation stages) and a negative correlation with de novo fatty acid content (r = −0.33 overall; range: −0.30 to −0.57). These associations suggest that this STRESS_SCORE reflects lipid mobilization. After transformation to achieve normality for STRESS_SCORE, genetic parameters were estimated using a test-day approach with a repeatability animal linear mixed model. Preliminary genetic parameter estimation showed a repeatability of 0.34 and a heritability of 0.22 (± 0.03). The STRESS_SCORE derived from MIR spectra is an indicator of nutritional stress and reflects lipid mobilization. It shows moderate repeatability and heritability, and supports the use of controlled experimental challenges to develop phenotyping indicators.

Physiological validation of heart rate variability as a sensor-based indicator of environmental and metabolic disturbances in grazing dairy cows

D. Vallejo-Timaran[1], P. Betancourth-Chaves[2], V. Castillo-Vanegas[3], J. Unigarro-Charfuelan[1], J. Lerma-Lasso[1], A. Zuluaga-Cabrera[2], J. Montoya-Zuluaga[2]

[1] Colombian Agricultural Research Corporation - AGROSAVIA, Obonuco Research Center, Obonuco Research Center -Km 5 Pasto - Obonuco, 520038 Pasto, Colombia, [2] University Vision de las Americas, Faculty of Veterinary Medicine and Animal Science, GisCA Research Group, Circular 73 #35-04, Laureles, 050031 Medellin, Colombia, [3] VITALAB Diagnostic Veterinary Lab, Scientific Director, Ciudadela complex local 22 piso 1, 054040 Rionegro, Colombia

Precision Livestock Farming through sensor-derived physiological signals could detect metabolic and environmental disturbances at early stages. Heart rate variability (HRV), measured using wearable sensors, reflects autonomic nervous system activity and has been proposed as a noninvasive indicator of stress and physiological imbalance in livestock. However, the physiological validation of HRV signals against metabolic biomarkers under grazing conditions remains limited. We hypothesized that HRV-derived autonomic signals could be useful as a physiological marker associated with metabolic status and environmental stress in grazing dairy cows. This study aimed to evaluate whether heart rate variability (HRV) responses are associated with physiological markers of metabolic status and environmental stress, and to assess their potential use as sensor-based indicators for early detection of disturbances in grazing dairy cows. A cross-sectional study was conducted in clinically healthy lactating Holstein cows (n = 330) under grazing conditions in the high-Andean tropics of Colombia. Arterio-venous coccygeal blood samples were collected for on-site blood-gas analysis. Subclinical metabolic alkalosis (MA) was defined as blood pH > 7.45, $HCO_3 \geq 28$ mmol/L, and/or base excess ≥ +3 mmol/L. Blood lactate concentrations were categorized as < 2.0, 2.0–4.0, and > 4.0 mmol/L. Tissue hypoperfusion was evaluated using lactate, acid–base parameters, anion gap, hematocrit, and renal perfusion indicators. Environmental conditions were continuously recorded using an on-farm meteorological station, and environmental heat load was characterized using the Temperature–Humidity Index (THI) and the Temperature–Humidity–Wind Index (THVI).. Autonomic responses were assessed through HRV monitoring using wearable heart-rate sensors (Polar system) and analyzed with Kubios software. Subclinical MA was identified in 29.9% of cows. Alkalotic cows showed higher bicarbonate and base excess and lower plasma chloride concentrations ($p < 0.05$). Blood lactate concentrations were generally low to moderately elevated and were not associated with acid–base alterations or indicators of tissue hypoperfusion. Moderate hyperlactatemia was accompanied by reduced HRV indices and increased LF/HF ratio, consistent with sympathetic activation and higher environmental heat indices. These results support the hypothesis that HRV-derived autonomic responses reflect physiological adaptations to environmental stress rather than metabolic hypoperfusion. The findings provide physiological support for the use of HRV-based wearable sensors as indicators within precision livestock farming systems, contributing to early-warning monitoring of environmental and metabolic disturbances in pasture-based dairy production.

Actionable indicators derived from milk fatty acids to assess rumen health, negative energy balance and production losses in dairy cows

I. Adriaens[1], E. Harms[1], J. Veneman[2], D. Schimmel[2], H. Taweel[3], R. Muller[4], M. Sol[1]
[1] CRV BV, Global Information Solutions, Rijksweg-West 2, 6842BP Arnhem, Netherlands, [2] De Heus BV, Rubensstraat 175, 6717VE Ede, Netherlands, [3] For Farmers, Kwinkweert 12, 7241CW Lochem, Netherlands, [4] Agrifirm BV, Landgoedlaan 20, 7325AW Apeldoorn, Netherlands

Metabolic health is essential for optimal production performance, fertility, and longevity in dairy cows. Early detection of excessive fat mobilization and impaired rumen function enables timely interventions at both group and individual cow level, helping to prevent milk losses and improve fertility. However, existing monitoring tools often lack sensitivity and provide limited actionable guidance for farmers and advisors. Milk fatty acids (MFA) reflect metabolic status but vary with lactation stage, parity, breed, and season, making them non-actionable when interpreted in isolation.The objective of this study was to develop actionable risk indicators based on the MFA profile while accounting for these covariates. Milk fatty acid profiles, predicted from mid-infrared spectra, were obtained from 181,794 milk samples collected through the national milk recording (MR) program at 52 farms over a four-year period (2021–2024). The dataset comprised 14,261 unique lactations and was combined with auxiliary cow data, daily milk yield records, and herd-level MR information on fat and protein yield.Three MFA-based risk metrics were developed to predict poor rumen function (days in milk [DIM] 0–450), negative energy balance (DIM 0–100), and early-lactation milk losses (DIM 0–42), with production losses evaluated over the first 150 days of lactation. Each metric classified cows into low, medium, or high risk categories. Odds ratios were calculated to quantify differences in milk losses between risk classes, and MFA-based risks were compared with existing ketosis alerts based on ketone measurements. A second validation study, conducted on 27 farms in 2025–2026, evaluated milk losses and farmer experiences.Cows classified as high risk based on MFA profiles were up to three times more likely to fall within the worst 20% quantile for milk losses compared with low-risk cows. Conversely, cows with a low-risk MFA profile were up to 3.5 times more likely to be in the lowest 20% for milk losses than high-risk cows. The MFA-based risk metrics demonstrated higher sensitivity than current ketosis alerts. In the second validation study, cows identified as high risk for both negative energy balance and rumen dysfunction exhibited an average milk loss of 0.6 kg/day, corresponding to 74% greater losses than cows with low risk scores. These MFA-based risk indicators enable farmers to optimize rations at group level and to identify individual cows requiring additional attention, thereby helping to prevent milk losses and improve metabolic management.

Quantification of drinking-induced rumen temperature change in dairy cows

H. Muraina[1], P. Hinke[1], R. Capota[1], R. Rivera Chacon[1], B. Foris[1]
[1] University of Veterinary Medicine, Center for Animal Nutrition and Welfare, Veterinaerplatz 1, 1210 Vienna, Austria

Intraruminal bolus temperature is widely used for health and physiological monitoring in precision dairy systems; however, the magnitude and persistence of drinking-induced thermal changes remain insufficiently quantified. We hypothesized that drinking behavior induces a distinct and temporally persistent rumen cooling signature that remains detectable at a 10-minute temporal resolution. We quantified the drinking-associated rumen temperature change using synchronized multimodal sensor measurements. We monitored seven late-gestation dairy cows with access to two drinkers (A and B) over a 4-month experimental window (range of days among cows: 6-10). We identified drinking behavior using manually video-labelled single-cow events within each interval (216 10-minute intervals, 3.05% of observations). We classified an interval as drinking if at least one drinking bout occurred within the 10-minute window. Rumen temperature was recorded using an intraruminal bolus (SmaXtec Classic Bolus, SmaXtec, Graz), providing both raw temperature and manufacturer-corrected "temperature without drink cycles". We recorded external water temperature from two trough loggers (HOBO Pendant MX2201 Temperature Sensor, LI-COR, Lincoln). Baseline temperature was defined as each cow's mean rumen temperature during intervals without video-confirmed drinking, excluding the drinking interval and the subsequent two intervals. Raw rumen temperature during video-confirmed drinking intervals averaged 37.87°C compared to 39.15°C during non-drinking intervals, corresponding to a mean cooling magnitude of −1.29°C (Cohen's d = 1.25; interval-level pooled SD). Across cows, the mean within-animal cooling effect was −1.10 ± 1.15°C (SD across cows). When accounting for temporal dynamics, peak cooling within the subsequent 20 minutes reached −4.14 ± 1.34°C relative to cow-specific non-drinking baseline, with nadir typically occurring in the first interval following drinking and observed in all seven cows (range −2.57 to −6.25°C). These findings demonstrate a substantial rumen temperature decrease that remains clearly detectable despite 10-minute aggregation. Analysis of post-drinking intervals revealed a sustained cooling trajectory. The difference between raw and corrected temperature averaged +1.56°C in the final drinking interval and peaked at +3.55°C in the first 10-minute interval following drinking, remaining elevated for up to 30 minutes before gradually returning toward baseline. Manufacturer-corrected temperature showed no appreciable difference between video-confirmed drinking and non-drinking intervals (Δ = +0.01°C). The correction magnitude averaged +1.56°C during drinking intervals and +0.27°C during intervals without video-confirmed drinking, indicating that the algorithm substantially attenuates drinking-associated cooling while applying minor adjustments outside labelled events. During video-confirmed drinking intervals, trough water temperature averaged 5.74 ± 1.83°C (Drinker A) and 6.72 ± 1.75°C (Drinker B). Collectively, these results demonstrate that drinking behavior induces an immediate cooling signature of approximately 1.3°C within drinking intervals and a peak cooling magnitude of approximately 4°C within 20 minutes. This signal can bias interpretation of raw bolus temperature when the objective is physiological monitoring, but it also provides a robust behavioral marker for drinking activity, underscoring the necessity of behavior-aware pre-processing in precision dairy monitoring.

FRESHEEP&GOAT: Adapting dairy sheep and goat barns to reduce heat stress due to climate change

M. Lambert[1], P. Massabie[1], J. M. Gautier[1], N. Litalien[2], G. Lagriffoul[2], F. Pingitore[3], F. Guillerault[4], P. Merino[5], E. Rosa[5], L. Rincón[5], A. Elhadi[6], A. A. K. Salama[6], G. Caja[6]

Dairy sheep and goats are common livestock activities on both sides of the Pyrenean territories where farmers share pastoral traditions and produce renowned cheeses which are socially, economically and culturally important for their communities. With this aim, as a part of the EU's initiative INTERREG-POCTEFA, a cooperation project was launched in 2026 to support regional development and to address shared challenges related with climate change in French and Spanish dairy sheep and dairy goat farms in the Pyrenean cross-border territories. Climate change is a significant concern which affects ruminant farming due to the rise of temperatures and the increased frequency and intensity of heat waves. Heat stress impacts on animals' health and well-being and impairs the productivity and profitability of dairy farms, as well as the quality of their products. Particularly exposed to climatic hazards, the POCTEFA territories are a key area for the development and implementation of appropriate practices and equipment. The FRESHEEP&GOAT EFA175/06 project aims to strengthen the resilience of dairy sheep and goat farms by adapting the farm buildings to different strategies to limit the effects of heat stress. It relies on the use common methodology and on collaboration between scientific, technical, and professional stakeholders to identify innovative and effective and cost-benefit solutions. The production, design, and environmental parameters of the buildings on 30 sheep and goat farms, including experimental and commercial farms, will be monitored on both sides of the French-Spanish border through 2026 to 2028. An algorithm linking meteorological data with environmental conditions and building design will also be developed. All these measures will make possible to establish solid benchmarks and ensure their transferability to commercial farms and its reproducibility on a larger scale.

Between-cow variation of responses to a subclinical ketosis challenge in early-lactating dairy cows

A. M. Reiche[1], J. Hendricks[1], J. Eichinger[3], F. Robertini[1], M. Marchese[5], R. Siegenthaler[2], L. Eggerschwiler[2], G. Lazzari[1], P. Silacci[4], F. Dohme-Meier[1]

[1] Ruminant Nutrition and Emissions, Agroscope, Rte de la Tioleyre 4, 1725 Posieux, Switzerland, [2] Research Contracts Animals, Agroscope, Rte de la Tioleyre 4, 1725 Posieux, Switzerland, [3] Veterinary Physiology, Vetsuisse Faculty, University of Bern, Bremgartenstrasse 109a, 3012 Bern, Switzerland, [4] Animal Biology, Agroscope, Rte de la Tioleyre 4, 1725 Posieux, Switzerland, [5] Department of Animal, Nutrition and Food Sciences, Università Cattolica del Sacro Cuore, Via Emilia Parmense, 84, 29100 Piacenza, Italy

Subclinical ketosis (SCK) in dairy cows shows marked inter-individual variability with some cows developing high beta-hydoxybutyrate (BHB) levels during negative energy balance (EB), while others do not. The mechanisms underlying this variability are not fully understood. The present pilot study investigated between-cow variation and potential contributing factors in early-lactating cows challenged by an experimental SCK-inducing feeding model (energy oversupply ante partum and energy undersupply post partum; n=8) and control cows (CON) fed according to requirements (n=8). Daily data (1- 28 d post partum) of serum BHB, non-esterified fatty acids (NEFA), glucose, aspartate aminotransferase (ASAT), alanine aminotransferase (ALAT), and gamma-glutamyl transferase (GGT), urine acetoacetate, milk acetone, dry matter intake, milk production, and body condition score (BCS) were collected, and energy intake and EB were calculated. Principal component analysis (PCA) and hierarchical cluster analysis were performed in R to explore whether cows within treatment groups formed distinct subgroups, and if so, to identify the characteristics that differentiated these groups. As intended by the experimental feed model, the EB of SCK cows was lower (mean: –32.4 MJ NEL/d) than that of CON cows (mean: –8.99 MJ NEL/d). On average, cows in the SCK treatment had serum BHB concentrations > 1.2 mmol/L (the diagnostic threshold for SCK) for 10 d (range of absolute values: 0.36 – 4.76 mmol/L; mean: 1.21 mmol/L), compared to 2 d in CON cows (range of absolute values: 0.43 – 2.27 mmol/L; mean: 0.85 mmol/L). Within both SCK and CON cows, cluster analysis identified two distinct groups of cows. For both treatments, the cluster assignment aligned with the directions of the first PCA axis, with cluster 1 cows on the positive side and cluster 2 cows on the negative side of the axis. For SCK cows, cluster 1 cows were associated with greater dry matter intake and milk yield and peaks of BHB, NEFA, ASAT, milk acetone and urine acetoacetate; cluster 2 cows with higher EB, BCS, and peaks of glucose, NEFA and GGT. For CON cows, cluster 1 cows were associated with greater energy and dry matter intake and EB, parity number, body weight and glucose and ALAT peaks; cluster 2 cows with higher milk acetone and urine acetoacetate peaks. In both treatment groups, distinct subgroups were present, reflecting high between-cow variation. In CON cows, clusters were mainly driven by intake capacity and energy intake, whereas in SCK cows, clusters were further influenced by metabolic markers of energy status and liver function. These findings indicate that cows vary in their energy and metabolic traits contributing to subgroup differentiation in both SCK-challenged and control cows. Ongoing omics analyses may offer insights into the underlying physiological mechanisms.

Temporal dynamics of breath acetone and blood β-hydroxybutyrate in early lactation dairy cows

J. Hendricks[1,3], J. Ko[4], A. M. Reiche[1], R. Siegenthaler[2], L. Eggerschwiler[2], A. Güntner[4], F. Dohme-Meier[1]
[1] Ruminant Nutrition and Emissions, Agroscope, Rte de la Tioleyre 4, 1725 Posieux, Switzerland, [2] Research Contracts Animals, Agroscope, Rte de la Tioleyre 4, 1725 Posieux, Switzerland, [3] Institute of Agricultural Sciences, Departement of Environmental System Sciences, ETH Zurich, 8092 Zurich, Switzerland, [4] Human-centered Sensing Laboratory, Department of Mechanical and Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

In early lactation, Holstein cows frequently experience negative energy balance and increased ketogenesis, raising the risk of subclinical ketosis (SCK). Diagnosis of SCK is commonly based on β-hydroxybutyrate (BHB) concentrations (≥ 1.2 mmol/L) measured from blood samples, requiring invasive collection. In contrast, breath acetone (BA) can be assessed non-invasively, making it a promising alternative diagnostic approach. A non-randomized controlled study was designed to compare longitudinal profiles of BA and BHB and evaluate BA as a non-invasive SCK indicator. Thirty-one healthy multiparous Holstein cows were allocated 42 d antepartum (ap) to one of two treatments based on body condition score (BCS). Cows with BCS ≥ 2.75 (n = 20) received SCK-inducing diets (high-energy diet ap, low-energy diet until 35 d postpartum (pp)), whereas cows with BCS < 2.75 (n = 11) were fed a standard diet (CON) according to requirements . Daily measures included dry matter (DM) intake (ap + pp), milk yield (pp), blood BHB (pp) and BA (pp). In addition, BHB and BA were assessed weekly during ap. Statistical analyses included linear mixed-effects models (fixed effects: treatment, day pp, interaction, baseline ap; random effect: animal), Spearman's rank correlation and principal component analysis (PCA). To evaluate time lags between BA and BHB, datasets were shifted by −3 to +3 days and analyzed using linear mixed-effects models, with animal as a random intercept. BA effects were further decomposed into within- and between- cow components. Receiver operating characteristic (ROC) analysis was performed, and area under the curve (AUC) and Youden's J were calculated to determine the optimal BA cut-off. During ap, cows in the SCK group had higher DM intake than CON cows ($p < 0.001$). Postpartum, SCK cows showed lower DM intake but higher milk yield than CON cows (both $p < 0.001$), resulting in a more pronounced negative energy balance in the SCK group ($p < 0.001$). BA and BHB were moderately correlated in the SCK group ($r = 0.63$, $p < 0.001$) and weakly correlated in the CON group ($r = 0.28$, $p < 0.001$), with a strong association observed at BHB concentrations > 2.6 mmol/L ($r = 0.74$, $p < 0.001$). Both BA and BHB showed substantial inter-individual variability, as reflected by large coefficients of variation (BHB: 44.7–47.1%; BA: 56.4–90.4%). PCA demonstrated separation between SCK and CON, with PC1 explaining 37.4% and PC2 explaining 10.9% of the total variance. BA was positively associated with blood BHB across all time shifts, strongest at d 0 ($\beta = 0.19$ mmol/L BHB per 1 ppm BA, $p < 0.001$). When BA was decomposed into within-animal and between-animal components, both increases in BA within animals over time ($\beta = 0.18$) and higher mean BA concentrations between animals ($\beta = 0.31$) were associated with higher BHB concentrations ($p < 0.001$). ROC analysis showed good discrimination of BA for detecting cows with BHB ≥ 1.2 mmol/L (cut-off 1.2 ppm; sensitivity 0.81, specificity 0.71, AUC 0.84). The association and temporal alignment of BA with BHB support BA as a biomarker for SCK. However, marked inter-individual variability in longitudinal ketone dynamics emphasizes the importance of analyses at the individual animal level.

Variability of urinary traits in lactating Holstein cows and their associations with milk quality traits

S. Magro[1], M. Kreuzer[2], G. Niero[1], M. Penasa[1], E. Visentin[1], A. Guerra[3], E. Chiarin[1], M. Renzi[4], M. Simoni[4], F. Righi[4], M. De Marchi[1]

[1] University of Padova, Department of Agronomy, Food, Natural Resources, Animals and Environment, Viale dell'Università, 35020 Legnaro, Italy, [2] ETH Zürich, Animal Nutrition, Institute of Agricultural Sciences, Department of Environmental Systems Science, Universitätstrasse 2, 8092 Zürich, Switzerland, [3] Associazione Regionale Allevatori del Veneto, Viale Leonardo Da Vinci 52, 36100 Vicenza, Italy, [4] University of Parma, Department of Veterinary Science, Via Taglio, 8, 43100 Parma, Italy

Monitoring urine composition is a valuable option for assessing animal health and physiological status, including the detection of nutritional imbalances and renal disorders. Although 24-h total urine collection is considered the gold standard, its application under commercial farming conditions is unfeasible due to housing constraints, collection procedures, and animal stress. Spot urine sampling offers a practical alternative; however, adjustment for urine concentration—through specific gravity—is required to account for individual variability. Building on a large-scale sample set, this study aimed to (i) evaluate the effects of stage of lactation and parity on urinary traits and (ii) investigate associations between urinary and milk traits to demonstrate which urine traits provide independent information. Spot urine and milk samples were collected from 1,271 Holstein cows across 17 farms in northern Italy. Farms were visited repeatedly, with different cows randomly sampled at each visit. Urinary pH, specific gravity, urea, protein, creatinine, allantoin, uric acid, glucose, and the protein-to-creatinine ratio were determined using reference methods. Milk composition was analysed using infrared spectroscopy and flow cytometry. Generalized linear mixed models were applied to assess sources of variation in urinary traits, including urinary specific gravity (as a covariate), stage of lactation and parity as fixed effects, and herd-test-date as a random effect. Pearson correlations were calculated within urinary traits and between urinary and milk traits. Urinary traits showed wide variability, with the protein-to-creatinine ratio exhibiting the greatest variability, whereas pH and specific gravity were the least variable. Specific gravity was significantly affected by stage of lactation and parity and explained a substantial proportion of the variability in all urinary traits, confirming its strength in adjusting for urine concentration. Stage of lactation influenced all specific-gravity adjusted urinary traits except pH and uric acid, whereas parity significantly affected only creatinine concentration. Most nitrogenous compounds were most concentrated in urine in early lactation and followed distinct temporal patterns across lactation. Herd-test-date accounted for a considerable proportion of variance, particularly for urinary pH and urea concentration. Strong correlations were observed within urinary nitrogenous compounds, whereas associations between urinary and milk traits were generally weak, confirming their independence in diagnostic value. Only milk urea concentration was closely correlated with urinary total nitrogen and urea concentrations. Milk urea concentration showed the strongest positive correlations with urinary total nitrogen and urea. These findings provide a robust baseline for interpreting urinary traits in lactating cows and identify key sources of physiological variability, thereby laying the foundations for the use of spot urine samples in diagnostic and herd management applications. This study received support from the project Cool-Cow 2023 of the Breeders Association of Veneto Region (ARAV, Vicenza, Italy).

Impact of the Bulmer effect is stronger than typically assumed when selecting on polygenic traits

Y. Wientjes[1], M. Calus[1], P. Bijma[1]
[1] Wageningen University & Research, Animal Breeding and Genomics, P.O. Box 338, 6700 AH Wageningen, Netherlands

Genetic variance is essential for genetic improvement through either natural or artificial selection. As a result of selection, the genetic variance decreases over time. A large part of this reduction is the result of a transient phenomenon known as the "Bulmer effect", which originates from the creation of negative covariances between loci. Usually, the infinitesimal model is assumed to account for the Bulmer effect when estimating breeding values and genetic variance components. However, there is increasing evidence that breeding goal traits are affected by very many loci that do not segregate independently because the number of chromosomes is limited. This creates linkage between loci, which influences the extent of the Bulmer effect. Here, we investigate the impact of linkage on the reduction in genetic variance under selection. Bulmer has shown that the reduction in genetic variance is a function of the harmonic mean of the recombination rate (rH) between loci. The rH is 0.5 when all loci are on separate chromosomes, resulting in a drop of for example ~21% of the genetic variance for mass selection on a trait with a heritability of 0.4 and a selection intensity of 20%. With 30 chromosomes of 1 Morgan each, the rH is ~0.33 when 30,000 loci are randomly spread along the genome, resulting in a drop of for example ~28%. We confirmed those predictions by simulating a population under either mass or genomic selection for 50 generations for a single trait with a heritability of 0.4 affected by 2000 additive loci, followed by 500 additional generations of random selection. The loci were either unlinked, by placing each locus on a separate chromosome, or in linkage, by placing the loci randomly over 10 chromosomes of 1 Morgan each. After 50 generations of mass selection, the loss in genetic variance due to the Bulmer effect was ~17% when loci were unlinked and ~34% when loci were linked. After selection was stopped, the genetic variance substantially increased in the first generations, mainly due to the breakdown of negative covariances between chromosomes. When loci were unlinked, the complete genetic variance was restored within seven generations. However, with linked loci, about 150 to 250 generations of random selection were needed before all negative covariances were broken down and the genetic variance was completely restored. With genomic selection, the Bulmer effect was slightly larger than with mass selection, both when loci were unlinked and linked. Altogether, our results show that the reduction in genetic variance due to the Bulmer effect can be considerably larger than typically predicted from the infinitesimal model, and that it takes much longer for the genetic variance to return to its original value. Therefore, the use of infinitesimal model assumptions, as for example done in the Animal Model, can create bias when estimating breeding values and genetic variance components.

Loss of Genetic Variance in Simulation Studies: Comparing the Effect of Selection on Classical and Deep Learning based Genetic Simulation Models

O. Onabanjo[1], T. Meuwissen[1], H. M. Gjøen[1], E. Karaman[2], T. T. Chu[2], P. Berg[1]
[1] Norwegian University of Life Sciences, Department of Animal and Aquacultural Sciences, Oluf Thesensvei 6, 1433 Ås, Norway, [2] Aarhus University, Center for Quantitative Genetics and Genomics, C.F. Møllers alle 3, 8000 Aarhus, Denmark

Stochastic simulation of breeding schemes provides a time- and cost-effective means of studying the effects of selection decisions in breeding programs. However, in several simulation studies, the long-term consequences of selection have been observed to lead to rapid exhaustion of genetic variance. These outcomes differ from real-life observations that we aim to replicate, thereby highlighting a fundamental limitation of current classical quantitative genetic simulation models. Deep learning (DL) models have demonstrated promising results in capturing complex interactions essential for maintaining genetic variance; thus, we hypothesize that DL-based genetic simulation models may preserve more genetic variance than classical models, because the biological pathways underlying complex traits exhibit interactions that classical models ignore. The objectives of this study were to compare classical and DL-based genetic simulation models with respect to retained genetic variance. Topigs Norsvin provided the genotype and phenotype dataset comprising 13,944 dam-line boars of different generations, which served as the founder population for the full-sib pig breeding program simulated using ADAM-Multi. The founders' genomes comprise 18 autosomal chromosomes and 35,977 biallelic SNPs, of which 12,000 were identified as QTLs. Haplotypes from founders were randomly sampled to generate unique genotypes for individuals before selecting the base population. Phenotypes were simulated using two classical quantitative genetics models: one with additive, dominance effects, and additive-by-additive epistatic effects (ADAA), and a model that includes all pairwise epistatic interactions (ADAAAAADDD). Simulating phenotypes for DL-based models (DL_medium and DL_complex) required training models using the founders' biallelic QTLs and phenotypes. The trained QTL weights were saved and served as a complex genotype-to-phenotype map. These weights were multiplied by the offspring's QTL genotypes to generate the total genetic value (TGV), which served as the phenotype. The parents (20 males and 200 females) of the next generation were selected based on TGV and mated randomly at a 1:10 male-to-female ratio. The simulation process was repeated for 40 generations and replicated 10 times. Our results showed a 202% increase in the initial additive genetic variance of the DL_complex model, with retention of 88% of its total genetic variance, while the DL_medium model retained 35% and 26% of its initial additive and total genetic variance, respectively. In contrast, the classical models retained 38-39% of additive and 40-48% of total genetic variance. In conclusion, a complex DL-based genetic simulation model exhibited greater retention of genetic variance. This might be due to the DL model's architectural properties, which intrinsically capture complex interactions that are converted to additive variance by selection; hence, affirming the role of non-additive genetic effects in maintaining long-term genetic variation.

Impact of non-additive genetic architecture, QTL number, and reference population size on the relative performance of machine learning and GBLUP models

J. Yang[1], P. Duenk[1], M. Calus[1], Y. Wientjes[1]
[1] Wageningen University & Research, Animal Breeding and Genomics, P.O. Box 338, 6700 AH Wageningen, Netherlands

Using machine learning (ML) models for genomic prediction has generated widespread interest in animal and plant breeding. The benefit of ML models over GBLUP likely depends on the ML model used, the size of the reference population, and the genetic architecture of the trait. Because ML models may capture complex interactions, it is of interest whether ML models show benefits over GBLUP with non-additive component (GBLUP-ADE) in the presence of non-additive genetic effects. The objective of this study was to compare the accuracy of different ML models with that of GBLUP-ADE under different non-additive genetic architectures, QTL numbers, and reference population sizes for prediction of total genetic values (TGV) and breeding values (BV). We used three representative ML models, random forest (RF), support vector regression (SVR), and multilayer perceptron with residual network (MLP-ResNet). Our results showed that the benefit of ML models over GBLUP-ADE depended primarily on the number of QTL underlying the trait, and to a lesser extent on the reference population size and genetic architecture. For TGV prediction, RF showed a benefit over GBLUP-ADE only when the number of QTL was 50 under a high level of dominance and a small reference population size. MLP-ResNet showed benefits over GBLUP-ADE when the number of QTL was small and the reference population size was large in the presence of epistasis. In all other scenarios, ML models showed lower prediction accuracy than GBLUP-ADE. For BV prediction, only MLP-ResNet showed a slight benefit over GBLUP-ADE, and only in scenarios with a small number of QTL and a large reference population size. Our results demonstrated that ML models showed benefits in only a few scenarios, and that these benefits were small and depended on the reference population size and the underlying genetic architecture. This study also suggests that ensemble methods (RF) and deep learning models (MLP-ResNet) can capture non-additive genetic effects in genomic prediction. These findings indicate that, for selection decisions aimed at predicting BV, GBLUP remains a robust and reliable method even when non-additive genetic effects are present. Overall, our results suggest that ML models may be considered alternatives to GBLUP(-ADE) for traits for which the infinitesimal model assumption does not hold.

A novel Monte Carlo method for approximating the null hypothesis in genomic-window genome-wide association analyses

D. López-Carbonell[1], M. Sánchez-Díaz[1], F. Barceló-Blasco[1], L. Varona[1]
[1] IA2, University of Zaragoza, C/ Miguel Servet, 177, 50013 Zaragoza, Spain

Genome-wide association studies (GWAS) are widely used to identify genomic regions associated with quantitative traits and diseases. To overcome the limited information from individual SNPs, window-based GWAS have been proposed. However, the proportion of variance explained by genomic windows is strongly influenced by factors unrelated to causal genetic effects, including SNP density, linkage disequilibrium patterns, allele frequency distributions, population structure, and gene–environment correlations. These factors may lead to biased identification of genomic regions and spurious associations. In this study, we propose a Monte Carlo procedure to approximate the null distribution of genomic-window statistics while preserving the genomic and genealogical structure of the population. The method was applied to cold carcass weight records from the Rubia Gallega beef cattle population. The dataset comprised 99,227 phenotypic records and a pedigree of 150,904 animals, including a total of 5,627 genotyped individuals. Variance components for linear mixed model were estimated using AIREML implemented in the BLUPF90. SNP effects were obtained using the SNP-BLUP transformation, and the proportion of additive genetic variance explained by 1-Mb genomic windows was calculated using postGSF90. To approximate the null hypothesis of no association, 1,000 simulated populations were generated. Phenotypic records were simulated by sampling environmental, additive genetic, and residual effects from multivariate Gaussian distributions parameterized by the REML variance estimates. Additive genetic effects were drawn from the stationary distribution defined by the H relationship matrix, thereby incorporating both pedigree and genomic structure. For each simulated dataset the full model was re-fitted and the proportion of variance explained by each genomic window was recomputed. The distribution of simulated estimates was then used to parameterize a gamma distribution, from which empirical p-values were derived by comparing observed and simulated statistics. The conventional window-based analysis identified several genomic regions explaining more than 0.5% of the additive genetic variance, but these signals were highly heterogeneous and strongly associated with marker density across the genome. The Monte Carlo procedure revealed that the expected variance explained by genomic windows under the null hypothesis varied substantially among regions due to genomic architecture. When empirical p-values were computed from the simulated distributions, strong signals were detected in genomic regions harbouring the well-known MSTN and LCORL genes. In addition, the method identified an additional region on BTA19 with a p-value below 0.0001 and several other regions with moderate significance that were not highlighted by conventional analyses. The proposed approach generates a null distribution that accounts for genomic architecture, pedigree structure, and environmental effects included in the model. The procedure also captures potential gene-environment correlations arising from the data structure. Consequently, the comparison between observed and simulated statistics reduces the occurrence of spurious associations while increasing sensitivity to detect genuine signals. In conclusion, the Monte Carlo framework provides a robust strategy for evaluating genomic-window GWAS results by explicitly modelling the stochastic behaviour expected under the null hypothesis. Although computationally demanding, this approach improves the reliability of genomic region detection and may enhance downstream applications such as weighted genomic prediction or functional interpretation of GWAS signals.

Optimising GCTA for improved parallelisation of large-scale association testing

A. Leonard[1], N. Kadri[1], N. Watson[1], Q. He[1], H. Pausch[1]
[1] ETH Zurich, Animal Genomics, Universitätstrasse 2, 8092 Zurich, Switzerland

Genome-wide association studies (GWAS) are a ubiquitous approach to identifying loci which contribute to complex traits. Livestock populations commonly have both large sample sizes, consisting of tens or hundreds of thousands of array genotyped animals, and extensive phenotypic records on numerous dairy- or beef-related traits. As such, livestock GWAS can be computationally burdensome and often require compromises subject to constraints like dividing samples into multiple independent subpopulations followed by meta-GWAS. The 1000 Bull Genomes (1000BG) consortium previously modified the GCTA (Genome-wide Complex Trait Analysis) software to consider genotype dosage and phenotype weights. Here, we further extend this version, focusing on two distinct aspects: improving computational throughput and parallelisation strategy, as well as enabling association testing with additional modes of inheritance. GCTA primarily functions as a monolithic program, with commands to calculate genomic relationship matrices (GRM), principal components (PCs), restricted maximum likelihood (REML), mixed linear model associations (MLMA) etc. However, these functions can have significantly different computational resource requirements or may be unnecessarily recalculated internally when parallelising across subsets of variants. By separating independent calculation steps and storing a binary representation of state, we implemented a more granular approach to parallelising with a REML-only step (memory-bound) and a MLMA-only (thread-bound) step. These steps also use different components of the input data, and so we implemented deferred loading of data until files were needed. Given the typical size of input files (i.e. nearly 1.5 TB of genotype files for 90k samples and 29M variants), this also reduces time wasted on input/output operations across sharded runs. GCTA also includes the ability to restrict analyses to specified genomic regions, but performs an inefficient linear scan across all variant sites. For genotypes provided in BCF/VCF format, we can directly leverage the indexed files to only extract the specified genomic regions rather than passing over the entire file, again reducing unnecessary input/output pressure. GCTA also mainly tests for additive associations, where genotypes are monotonically recoded under the additive inheritance model (aa: 0, aA: 1, AA: 2). Although additive associations are the most common form, other inheritance models (e.g., overdominant) and other biometrical models (where recoding accounts for allele frequency) are increasingly being used to reveal additional trait-associated loci. While the 1000BG version of GCTA could account for nonadditive recoding via the MACH dosage format, this introduced complications of “wide”- versus “long”-form data leading to high memory demands during conversion. Here, we added new functionality to allow greater flexibility of on-the-fly recoding genotypes according to user-specific models. We validated these changes by recovering recently reported non-additive loci for stature in Brown Swiss cattle. While we did not modify the core algorithms of GCTA, our reimplementation of several functions resulted in an order of magnitude higher throughput by separating memory-bound and thread-bound steps and minimizing redundant calculations across sharded runs. In addition, several quality-of-life improvements and the ability to recode genotypes under different nonadditive models also expands the range of association testing. Our version is freely available under the GPLv3 license of the original GCTA as a fork on GitHub.

Geometrical Linkage Disequilibrium between SNPs Dominance Effects and a Quantitative Trait

L. Gomez-Raya[1], W. M. Rauw[1]
[1] INIA-CSIC, Mejora Genética Animal, Carretera de la Coruña Km 7,5, 28040 Madrid, Spain

Linkage disequilibrium (LD) is the non-random association of alleles at two or more loci, not necessarily on the same chromosome. LD is central to our understanding of the genetic architecture of diploid organisms. The great majority of research investigating LD between Single Nucleotide Polymorphism (SNP) genotypes and quantitative traits considers only SNP additive effects. Geometrical Linkage Disequilibrium (GLD) is defined as the angle between SNP vectors of genotypic values centered at their mean. GLD is similar to a standard LD measures such as r. Orthogonal vectors (GLD = 90°) indicate no LD, whereas collinear vectors (GLD = 0°) indicate complete LD. The objective of this study is to extend GLD to incorporate dominance effects affecting a quantitative trait. The elements of the vector of dominance effects are $(1 - f)\delta$ for heterozygous individuals and $-f\,\delta$ for both types of homozygous individuals, where δ is the dominance effect and f is the frequency of the heterozygous genotype. We report the algebraic expression for the expected value of GLD for dominance effects as a function of α (additive effect), δ, and genotype frequencies. A computer simulation was carried out using an SNP allele frequency of 0.5, a population size of 300, and 10,000 replicates per simulation set. The quantitative performance was simulated using normal deviates with a phenotypic stardard deviation (psd) of 12.44. There was a very good agreement between simulated and observed estimates of GLD. Thus, GLD for $\alpha = 1$ psd and $\delta = 1$ psd was 69.21° and 69.30° for predicted and observed dominance effects, respectively. The GLD for $\alpha = 0$ and $\delta = 1$ psd was 65.85° and 65.91° for predicted and observed dominance effects, respectively. The standard deviation among replicates was 3.32° and 3.15° for the two scenarios considered. The main advantage of GLD is computational since it only involves the dot products of vectors. Therefore, the large-scale use of GLD may facilitate detection of dominance in large datasets, such as those generated by Next Generation Sequencing.

Misunderstood matrix: How changing the incidence matrix of social genetic effects changes the trait definition

B. Hegedűs[1,2], Z. Wang[1], C. A. E. M. Orsini[2], N. Galoro Leite[3], J. E. Bolhuis[2], P. Bijma[1]
[1] Wageningen University & Research, Animal Breeding and Genomics, Droevendaalsesteeg 1, 6708 PB Wageningen, Netherlands, [2] Wageningen University & Research, Adaptation Physiology, De Elst 1, 6708 WD Wageningen, Netherlands, [3] Topigs Norsvin Research Centre, Meerendonkweg 25, 5216 TZ 's-Hertogenbosch, Netherlands

Models including social genetic effects are a powerful tool to estimate the total heritable variation by including both direct (DGE) and social genetic effects (SGE) in the model. In these models, the SGE are linked to the phenotypes by using an incidence matrix, which is usually based on the group composition in animal breeding. In forest breeding, also the distance between the trees has been used to link the phenotypes and associated individuals. Recently, in animal breeding there is a trend of including the number of interactions between pairs of animals into the incidence matrix of SGE (ZSGE) to improve the estimation of variance components. While the use of distance in tree breeding uses information from the experimental design to scale the ZSGE, this method uses information based on observations to scale the ZSGE. Here, we hypothesize that by scaling the ZSGE based on observations instead of group composition the meaning of the estimated effects and thereby the targeted underlying traits change. Therefore, our objective was to understand how the choice of incidence matrix affects the meaning of the SGE and the resulting genetic change. We used pigs as an example and simulated a harmful behaviour with four underlying traits: (1) social tendency (= tendency to meet other pen mates), (2) tendency to bite given that two pen mates meet, (3) tendency to be bitten given that two pen mates meet, and (4) damage inflicted by the biter per biting event. Based on these four underlying traits we simulated movement and biting interactions between the pigs. Using the damage recorded on the victims as the phenotype we simulated ten generations of selection based on either SGE or total breeding values (also including DGE). We investigated three definitions of ZSGE. The three ZSGE were based on (1) pen composition, (2) scaled by number of meets and (3) scaled by number of biting events between pairs of animals. We chose the scenarios based on number of meets and number of events as this information will soon be available to breeders with the help of tracking and behaviour detection algorithms. Preliminary results show that the choice of ZSGE changed the underlying trait(s) of the estimated SGE. This resulted in different genetic gains in the four underlying traits depending on the choice of ZSGE, even though the phenotype remained damage of the victims in all cases. The SGE estimated with a ZSGE based on the number of events only targeted damage performed per biting event. In contrast, the SGE estimated with a ZSGE based on pen composition or number of meets targeted both the tendency to bite and the damage caused per biting event. Furthermore, when the selection was based on the total breeding value, the tendency of being bitten could also be reduced using a ZSGE based on pen composition or number of meets. However, it was not possible to select on direct effects when using the ZSGE based on number of events, as scaling the ZSGE by number of events resulted in no direct genetic variance in our simulation set up. In summary, scaling the incidence matrix of SGE based on behavioural observations lead to changes in the traits underlying both direct and social genetic effects. Therefore, researchers should be careful when applying such methods as it can lead to unexpected genetic change.

Deriving Metafounders from Cluster-Analysis: Application to Real Data

C. Edel[1], C. Anglhuber[1], E. C. Pimentel[1], R. Emmerling[1], J. Ertl[1]
[1] Bavarian State Research Center for Agriculture, Institute of Animal Breeding, Prof.-Dürrwaechter-Platz 1, 85586 Grub/Poing, Germany

In a recent publication we investigated an approach to define Metafounders (MF) based solely on the assignments of an unsupervised cluster-analysis of estimated founder-gene-contents by performing a semi-stochastic simulation using true genotypes and a complex pedigree of more than 20k genotyped Fleckvieh (FV) animals. Results of this simulation indicated that an integration of the approach into a Single-Step routine-evaluation in dairy cattle could be feasible and beneficial in increasing validation reliability and reducing inflation of predicted EBV in a trait with a strong genetic trend. In the following we present first results of an adaption of the above approach to data of the current Single-Step routine evaluation for protein yield in German/Austrian Brown-Swiss dairy cattle. To ensure a sufficient level of informativity for the estimation of the gene-contents of pedigree-founders, we used a maximum distance of two generations between the first genotyped (gt) descendants and the ungenotyped (non-gt) pedigree-founders and used this criterion for the truncation of pedigree and phenotypic data. Based on a final pedigree of ~1.4m animals, phenotypic data of ~1.3m animals and ~118k genotypes, we isolated a core-set of ~38k founders related to gt animals, calculated their gene-contents and assigned them iteratively to an increasing number of MF by using a kmeans cluster-algorithm. Pedigree-founders not related to gt animals were assigned to a base-set of 34 MF that was established using standard criteria for the definition of unknown parent groups (e.g. a combination of birth-year and country or origin). Using both assignments, the relationship matrix of MF (Γ) was calculated applying additional restrictions to ensure numerical stability and connectedness to phenotypic data. Finally, Single-Step evaluations with MF using full and reduced phenotypic data (minus 4 years) and standard validation procedures were performed to compare results to the current routine evaluation and to evaluate the impact of using an increasing number of MF. All MF models outperformed current routine-evaluation with respect to validation reliability. However, modelling a (too) low number of MF resulted in a higher bias and considerably more inflation when compared to current routine-evaluation. Modelling ~800 MF was optimal when considering bias, inflation and validation reliability (-1.9, .98, .89) simultaneously. Improvements observed were in good agreement with observations made using simulated data. Given the considerable differences between the current routine-evaluation and the different MF-models investigated, the correlation of breeding values observed in different groups of interest (young/old, gt/non-gt) were high (.96-.98). We observed that the different MF-models largely operate on overall, within and between group variances of EBV. When varying the residual polygenic component in the MF model (~800 MF) the optimum of 25% currently used in routine evaluation was outperformed by variants using 10% and even more when using 5%. By transferring structural information (via Γ) into the conventional relationship matrix, the resulting matrix seems to improve genomic predictions without the need for a large polygenic component in the model. Remarkably, foreign bulls, that are currently integrated into national Single-Step via deregressed MACE EBV validated best when modelling a single MF only (assumption of a homogeneous pedigree-base). MACE, by representing foreign information on national scales, seems to attenuate the stratum characteristics of foreign animals. This suggests that the current integration approach for foreign bulls might not be ideal when switching to MF models.

Estimating variance components and genetic parameters in large genotyped populations

D. Lourenco[1], M. Bermann[1], G. Gowane[1,2], I. Misztal[1]
[1] University of Georgia, Animal and Dairy Science, 425 River Road, 30605 Athens, United States, [2] ICAR-National Dairy Research Institute, Animal Genetics and Breeding Division, 1345 GT Rd, 132001 Karnal, India

Accurate genetic parameters require using all data that were available upon selection. However, estimating variance components and genetic parameters in large genotyped populations was infeasible until now. In this study, we present two methods for variance components estimation in large populations under genomic selection. The first is to estimate variance components for the base population, and the second is to compute genetic parameters (heritability and correlation) across time slices to investigate changes over time. The first combines Monte Carlo REML, which uses a Monte Carlo estimator of the trace term of the first derivatives of the restricted log-likelihood to avoid inverting the MME, with an efficient simulation of GEBV under the ssGBLUP framework. This was named MC-ssGREML and implemented in the BLUP90IOD3+ software from the BLUPF90 software suite. The second combines within- and across-trait predictivity formulas with a deterministic formula to predict the accuracy of genomic breeding values, which is named genetic parameters via predictivity (GPP). We tested MC-ssGREML and GPP on real and simulated datasets with up to 330,000 genotyped animals, using single- and multi-trait models. Both methods were compared with REML with (small data) or without (large data) genomic information. For GPP, time slices included three generations, two for training and one for validation. GPP estimates of heritability and genetic correlation closely matched the simulated values, whereas REML was slightly biased. For a dataset with 300,000 genotyped animals, GPP computations took close to one hour for a one-time slice run, including GEBV estimation. GPP had an approximately linear cost with the number of genotyped animals. For MC-ssGREML in a small dataset with 10,000 genotyped animals, variance components were similar to those from ssGREML, and running times were 22 hours for MC-ssGREML and 154 hours for ssGREML. For a dataset with 300,000 genotyped animals, MC-ssGREML required 5 days and 53GB of memory. Both MC-ssGREML and GPP are feasible tools for estimating genetic parameters and variance components in large datasets with many genotyped animals, with the former designed for base-population estimation and the latter for time-slice estimation.

Validating Indirect Genomic Predictions for Low and Moderately Heritable Traits

J. Thomason[1], F. Bussiman[1], A. Lima[1], S. Sanchez[1], A. Garcia[2], D. Lourenco[1]
[1] University of Georgia, Animal Breeding and Genetics, 425 River Rd., 30602 Athens, United States, [2] Angus Genomics Incorporated, 3201 Frederick Ave., 64506 St. Joseph, United States

Indirect predictions (IP) can serve as a vital tool for modern breeding programs as the number of genotyped animals continues to increase. It provides efficient genomic predictions based on SNP effects and SNP content for the gaps between official evaluation runs, early predictions for young selection candidates, and for commercial animals that may never make it into an evaluation. However, the application and use of IP depend on its reliability, and there is evidence that the method fails to provide satisfactory predictions for traits with low heritability. Our objectives in this study were to investigate whether IP are consistently reliable for traits with low heritability, and whether the choice of core animals in the Algorithm for Proven and Young (APY) can affect IP. Data were provided by the American Angus Association (AAA), which uses IP both as interim evaluations and through the GeneMax advantage program, where they provide genomic percentile scores for commercial heifers. IP were computed for 19 traits with heritabilities ranging from 0.04 to 0.56, using the blupf90 suite of programs. The data included over 15 million phenotypic records with 12 million animals in the pedigree, of which 1.7 million were genotyped. First, benchmark GEBV were calculated with all the available data, including genotypes from validation animals, via single-step GBLUP (ssGBLUP) with APY. Then, data for the validation animals were removed; thus, GEBV were computed based only on information for training animals (all but the validation animals), and back-solved to obtain SNP effects. After that, the IP for validation animals were computed via matrix multiplication using the vector of SNP content and SNP effects. The mean GEBV from the main evaluation (excluding animals having IP) was added to IP, so that IP has similar mean to the benchmark GEBV, thus allowing for direct comparison. Finally, IP for the validation animals were compared to their benchmark GEBV. Traits with high heritability and millions of records produced GEBV and IP that were nearly identical, with Pearson and Spearman correlations greater than 0.99. For lower heritability traits with less data, correlations remained greater than 0.99, except for a trait evaluated using a random regression model, which had a correlation of 0.97. The trends amongst the results were independent of the choice of core animals in APY. Slight differences do exist between GEBV and IP for traits with low heritability, however these are negligible. Thus, demonstrating that IP can be used as interim predictions across traits with varying heritabilities.

Fine-tuning Monte Carlo single-step genomic REML for variance components estimation in large datasets

M. Bernardes[1], M. Bermann[1], A. Álvarez-Munera[1], I. Misztal[1], D. Lourenco[1]
[1] University of Georgia, Animal and Dairy Science, 425 River Road, 30602 Athens, United States

As phenotypic and genomic information accumulates over time, estimating variance components (VC) becomes challenging due to computational limitations of approaches that rely on sparse matrix inversion, such as Expectation Maximization (EM) or Average Information (AI) REML. Nevertheless, estimating VC using the same dataset as in the genetic evaluation remains important, as changes in heritability can significantly affect prediction accuracy. The Monte Carlo single-step Genomic REML (MC-ssGREML) estimates VC using either EM or AI-REML, without large matrix storage or inversion. It offers high computational efficiency and low memory requirements for large datasets and complex models involving pedigree and genomic information. Compared to exact approaches, MC-ssGREML approximates the traces of the first derivatives of the restricted log-likelihood (tr(H^(-1)C^(uu))) using an average of quadratic forms, obtained from a sampling process. Although MC-ssGREML is highly efficient, it is preferable to keep the sample size as small as possible, as using hundreds of samples makes the estimation impractical. The feasible number of samples for genetic evaluations (in the order of tens) is limited by a relatively large MC noise near convergence, which can stall the algorithm. The current convergence criteria for MC-ssGREML are limited by MC noise when the sample size is not large enough. The MC noise decreases asymptotically as the number of samples increases. However, this behavior may not be consistent for a smaller sample size. Furthermore, in MC applications, the requirement for MC samples is not constant; more samples are needed towards the end of the estimation process than at its initial stage. In this sense, it is important to select an appropriate number of MC samples to capture the method's convergence nature. This research aims to 1) develop a method for selecting the optimal number of MC samples to improve convergence and keep computing time reasonable, and 2) determine whether a small increase in the number of samples reduces MC noise. We implemented an adaptive sampling scheme that increased the sample count by five whenever the norm of the scaled first derivatives of the restricted log-likelihood (Δc) fluctuated near convergence. We tested it on a four-trait repeatability model with over 210,000 records, 213,297 animals in the pedigree, and almost 16,000 genotyped animals. Starting with five samples, the algorithm ran until it reached 200. Increasing the number of MC samples did not necessarily yield better estimates of tr(H^(-1)C^(uu)) or smoother convergence for complex models. This behavior can be a consequence of the relatively small number of MC samples used in MC-ssGREML, which were insufficient to reduce MC noise significantly. In conclusion, the results indicated that adaptive sampling based solely on Δc did not reduce MC noise or improve the convergence behavior of MC-ssGREML. Addressing the MC sample size challenges and improving convergence requires incorporating MC noise into the adaptive sampling scheme. Nevertheless, MC-ssGREML is a valuable and scalable framework for VCE in large, complex genomic datasets. Further methodological refinements that explicitly address MC noise are expected to enhance its robustness.

Modelling missing pedigree using metafounders and validating genomic predictions in small sheep population

A. Phillips[1], C. M. Rochus[1], J. Ramljak[2], Z. Barać[3], M. Špehar[4], A. Kasap[2], I. Pocrnić[1]
[1] University of Edinburgh, The Roslin Institute, Easter Bush Campus, EH25 9RG Edinburgh, United Kingdom, [2] University of Zagreb, Svetosimunska 25, 10000 Zagreb, Croatia, [3] Croatian Association of Sheep and Goat Breeders, Jarnoviceva 17c, 10000 Zagreb, Croatia, [4] Croatian Agency for Agriculture and Food, Svetosimunska 25, 10000 Zagreb, Croatia

Genomic selection has been successfully implemented in many livestock species to advance genetic gain. With this, many small-scale breeding programmes for local breeds have begun the transition from traditional selection to genomic selection. However, the success of genomic selection in small-scale breeding programmes can be limited due to lack of organised breeding infrastructure (e.g., lack of widespread use of artificial insemination) and incomplete or incorrect pedigrees. One example of a local breed transitioning to genomic selection is the Pag sheep, a Croatian breed locally adapted for milk and meat production in the Mediterranean climate. To address the mentioned limitations of small, extensively held populations, previous studies have used unknown parent groups (UPG) or metafounders (MF) to model missing relationships. Coupled with leveraging genomic information to correct pedigree errors, UPG and MF showed improved model performance. In that sense, the objective of this study was to analyse bias, dispersion, and accuracy in genomic evaluations for milk yield in Croatian Pag sheep. The dataset consisted of 30,203 whole lactation records for 9,935 sheep across 107 flocks. Genomic information was available for 2,641 sheep of which 2,113 had phenotypes. Initial pedigree was corrected using SeekParentF90 software and then was trimmed to include all phenotyped and genotyped individuals, along with three generations of their ancestors without phenotypic or genotypic information, yielding a total of 12,095 animals. We compared pedigree-based best linear unbiased prediction (BLUP) and single–step genomic BLUP (ssGBLUP), with and without inclusion of UPG and MF. Both UPG and MF were defined based on the year of birth and generation interval. All models were run using blupf90+ program and model comparison was done using the linear regression (LR) validation approach as implemented in validationf90 software, with two validation cohorts: genotyped and phenotyped ewes born in the last generation and genotyped rams of phenotyped ewes born in the last two generations. In our dataset, including genomic information within ssGBLUP improved accuracy compared to BLUP models. The differences in terms of bias and dispersion between the models including UPG and MF, were subtle. While our results highlight the suitability of UPG and MF to improve genetic evaluations in small-scale breeding programmes with missingness in the pedigrees, future studies (e.g., fine-tuning UPG and MF definitions and how they are fit within ssGBLUP framework) are needed to justify their routine use in this population.

Visualization of changes in relationships among traits over time – example in type traits

M. Misztal[1], I. Misztal[1], D. Lourenco[1]
[1] University of Georgia, Animal and Dairy Science, 425 River Road, 30602 Athens, United States

Genetic evaluation usually includes many correlated traits. Their evaluation and their use in the selection index rely on the genetic parameters. The genetic parameters are changing, especially under the genomic selection. However, estimating the changes and their interpretation are difficult. The purpose of this study is to present methodology to visualize changes in complex relationships among traits over time. Changing correlations indicate change in relationships among the traits but the multivariate changes are hard to understand only using the genetic correlations. Data in this study were genetic correlations among 18 type traits, which were recorded by the Holstein Association, USA. The correlations were computed by GPP (Genomic Prediction by Predictivity) for years 2010 to 2020 yearly using all available pedigree, phenotypic and genomic information. For year 2010, the reference population included cows born in 2000-2008, and the validation population included cows born in 2009-2011. Subsequent years moved the populations by one year. Using genetic correlations for year 2020, for each trait we computed best prediction equations as indicated by the best fit (R^2) involving 2, 3 and 4 other type traits. Then the coefficients of the prediction equations were recomputed for years 2010-2019. Graphs of the coefficients over time for each trait and 2-4 prediction traits indicated dynamics among the traits and their changes over time. For example, Fore Attachment was a function of Rear Udder Width and Udder Depth (R^2=0.83), with the proportion of Rear Udder Width increasing over time. Adding Dairy Form increased R^2 to 0.86, and replacing Dairy Form by a combination of Stature and Strength increased R^2 further to 0.89. In general, predictions with 4 traits were less stable. GPP can be used to calculate genetic parameters in time slices with data from complete populations. Changes in dynamics of correlated traits can be visualized by prediction coefficients from equations involving 2 to 3 correlated traits.

Establishment of a Nationwide Monitoring System for Genetic and Phenotypic Trends in German Dairy Cattle

J. Gürtler[1], B. Albert[2], C. Edel[1], R. Emmerling[1], C. Schmidtmann[2]
[1] Bavarian State Research Center for Agriculture, Institute of Animal Breeding, Prof. Dürrwaechter Platz 1, 85586 Grub, Germany, [2] IT Solutions for Animal Production, , Heinrich-Schröder-Weg 1, 27283 Verden, Germany

Since the early 2000s, livestock husbandry has gained public attention. Central topics include animal health, welfare, and environmental impacts of dairy cattle farming. In this context, animal breeding has also increasingly moved into the societal spotlight. Although routine evaluations are conducted regularly, there is a lack of nationwide monitoring of breeding-relevant facts at the level of entire populations and complete sets of traits as a standardized basis for scientific and societal discussions. Genetic and phenotypic trends are particularly relevant in this context, as they reflect the results of breeding work as well as management and environmental effects. Current German statistics are published annually, but phenotypic trends are largely limited to milk yield and productive lifespan. Regional milk recording data cover only specific areas. Nationwide genetic trends beyond milk traits are mostly shown as aggregated selection indices, without trends for individual traits. Overall, there is no comprehensive, regularly updated, centrally compiled monitoring system with comparable presentations of genetic and phenotypic trends. For this reason, the project "Monitoring of Genetic and Phenotypic Trends" (MGPT) was initiated in Germany. The aim of this project is to establish a comprehensive, largely automated monitoring system for genetic and phenotypic trends in German dairy cattle breeding. The range of traits considered starts with the set of trait complexes currently included in breeding value estimation, since monitoring genetic trends is based on current estimated breeding values. These trait complexes consist of numerous individual traits which, depending on data availability, are also intended to be integrated into the monitoring system. Particular emphasis is placed on functional traits such as stillbirth rate, calving performance, and health traits. The monitoring initially focuses on three breeds: Holsteins, dual-purpose Fleckvieh, and Brown Swiss. Different breeding goals, genetic parameters, and trait definitions will hamper a direct comparison of trends between breeds. However, comparing phenotypic levels gives information on the selection response of the breeding programs at the national level. Based on the monitoring system, the frequently asked question by farmers and breeders — how breeding values are actually reflected in phenotypes — can be addressed. As an example, breeding values for mastitis (MAS) of 9,028 Fleckvieh bulls born from 2000 onwards and the phenotypes of somatic cell count (SCC) of their first lactation daughters (n = 2,808,115) were analysed. The phenotypes are based on test-day records and were summarised across all test days into a mean SCC per cow. Only bulls with at least 20 daughters with phenotypic records were included in the analysis. In addition, the bulls were grouped into classes from −3 to +3 standard deviations around the mean of their standardized MAS breeding values (mean ≈ 100 points). For each breeding value class, the average phenotypic SCC of the daughters was calculated. The results clearly show that as the MAS breeding values of the bulls increased, the average SCC of their daughters decreased. Using this approach, it would be possible to systematically map all trait complexes included in breeding value estimation and their corresponding phenotypes. This exemplary analysis illustrates the general potential of the monitoring system to make genetic developments traceable at the population level and to demonstrate their corresponding phenotypic outcomes in a transparent manner.

Temporal Dynamics of Major SNPs Identified by Large-Scale Single-Step GWAS in Broiler Chicken Populations

B. Moreno[1], M. Bermann[1], F. Bussiman[1], N. Stafuzza[1], V. Likness[2], D. Lourenco[1]
[1] University of Georgia, Animal and Dairy Science, 425 River Road, 30602 Athens, United States, [2] Cobb-Vantress, 4703 U.S. Highway 412 E, 72761 Siloam Springs, United States

Genome-wide association studies (GWAS) identify significant associations between single-nucleotide polymorphisms (SNPs) and phenotypes, often reflecting quantitative trait loci (QTL) through linkage disequilibrium (LD). Methods based on marker effects or variance explained may fail to account for uncertainty and LD among markers, so p-values are commonly used to detect significant SNP-trait associations. As allele frequencies and LD patterns shift across generations due to selection, migration, and genetic drift, both QTL effects and their statistical detectability can change over time, influenced by trait heritability, selection intensity, population size, and the number of genotyped animals. Single-step GWAS is widely used but is computationally costly for large datasets because it requires solving mixed model equations. The Algorithm for Proven and Young (APY) offers a sparse approximation of the inverse genomic relationship matrix (G) by splitting the genotyped animals into core and noncore. This study evaluated SNP consistency across generations, identified significant markers using frequentist p-values, assessed the impact of different APY core sizes, and compared marker effect and variance explained approaches. Data from Cobb Vantress Inc. included 1,515,952 broiler chickens, of which 721,041 were genotyped for 46,199 SNPs. Traits analyzed included body weight (BW), breast meat percentage (BM%), and leg score (LS). A multi-trait model accounted for sex, contemporary group, additive genetic effects for all traits, and a maternal permanent environment effect for BW. SNP effects were backsolved from GEBVs and applied in ssGWAS using four APY core sizes, corresponding to eigenvalues explaining 99%x2, 99%, 99%/2, and 99%/3 of the variance of G across generations 1-3, 2-4, 3-5, and 4-6. Additionally, marker effects and their percentage of variance explained were also evaluated for the same time periods. Analyses were performed with the BLUPF90 software suite. GWAS revealed stable SNPs across generations, with BW peaks on GGA1 linked to RING-type domain protein. Similar patterns were observed for BM% on chr5 (ALOX15B, lipid and arachidonic acid metabolism) and chr15 (SLC25A1, mitochondrial citrate transport and negative ferroptosis regulation), and for LS on chr12 (LOC107049643, calcium and phospholipid binding). Mapping resolution improved over generations, likely due to increased genomic information. APY core sizes typically used for genetic evaluations (99% and 99%x2) maintained resolution, whereas smaller cores (99%/2 and 99%/3) reduced precision, occasionally causing peaks to disappear or become less defined. Compared with p-values, marker effect and variance explained approaches revealed diffuse signals, moderate-effect loci and distributed contributions, reflecting limitations that ignore uncertainty and marker correlations. Therefore, major SNPs remained consistent across generations, with p-value analyses identifying clear, stable peaks. APY core sizes used for genetic evaluations maintained mapping resolution, whereas smaller cores reduced precision. Marker effect and variance-explained approaches identify more diffuse signals, providing less informative results than p-values.

Enhancing individual egg number records in group-housed laying hens through integration of behavioral patterns and automated nest system records

C. M. Sun[1], C. Reimer[1], A. Weigend[1], N. Goetzke[1], S. Weigend[1], J. Geibel[1]
[1] Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Höltystr. 10, 31535 Neustadt, Germany

Group housing improves laying hens welfare but complicates individual egg recording necessary for research and breeding, due to shared nest boxes. Automated nest systems Weihenstephaner Muldennest (WSMN, from Big Dutchman) with RFID technology can identify hen visits and potential laying events, yet assignments remain imperfect. Additionally, floor eggs laid outside nests are completely missed, which reduces phenotyping accuracy. We developed an imputation algorithm integrating behavioral data from WSMN records with manual egg counts to improve individual egg number estimation under uncertain identification. Our data came from three German local chicken breeds—Altsteirer (ALT, N=73), Bielefelder (BIE, N=51), and Ramelsloher (RAM, N=86)—housed in group pens each equipped with four automated nest boxes from WSMN. Egg laying was monitored from 24 weeks of age, while the following analysis presented imputation of 69—72 weeks of age, using: 1) WSMN records (hen ID, visit times, egg events); 2) daily manual nest and floor egg counts. Reliable WSMN records were identified based on validity, timing, and frequency criteria. Time offset correction improved match rates between WSMN records and manual counts from 94.6% to 95.2%. The imputation utilises a bayesian update algorithm, iteratively updating egg-hen assignment probabilities using behavioral likelihoods. For each pen-day, trusted assignments from reliable WSMN records matched with manual counts were identified and excluded from imputation. Unassigned eggs (uncertain nest and floor eggs) and candidate hens received a discrete uniform prior, sequentially updated in a bayesian way, using likelihoods from three weighted behavioral features: 1) Individual laying patterns predicted from fitting the reliable WSMN records to a four-state Hidden Markov Model (depmixS4 package), with laying state probabilities served as likelihoods; 2) Short-term laying and nest visitation habits within a ±2-day window, nest likelihoods were accessed by laying and nest visitation frequency incorporating switching penalties, leftover likelihoods were considered for floor eggs; 3) Long-term nest time spent for a hen across the laying period, with proportions served as nest likelihoods. A greedy algorithm assigned eggs to hens with highest posterior probabilities, resolving ties using leftover probabilities or overall laying counts. Cross-validation (3×5-fold) based on trusted assignments evaluated model accuracy. Finally, heritabilities (h^2) were estimated for imputed egg counts via bayesian genomic best linear unbiased prediction (BGLR package) using 52,903 SNPs after quality control. Of 1,721 eggs assigned, 87.5% were trusted matches, 8.4% floor eggs, and 4.1% uncertain nest eggs. RAM had lowest trusted assignments (81.5%) and highest floor eggs (16.6%), while ALT and BIE exceeded 90% trusted eggs and floor eggs below 6.7%. Model accuracy ranged from 0.86–0.93 across breeds. Median h^2 estimates ranged from 0.29–0.33, with RAM highest. Compared to raw WSMN records, imputation increased median h^2 by 0.04, 0.07, and 0.15 for RAM, BIE, and ALT, respectively. The study demonstrates how integration of behavioral data can handle assignment uncertainty while maintaining genetic variance. The flexible structure allows incorporation of additional behavioral or sensor data. However, limitations include reliance on nest visitation, validation based solely on trusted nest eggs potentially overestimating performance. Further, the current prototype only shows slight h^2 improvements in some breeds, which implies the need for optimization of the algorithm over a longer recording phase.

Breeding strategies for pike-perch (Sander lucioperca) in recirculating aquaculture systems in Denmark

H. M. Nielsen[1], J. Willemijn Verweij[1], J. Overton[2], T. Boutrup[2], T. Tuan Chu[1]
[1] Aarhus University, Center for Quantitative Genetics and Genomics, C.F. Møllers Alle 3, 8000 Århus, Denmark, [2] AquaPri Innovation, Lergårdsvej 2, 6040 Egtved, Denmark

The global production of pike-perch (Sander lucioperca), a freshwater fish species, is increasing. In Denmark, pike-perch are farmed by AquaPri, who produces up to 700 ton per year in recirculating aquaculture systems (RAS). Selective breeding can be a tool to adapt the fish to RAS and to improve efficiency of pike-perch production. This simulation-based study explored different low- cost phenotyping strategies and selection methods for selective breeding in pike-perch. In a basic setup of the breeding program, fish were size graded using a sorting system and selected based on visual inspection of exterior. We modelled this phenotyping strategy by simulating fish size and visual inspection (VI) as two categorical traits. This basic phenotyping strategy was compared with two alternatives. In the first alternative (scaling), fish were weighed using a scale and examined visually for different fish exterior characteristics. Both weight and VI were simulated as continuous, normally distributed variables. In the second alternative, fish were phenotyped using image analysis. The results from the image analysis were used as indicator traits for weight and VI with genetic correlations assumed to be either 0.7 or 0.9, respectively. The basic scenario with sequential selection was compared with multi-trait selection using an aggregated breeding goal. A breeding program for pike-perch in RAS was simulated for 25 years. In a year, there were four batches, in each of which 5 females were mated with 10 males, producing 10 families. In practise a female produces 50k to 60k offspring, but due to computation challenges, we assumed that a batch consisted of 750 fish only, where each of the 10 families contributed 75 fish. Selection was carried out in two rounds at 1 year old fish. In the first round, 150 fish were chosen. In the second round where different phenotyping strategies were applied, 30 fish were selected to become breeders. Sex of the fish was unknown at the time of selection and selected broodstock were used when they were 3 years old. Replacing fish grading with scaling improved genetic gain by 30%. Image-based phenotyping only increased genetic gain when the genetic correlation was 0.9 (19-21%) In addition, multi-trait selection increased genetic gain compared to sequential selection and reduced rate of inbreeding by 2-10%. We recommend adopting scaling and image analysis for phenotyping coupled with multi-trait selection, which requires relatively few operational changes, making it suitable for small breeding programs.

Optimal SNP selection for parentage discovery in large, genotyped populations

A. Garcia[1], P. Ramos[1], R. Medeiros[1], L. Novo[1], K. Retallick[1]
[1] Angus Genetics Inc, 3201 Frederick Av, 64506 Saint Joseph, United States

Genotyping is widely used by USA Angus breeders, with over 1.9M animals genotyped, enabling accurate genomic evaluations and allowing pedigree verification and discovery. The American Angus Association uses the ISAG200 panel to verify breeder-submitted pedigrees and to search for parents when pedigree mismatches or missing information occur. Parentage assignment relies on counting the number of opposing homozygotes (NOH), which can become challenging when searching across large populations. If the SNP set is not large enough it could lead to many false positive or negative results and while larger SNP sets improve accuracy, they increase computing time, and exclusion thresholds influence both false positives and false negatives. This study aimed to identify an optimal SNP set and exclusion threshold that balance accuracy, false discoveries, and computing time for parentage discovery in the Angus population. Genotypes for 1.9M animals (54,609 SNP) were available. Two target sets of genotyped trios were selected: 7,775 animals to evaluate eight SNP sets (ISAG200, ISAG554, and custom panels of 200, 554, 1K, 2K, 4K, and 13K SNP), and 74,540 animals to test exclusion thresholds (1–10%) using the 2K SNP panel. Custom SNP sets were sampled from markers with call rate >0.99 and MAF >0.35. Parentage status was determined by counting the NOH. Performance was assessed by the proportion of animals with two parents correctly identified and the distribution of the number of candidate parents found. Panels with ≥1K SNP performed similarly, with >98% of animals having both parents correctly identified, while smaller panels produced more false positives or missed parents. Panels constructed from SNP with high MAF outperformed ISAG panels of equal size. This was largely due to many SNP in the ISAG sets having low MAF in the Angus population. This result demonstrates the importance of selecting markers with high MAF within the target population. In the large target population, exclusion thresholds of 2% and 3% showed the best performance (≥94% correct assignments), while thresholds of 1% or 5% slightly underperformed, and 10% produced many false positives (77.8% correct assignments). Across the 74,540 animals, 98.5% had two parents correctly assigned; only three had more than five candidate parents, all explained by cloned dams. Some animals with zero or one parent identified could reflect sampling or pedigree identification issues and would need to be further investigated to conclude. Sampling SNP within the population using high call rate and high MAF produced the best results. A 1K SNP panel provided optimal accuracy without unnecessary computing load. Because breeder-provided information aids parentage resolution, a threshold that allows a small number of additional candidate parents is preferred. A 3% exclusion threshold was identified as optimal for the American Angus population.

Partitioning the genetic architecture of reproduction traits in Holstein cattle using local heritability

L. Schwarz[1], J. Bennewitz[2], J. Tetens[3], G. Thaller[1]
[1] 1 Institute of Animal Breeding and Husbandry, Christian-Albrechts-University, Hermann-Rodewald-Straße 6, 24118 Kiel, Germany, [2] Institute of Animal Science, University of Hohenheim, Garbenstr. 17, 70599 Stuttgart, Germany, [3] Department of Animal Sciences, Georg-August-University, Burckhardtweg 2, 37077 Göttingen, Germany

Reproduction is the prerequisite for lactation and progeny in dairy cattle, but challenging for breeding and genetic improvement. The underlying genetic architecture for such functional and health related traits remains largely unknown and the corresponding heritabilities (h^2) are usually low. Genome-wide association studies (GWAS) are established to identify associated genomic regions even for such low heritable traits, but do not directly quantify the relevance of these regions for the total h^2. However, GWAS summary statistics can be used for additional analyses combined with the linkage disequilibrium (LD) structure of the genome to obtain individual contribution of distinct genomic regions to individual traits. Methodological tools like ρ-HESS or LAVA can be used for this kind of identification and quantification of distinct regions and are also able to identify relevant genomic regions for multiple traits, potentially harboring pleiotropic variants. Subsequently, local genomic regions with higher multi-trait relevance and significance for individual h^2 can be focused on to investigating the genetic architecture. The aim of the present study was to identify and quantify the contribution of individual genomic regions to the total h^2 of selected reproduction traits in German Holstein cattle, using two local h^2 approaches. GWAS summary statistics for seven reproduction traits, namely calving ease direct and maternal (CEd/CEm), metritis (MET), retained placenta (NGV), stillbirth direct and maternal (SBd/SBm) and ovary cycle disturbances (ZYS) were analysed. Up to 250,000 genotyped cows were used for LD reference to estimate 1,906 distinct genomic regions across the 29 autosomes and the X-chromosome. The number of cows for GWAS analyses varied between 110,629 (ZYS) and 192,188 (SBm), and a total of 44,994 SNPs were tested on autosomes and X-chromosome. For all traits between 2 and 33 markers per trait were identified as genome-wide significant after Bonferroni-correction. The total h^2 estimates, derived as sum of all local individual estimates per region and trait differed slightly between the methods ρ-HESS (h^2Hess) and LAVA (h^2LAVA) but were within a similar range (e.g. MET h^2HESS = 0.103, h^2LAVA = 0.087). Across all reproduction traits the h^2 estimates varied between 0.078 (h^2HESS SBm) and 0.127 (h^2LAVA SBd). The relative contribution of each individual region was compared in relation to the overall estimate per method and trait. This comparison revealed similar patterns for the contribution per region and highlighted multiple regions of interest for individual traits. For example, for SBd multiple significant genomic regions were identified distal on chromosome 18 around 58,587 kilobase pairs with both methods, highlighting the relevance of this region for the overall h^2. Finally, both local h^2 approaches identified similar patterns and significant genomic regions contributing to the relatively low overall h^2. This facilitates direct comparisons between traits and allows the assessment of the relative importance of specific regions within and across traits. The obtained results could therefore be used for additional analyses to further pinpoint the relevance of selected genomic regions and investigate their pleiotropic potential across traits.

Large-scale identification of breed-specific alleles in cattle and their potential impact

J. S. Schlüter[1,3], F. Heinrich[1,3], M. Gültas[2], A. O. Schmitt[1,3]
[1] University of Göttingen, Department of Animal Sciences, Margarethe-von-Wrangell-Weg 7, 37075 Göttingen, Germany, [2] South Westphalia University of Applied Sciences, Faculty of Agriculture, Lübecker Ring 2, 59494 Soest, Germany, [3] Center for Integrated Breeding Research (CiBreed), Von-Siebold-Str. 8, 37075 Göttingen, Germany

Cattle are among the most economically significant livestock, representing a diverse species with two subspecies. Within these subspecies, numerous breeds are adapted to specific environments and production purposes and contain breed-specific alleles. For candidate allele detection, analyses of private alleles are frequently limited to smaller breed panels. Private alleles (breed-specific alleles) represent variants occurring in only one population (breed), regardless of their frequency in that population. In our approach, we analyse a large set of breeds and examine variants that are private to single breeds and their predicted impact to identify potential targets for further studies. For the initial analysis we considered the 1000 Bull Genomes Project and analysed private alleles for 280 breeds across 120 million positions. Breeds were filtered to include only those with at least 15 individuals. For breeds with more than 30 individuals, sample sizes were limited to 30 by random sampling. This process was repeated five times, retaining only the private alleles common to all repetitions. By setting lower and upper boundaries, we aim to obtain representative samples of breed diversity while limiting bias by large breeds on the detection of private alleles. Additionally, comparison was also made against all animals of all smaller breeds as a control group in the identification of private alleles to minimize the false-positive detection of private alleles due to the limited set of breeds passing the filtering step. To identify private alleles, PLINK was used to calculate variant frequencies across breeds, combined with custom scripts for filtering individuals and variants. The identified private alleles were then annotated using SnpEff to predict functional consequences and further filtered for high-impact variants. To investigate potential biological relevance, information from the Animal QTL Database was downloaded and integrated with the private allele data. After filtering for breed size, 62 breeds with 1,544 individuals remain for detection of private alleles. Among breeds, Buryat exhibited the greatest number of private alleles (n = 444,496; 0.4% of all positions), while Holstein had the least (n = 1,479). Initial analyses revealed a total of 2,238 high-impact private alleles across the whole genome. The distribution of private alleles across impact categories differed significantly from that observed in randomly sampled variants. In contrast, only 1,080 high-impact annotations were found among an equivalent number of randomly selected variants, indicating a significant overrepresentation of high-impact variants in private alleles ($p < 0.05$, Fisher exact test), which may point to their potential biological relevance. Angus harbored the greatest number of high-impact private alleles (n = 815), whereas no high-impact private alleles were identified in Holstein Red or Modern Danish Red cattle. Considering the position of private alleles, many are found within regions previously associated with known traits. The categories most frequently overlapping with private alleles were meat and carcass traits, particularly for Angus cattle, and reproductive traits, respectively.

Detection of sex chromosome aneuploidies using SNP array intensity data: an application in pigs.

M. Londoño-Gil[1], M. F. L. Derks[2], N. G. Leite[1], C. Sevillano[1], E. Grindflek[1]
[1] Topigs Norsvin, Research, Meerendonkweg 25, 5216 TZ 's-Hertogenbosch, Netherlands, [2] Wageningen University & Research, Droevendaalsesteeg 1, P.O. Box 338, 6700 AH Wageningen, Netherlands

Sex chromosome aneuploidies, including XXY (Klinefelter syndrome), XO (Turner syndrome), and XXX (X trisomy), are known to affect reproductive physiology, secondary sexual development, and metabolic traits in humans. However, their prevalence and phenotypic consequences in commercial pig populations remain largely unknown, primarily due to the lack of large-scale detection strategies. We hypothesize that sex chromosome aneuploidies occur at detectable frequencies in pig populations and that they have measurable effects on fertility, growth, and carcass traits consistent with manifestations described in other mammals. This study aims to identify XXY, XO, and XXX individuals using SNP array intensity metrics, Log R Ratio (LRR), and B Allele Frequency (BAF), from ~630K genotyped pigs, and to characterize their performance. Classification will be based on X-chromosome heterozygosity, deviations in mean X-LRR, BAF peak distributions, and Y-chromosome signal intensity. Visual inspection of individual LRR and BAF profiles will further support classification accuracy. Normal euploid males (XY) are expected to show near-zero heterozygosity across the X chromosome, a baseline X-LRR, and a BAF clustering at 0 and 1, consistent with a single X copy, and a clear Y-chromosome signal. In contrast, XXY males are expected to present increased X-chromosome heterozygosity relative to XY males due to the presence of two X chromosomes, a positive shift in mean X-LRR consistent with an additional X copy, BAF clustering compatible with disomic states (peaks at 0, 1/2, and 1) across most loci, and preserved Y-chromosome signal. XO females are anticipated to exhibit minimal or absent heterozygosity across the X chromosome, markedly reduced X-LRR (reflecting monosomy), BAF clustering at 0 and 1 (consistent with a single X copy), and no detectable Y signal. Conversely, XXX females are expected to have elevated mean X-LRR consistent with trisomy, BAF peak distributions at 0, 1/3, 2/3, and 1 across loci with greater heterozygosity, and absence of Y signal. In the first screening, 0.003% XO and 0.014% XXX among total females, and 0.2% XXY among total males, were identified. Based on evidence from human and comparative mammalian studies, we expect XXY males to show impaired spermatogenesis, an increased incidence of testicular hypoplasia, and reduced fertility. We also expect an altered androgen–estrogen balance associated with supernumerary X-linked gene dosage, which may influence muscle deposition and fat metabolism, potentially leading to differences in body weight and backfat thickness compared with euploid males. For XO females, we hypothesize (near-)complete infertility due to gonadal dysgenesis, although some individuals may display estrous behavior without successful conception. For XXX, we predict partial reproductive impairment, with subfertility manifested as reduced farrowing rate or smaller litter size. Hence, for the next steps of the analysis, phenotypic effects will be evaluated through case-control comparisons within genetic line, birth year and month, and farm to isolate chromosomal effects from environmental and management confounders. In the future, we hope that SNP-intensity–based screening will enable routine, large-scale identification of sex chromosome aneuploidies during the selection of breeding candidates, thereby improving reproductive efficiency management in pig production.

Estimation of semen variability phenotypes in boars used for artificial insemination

P. Sá[1], R. Mezencio Godinho[1], E. Grindflek[1,2]
[1] Topigs Norsvin Research Center B.V., Meerendonkweg 25, 5216 TZ 's-Hertogenbosch, Netherlands, [2] Norsvin S.A., Storhamargata 44, 2317 Hamar, Norway

The swine industry relies strongly on the regular and reliable production of high-quality fresh semen. In production centers of semen doses, it is of utmost value to predict the number of doses that can be produced weekly from a boar. Therefore, boars with lower variability in semen quantity are desired. The objective of this study was to estimate new phenotypes for boar-level variability in semen using the residual variance of these traits. Ejaculates were collected between 2021 and 2026 and evaluated using a Computer-Assisted Sperm Analysis (CASA) system. The phenotypic dataset included records from 188,852 ejaculates collected from 2,373 boars from a synthetic sire line. Pedigree information included 9,289 animals spanning 15 generations. We considered semen quantity (number of sperm cells, concentration and volume of the ejaculate) and sperm quality parameters (sperm total and progressive motility of fresh semen and total morphological abnormalities). We estimated residuals using a univariate analysis with a repeatability model accounting for fixed effects at semen collection. The boar-level residual variance was calculated and transformed using an inverse normal transformation. We used a univariate model to estimate genetic parameters for boar-level residual variance and a bivariate model to estimate genetic correlations with boar-level mean of the trait. Results indicate that boar-level semen quantity and sperm quality variability phenotypes (residual variance) have moderate heritabilities (0.15 – 0.27) and can be improved by means of selection. For semen quantity traits, the boar-level variability has a positive genetic correlation with boar-level mean of the trait (0.52 – 0.74). For sperm quality traits, the boar-level variability is moderately or not correlated with boar-level mean of the trait (-0.13 – 0.43). These results indicate that both semen quantity and semen quantity variability should be included in the breeding program, in order to allow for increased genetic gain on semen quantity while preventing selection for boars with less predictable number of sperm cells per ejaculate.

easybreedeR: An integrated R shiny application for breeding data analysis

H. Tang[1], H. A. Mulim[1], H. R. D. Oliveira[1]
[1] Purdue University, Animal Science, 270 S Russell St, 47906 West Lafayette, United States

Abstract Phenotypic, pedigree, and genomic data form the foundation of modern animal and plant breeding. Before the analysis process, these datasets must undergo biological and statistically rigorous quality control to ensure accurate estimation of genetic parameters and breeding values. However, the process of preparing and validating the breeding datasets, as well as the generation of parameter files for genetic and genomic evaluations (e.g., using the BLUPF90 family of programs), often involves fragmented tools and manual scripts. This workflow is usually time-consuming and prone to errors, which may become a major barrier for new users; especially those without extensive programming experience. To address this gap, we introduce easybreedeR, an integrated online interactive toolkit for the purpose of breeding dataset verification, quality control, and the automatic generation of parameter files used by the BLUPF90 programs. By standardizing data structures and model specifications, easybreedeR reduces manual errors, improves reproducibility in genetic and genomic evaluations, and significantly reduces the challenges for new researchers interested in the field of breeding. The easybreedeR toolkit also provides clear, comprehensive summaries of phenotypic, pedigree, and genomic data, offering a user-friendly environment that bridges data preprocessing and genetic evaluation. By integrating quality control and automated parameter-file generation within a single platform, easybreedeR streamlines complex breeding workflows and makes advanced analyses more accessible to researchers and breeding practitioners. Availability: easybreedeR is developed primarily in R with Rcpp and implemented as an interactive Shiny application. The development version is maintained at https://github.com/rojaslabteam-rgb/easybreedeR. An online version has been deployed on shinyapps.io and is available at https://vb6clt-huangyi-tang.shinyapps.io/easybreeder-suite/.

Towards a Stillbirth Monitoring System for German Holstein Dairy Cattle in the MGPT Project

F. Fischer[1], L. Hüneke[4], L. Völker[5], Y. Zheng[1], C. Schmidtmann[4], G. Thaller[5], C. Reimer[1], C. Klein[1], C. Kühn[2,3], J. Geibel[1]

[1] Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Höltystr. 10, 31535 Neustadt am Rübenberge, Germany, [2] Friedrich-Loeffler-Institut, Südufer 10, 17493 Greifswald, Germany, [3] University of Rostock, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany, [4] IT Solutions for Animal Production (vit), Heinrich-Schröder-Weg 1, 27283 Verden, Germany, [5] Christian-Albrechts-University, Institute of Animal Breeding and Husbandry, Olshausenstraße 40, 24098 Kiel, Germany

Stillbirths in dairy cattle do not only have economic consequences but are also highly relevant from an animal welfare perspective. The literature associates factors such as under- and over-conditioned transition cows, male sex, primiparous calvings, dystocia, as well as twin births and obstetrical interventions with increased stillbirth rates. In addition, various infectious agents may influence stillbirth rates depending on regionally differing epidemiological conditions, e.g. BTV-3. Known genetic defects are mostly recessive mutations that are widespread within the population. Large datasets of genotyped healthy cattle enable the identification of haplotypes carrying unknown lethal defect alleles due to missing homozygous animals in the population. However, identifying such alleles requires a certain frequency within the population and targeted monitoring to allow statistical detection. Rare and potentially novel mutations are therefore generally unknown and may cause considerable damage until they are discovered, particularly as they are often investigated systematically only at a later stage. Given this complexity, the causes of stillbirth are heterogeneous in aetiology and require comprehensive and differentiated recording of relevant influencing factors. On the other hand, specific challenges arise in collecting such data, as stillborn calves have no economic value for farmers, and in-depth investigations or genotyping are therefore performed only in exceptional cases. In this context, the project MGPT (Monitoring of Genetic and Phenotypic Trends) aims to establish a monitoring system for stillborn calves in the German Holstein Friesian dairy cattle population. Specific phenotypic characteristics recorded include time of death (intrapartum or postpartum), the course of parturition, fetal development, externally visible abnormalities or malformations, chest circumference, birth weight, sex, and the body condition of the dam. In addition, photographs can be taken to allow subsequent estimation of calf size and retrospective assessment of abnormalities. For analysis, the recorded data are merged with routine data collected by vit (IT Solutions for Animal Production), such as previous calvings, lactation number, breeding values, genetic characteristics, insemination data, and any prior stillbirths. This enables classification according to potentially common causalities. The phenotyping is accompanied by SNP genotyping of stillborn calves, while their parents are routinely genotyped. Since the beginning of 2025, 87 farms with a total of approximately 16,000 cows have participated. As of 28 February 2026, a total of 556 stillbirths have been recorded. The monitoring will continue to enlarge the reference population for the identification of phenotypic and genotypic causes of stillbirth and to develop a prospective risk monitoring system for defective alleles, enabling early breeding intervention.

Monitoring of Genetic and Phenotypic Trends in German Dairy Cattle – Project MGPT

B. Albert[1], J. Gürtler[2], R. Emmerling[2], L. Hüneke[1], C. Kühn[3], G. Thaller[4], J. Bennewitz[5], C. Schmidtmann[1]
[1] IT-Solutions for Animal Production (vit), Heinrich-Schröder-Weg 1, 27283 Verden, Germany, [2] Bavarian State Research Center for Agriculture (LfL), Institute of Animal Breeding, Prof. Dürrwaechter Platz 1, 85586 Grub, Germany, [3] Friedrich-Loeffler-Institut, Südufer 10, 17493 Greifswald, Germany, [4] Kiel University, Institute of Animal Breeding and Husbandry, Christian-Albrechts-Platz 4, 24118 Kiel, Germany, [5] University of Hohenheim, Institute of Animal Science, Garbenstraße 17, 70599 Stuttgart, Germany

In recent years, dairy cattle breeding has undergone substantial changes. Alongside technological innovations such as genomic selection, breeding objectives have shifted considerably. Functional traits, animal health, animal welfare, and aspects of resource and climate efficiency are increasingly being prioritized, thereby complementing established breeding objectives in a sustainable manner. Despite these adaptations, however, dairy cattle breeding is facing increasing scrutiny in public perception and political discourse. A robust evaluation of trait development in dairy breeding requires a comprehensive analysis of both genetic and phenotypic trends. These trends are instrumental, as they reflect the cumulative effects of selection decisions as well as the influence of management practices and environmental conditions over time. In Germany, such assessments are limited and address only parts of the dairy cattle population. The collaborative project "Monitoring of genetic and phenotypic trends" (MGPT) aims to close this gap by developing a nationwide monitoring system covering breeding-relevant parameters at the level of entire populations and comprehensive trait sets. Initially, the monitoring will focus on the breeds Holstein, Fleckvieh, and Brown Swiss, with a long-term perspective of gradual expansion to include additional populations, particularly traditional and endangered breeds. Special emphasis will be placed on animal welfare- and environment-related traits, thereby establishing a scientific basis for assessing dairy production systems in the context of climate change. Ultimately, the goal is to establish a centralized, publicly accessible information platform that provides robust data to support evidence-based decision-making for policymakers and industry stakeholders, while simultaneously offering an objective foundation for societal discourse on dairy farming. Furthermore, methodological frameworks will be developed to enable the routine monitoring of stillbirth incidence, a trait of particular relevance to animal welfare, and to facilitate a deeper investigation of its underlying causes. At present, the recording of stillbirths does not differentiate between calves born dead and those that die within the first 48 hours postpartum. A more precise phenotypic definition, together with improved knowledge of both genetic and non-genetic determinants and a more detailed recording of environmental influences, may contribute to further reductions in stillbirth rates and the incidence of severe calving events. In the long term, this approach aims to establish the foundation for an early warning system that supports timely breeding interventions. For instance, it would enable the identification of deleterious mutations associated with increased defect rates and adverse welfare outcomes before they become widespread, thereby preventing costly counter-selection measures and potential losses in genetic diversity. The resulting insights will be systematically incorporated into the monitoring framework.

High-Sensitivity Detection of Genome-Edited Pigs and Cattle by CAST-PCR

F. Poulain[1], M. Dias Mirandela[1], F. Debode[2], V. Gelhay[2], C. Muys[1], B. Renaville[1]
[1] Progenus, rue Camille Hubert 7A, 5032 ISNES, Belgium, [2] Walloon Agricultural Research Centre, Chaussée de Charleroi, 234, 5030 Gembloux, Belgium

With the development and increasing use of new genomic techniques (NGTs) for genome editing to generate novel genetically modified animal products, new detection approaches must be developed. Because NGT-modified organisms may differ from non-modified strains by as little as a single nucleotide mutation and do not necessarily contain foreign DNA, a high level of specificity and sensitivity in mutation detection is required. To address this challenge, and as a partner in the European project DETECTIVE (Detection of NGT products to promote innovation in the European Union), PROGENUS has developed a CAST-PCR (Competitive Allele-Specific TaqMan PCR) approach to detect a two-nucleotide deletion in the bovine PMEL gene and in the pig CD163 gene. This technique is based on target-specific amplification and detection using TaqMan qPCR, involving primer competition between the wild-type and mutated sequences. Preliminary tests highlight a limit of detection (LOD) under 10 copies. In addition to its sensitivity, the CAST-PCR detection test developed is robust, easily applicable in routine laboratories without the need for specialized equipment, and cost-effective. These development efforts will provide new analytical tools enabling the detection of NGT-introduced mutations in derived products.

Genetic investigation of the boar taint compounds androstenone and skatole using SNP chip data and whole genome sequencing data in dam lines

K. M. Flüchten[1], I. Brinke[1], C. Große-Brinkhaus[1,2], M. J. Pröll-Cornelissen[1,3], H. Henne[4], E. Tholen[1], C. M. Dauben[1]
[1] University of Bonn, Institute of Animal Science, Endenicher Allee 15, 53115 Bonn, Germany, [2] Georg-August-University Göttingen, Department of Animal Sciences, Animal Breeding and Genetics, Albrecht-Thaer-Weg 3, 37075 Göttingen, Germany, [3] German Livestock Association, Adenauerallee 174, 53113 Bonn, Germany, [4] BHZP GmbH, An der Wassermühle 8, 21368 Dahlenburg-Ellringen, Germany

Due to consumers' rising animal welfare concerns, surgical castration without anaesthesia is discussed critically in Europe and was banned in Germany in January 2021. Besides surgical castration under anaesthesia, fattening entire boars is a promising alternative. However, this method is restrained by the slight risk of boar-tainted meat and an unfavourable fatty acid composition of the back fat. To lower this risk, breeding organizations have started breeding against boar taint, based on either records from human sensory scoring (SENS) systems or the chemical components androstenone (AND) and skatole (SKA). Previous studies have shown that these phenotypes have moderate (SENS) to high (AND) heritabilities ranging between 0.15 to 0.52. It has been demonstrated that AND exerts an inhibitory effect on cytochrome CYP2E1 activity, leading to an antagonist effect on the SKA degradation in the liver. The genetic correlation between AND and SKA is moderate (rg= 0.42 – 0.57). Another potential risk is the possibility of an antagonistic relationship between AND and endocrine fertility parameters (EFP). Quantitative genetic analyses of maternal nucleus lines of a German breeding organization showed only a weak genetic correlation between AND and different fertility parameters (rg= 0.03 to 0.36), but a strong genetic correlation between AND and the EFP testosterone (rg= 0.62 and 0.83). Based on routinely collected SNP chip data (Illumina PorcineSNP60 BeadChip), our group performed genome-wide association studies for boar taint components as well as for fertility parameters and EFP. The studied data originated from the project G-I-FER (supported by funds of the Federal Ministry of Food and Agriculture based on a decision of the Parliament of the Federal Republic of Germany via the Federal Office for Agriculture and Food under the innovation support programme; FKZ: 2817904115). In these studies, 15 QTL for AND and 28 QTL for SKA in Landrace (LR) and Large White (LW), and a few suggested significant QTL for fertility parameters, and EFP were identified.Therefore, the objective of the current study is to characterize genomic regions associated with AND and SKA based on imputed whole-genome sequencing (iWGS) data of LR and LW populations. The SNP chip genotypes of phenotyped animals for AND and SKA were imputed based on a subset of 57 animals with WGS data. These reference animals were carefully selected in a combined haplotype- and pedigree-based approach within the framework of a project aiming to improve survivability and immunocompetence. The WGS data originated from the project pigFit (supported by funds of the German Government's Special Purpose Fund held at Landwirtschaftliche Rentenbank; FKZ28-RZ-3-72.038). Animals are assumed to capture the genetic structure of the LR and LW populations.Target regions based on our previous studies and the AnimalQTLdb include SSC5 (21.17 – 24.5 Mb) and SSC6 (53.16 – 81.9 Mb) for AND and SSC7 (71.0 – 75.04 Mb) and SSC14 (140.6 – 141.7 Mb) for SKA. Imputed WGS data enables fine mapping of the regions associated with boar taint compounds. Therefore, a deeper insight into the genomic background of AND and SKA is assumed, and these insights may be incorporated in the genomic selection of boars with reduced boar taint potential.

How Pure is Pure Breeding? A Case Study of a commercial German pig breed

L. Kistner[1], A. Olschewsky[1], L. Vollmer[2], C. Reimer[2], D. Hinrichs[1]
[1] Universität Kassel, Organic Agriculture, Nordbahnhofstraße 1a, 37213 Witzenhausen, Germany, [2] Friedrichstraße Löffler Institut, Farm Animal Genetics, Höltystr. 10, 31535 Neustadt, Germany

Traditional pig breeds, such as the German Edelschwein (DE), are mainly preserved through purebreeding to maintain breed identity. Herdbooks regulate inbreeding, kinship, and crossbreeding. Purebreeding programs may use targeted crossbreeding, but the extent and effects of introgression remain poorly studied. Pedigree-based analyses may underestimate population trends, especially inbreeding, due to incomplete ancestry information, whereas genomic data provide a more independent assessment.The DE breed has been independent since 1904 and, alongside the German Landrace, is a major maternal line in commercial crossbreeding in Germany. As a case study, introgression events in DE were analyzed using pedigree and genomic data. Objectives were (1) to quantify introgression dynamics and population metrics (effective population size (Ne), inbreeding) from pedigree and (2) to assess how well pedigree-based estimates of genetic contributions reflect actual genomic breed composition. The pedigree dataset comprised 77,999 pigs born between 1978 and 2025 after data cleaning. Pedigree analyses used R (optiSel), PEDIG, and POPREP. Genomic data from DE and Large White pigs were evaluated using an Illumina SNP array (~80K markers BeadChip). 234 animals per breed (DE and Large White) born between 2010 and 2023 were available. Genomic characterization was performed via ADMIXTURE analysis and principal component analysis (PCA).For animals born within the last ten years, pedigree completeness was 88.5% in the first generation and 57% by the sixth. The average maximum generation depth was 14.08, with overall completeness of 0.13; the generation interval averaged 2.1 years.DE population size has fluctuated. Between 2005–2007, Ne declined to 562 with inbreeding coefficient F = 0.15. From 2010 onwards, inbreeding increased alongside improved pedigree completeness, suggesting trends may partly reflect data depth. In 2016, Ne peaked at 1,276 with F = 0.03; since then, population size has declined.Pedigree analysis identified 476 animals with parents from different breeds, mainly Large White; 257 crossbreeding individuals were born between 2002–2006. Consequently, 22% of DE exceeded 50% foreign breed proportion in 2006. In the current reference population (n = 2,315), foreign contributions remain in ~30% of animals but each <1%. The PCA of the genotype data shows changes over time that may reflect introgression.These results show that even formally managed purebred populations may contain contributions from other breeds. Classifying animals with up to 50% foreign ancestry as members challenges the concept of genetic purity. The results aim to evaluate whether short-term introgression events may lead to long-term changes in the genetic composition of the DE population and, consequently, raise questions about how much of the original DE genetic background remains.

Local ancestry aware genome-wide association study of dairy traits using both purebred and crossbred data

B. Poulsen[1], H. Liu[1], E. Karaman[1]
[1] Center for Quantitative Genetics and Genomics, C. F. Møllers allé 3, 8000 Aarhus C, Denmark

The availability of phenotypes on crossbred individuals is increasing. These phenotypes can increase the number of observations when a trait can be assumed to be the same in crossbreds and purebreds. The crossbred phenotypes should be analyzed with specialized multi-breed genome-wide association studies (GWAS) and genomic prediction models to account for breed differences in allele frequencies and allele substitution effects. These specialized models are generally referred to as breed-of-origin (BOA) models, and they are linear mixed models that provide estimates of breed-specific marker effects by forming breed-specific model matrices for genomic information using inferred ancestry of each marker allele. Such local ancestry aware models have been shown to improve the accuracy of genomic predictions in cattle and increase the power to identify influential loci in admixed human populations, but they have scarcely been used for GWAS of livestock populations. We hypothesized that combining purebred and crossbred data in a local ancestry aware GWAS improves the statistical power over within-population GWAS. This research question was investigated using phenotypes adjusted for fixed effects for fat, protein, and milk yield in the Nordic breeds for Holstein (N=48,647), Jersey (N=27,503), Red Dairy (N=9,991), and Crossbreds (N=6,517). All animals with adjusted phenotypes had SNP information from 41,238 marker loci. The local ancestries were inferred for crossbred animals using the purebred animals as reference animals. We performed one GWAS for each breed with data from only purebred individuals, and we performed a combined GWAS with data from both purebred and crossbred individuals. The GWAS models were fitted with the Tractor software, where inferred local ancestry is used to decompose each SNP genotype into breed-specific dosages, and breed-specific allele substitution effects are defined as fixed regressions on these dosages. We corrected for multiple tests using the Bonferroni correction with P(<0.05) and for 41,238 tests. In the purebred analyses, we found 8,347-12,289 influential loci for Holstein, 4,672-6,788 for Jersey, and 1,462-4,193 for Red Dairy. For these loci, more than half of the P-values were smaller in the combined analysis than in the purebred analyses (Holstein: 57-60%, Jersey: 71-84%, Red Dairy: 53-72%). Furthermore, the combined analysis found more significant loci than the purebred analyses across all traits (Holstein: 130-175 loci, Jersey: 367-671 loci, Red Dairy: 314-645 loci). This increase may partly reflect the larger sample size in the combined analysis, and further work is needed to separate sample size and model effects. In conclusion, the results indicate that the local ancestry aware GWAS was able to utilize genetic signals in the crossbred data in combination with the purebred data to achieve greater statistical power than the per-breed GWAS with the caveat that the results should be verified on simulated data for certainty.

Genetic Markers Associated with Slaughter Yield in Intensively Fattened Lambs Raised in Latvia

E. Leonova[1], M. Martins[1], D. Malakovska[1], S. Plavina[1], N. Krasnevska[1], J. Paramonovs[1], D. Kairisa[2], N. Paramonova[1], I. Trapina[1]

[1] University of Latvia, Department of Pharmaceutical Sciences, Faculty of Medicine and Life Sciences, Jelgavas street 3, LV-1004 Riga, Latvia, [2] Latvian University of Life Sciences and Technologies, Department of Animal Sciences, Liela street, 2, LV-3001 Jelgava, Latvia

Improving carcass performance is a primary objective in meat sheep production systems, as slaughter yield directly affects farm profitability. Genetic improvement of this trait offers a sustainable approach to enhancing production efficiency in local breeding populations. This study evaluated associations between selected candidate gene polymorphisms and slaughter yield in intensively fattened lambs raised in Latvia. The experimental group consisted of 160 lambs, including 59.5% Latvian Dark-Head animals, managed under standardized feeding and housing conditions. Slaughter yield averaged 44.45 ± 2.52% and was recorded at 149.65 ± 14.26 days of age. Fifty-seven SNPs across eight biologically relevant candidate genes were genotyped. Association and regression analyses identified 23 SNPs (40.35%) significantly related to slaughter yield. The strongest associations were observed for variants in the UPC2 and MTOR genes. For UPC2, lambs homozygous for the common allele demonstrated higher slaughter yield, although this genotype occurred at low frequency. In the MTOR gene, superior performance was observed in both homozygous common and heterozygous genotypes, which together represented approximately 25% of the population. These findings indicate that specific genomic variants may be incorporated into breeding strategies aimed at improving carcass efficiency in Latvian sheep populations. The results provide a foundation for marker-assisted selection targeting economically important production traits. Acknowledgements: This study was supported by the University of Latvia Postdoctoral Project No. 1.1.1.9/LZP/1/24/027 and by the Latvian Council of Science, Latvia, project No. LZP-2021/1-0489.

Semen Cryopreservation as a Conservation Strategy for the Native Species Salmo ghigii in Sardinia: Results on Fertilization and Embryonic Development

F. Chessa[1], F. Curreli[3], L. Mara[1], I. Cossu[1], A. Sabattini[2], P. Casula[3]
[1] Agris, Animal Reproduction, SS 291 Km 18,600, 07100 Sassari, Italy, [2] University of Cagliari, Department of Life and Environmental Science, Via T. Fiorelli 1, 09126 Cagliari, Italy, [3] Forestas, Servizio Tecnico, Viale Merello n. 86, 09123 Cagliari, Italy

The Mediterranean trout (Salmo ghigii) represents one of the most vulnerable native salmonids in Southern Europe, severely threatened in Sardinia by extensive introgressive hybridization with non-native domestic strains. Conservation programs rely on supportive breeding of genetically validated wild spawners; however, reproductive asynchrony among breeders frequently limits fertilization success and reduces effective population management. In this context, semen cryopreservation may represent a strategic tool to decouple gamete availability and enhance long-term genetic conservation. During the 2024–2025 reproductive season, semen was collected from three wild males, pooled to maximize genetic representation, diluted (1:4) in Fish Freezing Medium, and cryopreserved in 0.25 ml straws using a controlled-rate freezing protocol (–13.6°C/min to –140°C). Post-thaw sperm quality parameters were compatible with fertilization, with total motility ranging from 16–22% and progressive motility from 10.7–16.2%. In the subsequent 2025–2026 breeding season, eggs from sixteen genetically confirmed females were equally divided and fertilized using either fresh or cryopreserved semen under standardized hatchery conditions. A total of 1069 eggs were fertilized with fresh semen and 1127 with cryopreserved semen. Embryo survival to release reached 830/1069 (77.6%) in the fresh group and 422/1127 (37.4%) in the cryopreserved group, while embryo mortality was 3.4% and 8.3%, respectively. Statistical analysis (Welch's t-test) showed no significant differences between treatments in fertilized egg number or mortality rate ($p > 0.05$). Conversely, viable embryo output and survival percentage were significantly higher in the fresh semen group ($p = 0.0017$ and $p < 0.001$, respectively), confirming a measurable efficiency gap between treatments. Despite the reduced performance of cryopreserved semen, it generated 422 viable juveniles, contributing to the release of 1252 individuals into native habitats. These results demonstrate that semen cryobanking, although less efficient than fresh fertilization, provides a substantial and operationally reliable contribution to recruitment, reduces the need for prolonged broodstock maintenance, and enhances flexibility in genetic management strategies. Overall, cryopreservation emerges as a robust complementary conservation tool capable of mitigating reproductive asynchrony and strengthening long-term preservation efforts for S. ghigii in Sardinia.

Characterization of Missense Mutations in Acute Phase Proteins in a Cellular Model for Chicken Amyloid Arthropathy

N. F. Paul[1], E. Maier[1], J. Tetens[1,2], C. Falker-Gieske[1,2]
[1] Georg-August-University, DNTW, Functional Breeding, Burckhardtweg 2, 37077 Göttingen, Germany, [2] Georg-August-University, Center for Integrated Breeding Research, Albrecht-Thaer-Weg 3, 37075 Göttingen, Germany

Amyloid arthropathy (AA) in laying hens is a form of amyloidosis characterized by deposition of amyloid in large joints, which consists mainly of Serum Amyloid A (SAA). The disease is induced by bacterial infection, most frequently by Enterococcus faecalis (E. faecalis), which is the most frequent isolate in field cases and a major multidrug-resistant poultry pathogen. Brown-egg-laying hens (BL) are affected, whereas white-egg-laying hens (WL) appear resistant, with a line-specific immune system (cell-mediated in WL vs humoral in BL). We identified and functionally characterized a dysfunctional missense mutation in SAA (SAA.R90S) in WL, and we discovered six associated missense variants in the fibrinogen alpha chain (FGA) gene in BL. While SAA is a key driver of AA, fibrinogen has not previously been implicated, despite being amyloidogenic and capable of binding free SAA to promote amyloid formation. We therefore investigated whether SAA and FGA variants affect cellular programs relevant to AA. Stable cell lines overexpressing SAA.WT, SAA.R90S or empty vector control were co-transfected with fibrinogen subunits (FGA.WT or FGA.MUT [carries six missense mutations], FGB, FGG) co-expressing distinct fluorophores via P2A. Triple-positive cells were FACS-isolated to obtain cell populations that express the fully functional fibrinogen complex. These cells were then subjected to RNA-sequencing for differential gene expression analysis. Reads were aligned to the reference genome, followed by differential gene expression and gene set enrichment analysis (GSEA) using R (DESeq2, clusterProfiler). FGA overexpression (MUT vs Cntrl or WT vs Cntrl) elicited hundreds of shared differentially expressed genes (DEGs) across SAA backgrounds (435 for FGA.MUT, 458 for FGA.WT), reflecting metabolic stress and cellular stress responses (oxidative phosphorylation, ribosome, peroxisome, DNA replication). Venn diagrams further revealed SAA variant-specific signatures, with a stronger effect of SAA.WT on overall gene expression (129 vs 40 for SAA.R90S), enriched for developmental and regulatory pathways, including TGF-β signalling, cell cycle, and Hedgehog signalling. In contrast, SAA.R90S preferentially enriched proteasome and MAPK signalling, and integrin/ECM-related pathways, consistent with activation of protein quality control and enhanced stress adaptation. FGA.WT and FGA.MUT induced largely overlapping transcriptional programs across SAA backgrounds, with only minimal differential gene expression between variants. These findings indicate that SAA variants qualitatively shape the amyloid-relevant cellular response, while FGA variants amplify metabolic stress, supporting genetic contributions to line-specific AA susceptibility. Complementary proteomic studies are planned to dissect context-dependent SAA-fibrinogen interactions driving disease.

De-novo assembly of a high-quality, haplotype-resolved genome assembly for the Ugandan Ankole cattle

R. Okwasiimire[1,2], M. Weldenegodguad[2], M. Makgahlela[5], N. Ghanem[6], C. Ginja[7], R. Crooijmans[4], D. Kugonza[3], J. Kantanen[2], K. Pokharel[2], P. Uimari[1]

Cairo, Egypt, [7] Universidade do Porto, CIBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, Vairão, Portugal, . Vairão, Portugal

The Ankole is a long-horned Sanga cattle breed (Bos indicus africanus) native to Uganda and widely distributed across sub-Saharan Africa and beyond. It is valued for disease and parasite tolerance, adaptation to the harsh tropical environment and unique cultural significance. The ARS-UCD2.0 cattle reference genome is based on a Hereford cow (Bos taurus taurus), and introduces reference bias in indicine cattle studies. To better understand the distinctive features of the Ankole, we generated a haplotype-resolved assembly (PacBio HiFi + Hi-C) to improve discovery of previously unresolved variants of this breed. PacBio SMRTbell and Dovetail Omni-C libraries were prepared from genomic DNA and sequenced on PacBio-Sequel (~67X) and Illumina-HiSeqX (~30X) platforms respectively. Draft assemblies were created with Hifiasm, cleaned with blobtools2, and haplotigs removed with purge_dups3, to produce two haplotype assemblies that were scaffolded with Omni-C reads using HiRise and super-scaffolded using PAFScaff. Assembly quality was assessed using BUSCO with eukaryota_odb12 data. For validation, whole genome sequence reads from 19 Ankole cattle were mapped to 29 autosomes of each haplotype assembly and the reference genome using BWA. Mapping rate was normalized by assembly length and compared with paired t-test. Variants were called using Deepvariant, summarized with bcftools and compared with the Wilcoxon signed-rank test. Haplotype-resolved assembly sizes were 3.20 Gb (963 scaffolds, contig N50: 68 Mb, scaffold N50: 75 Mb) for haplotype1 (H1) and 2.99 Gb (887 scaffolds, contig N50: 67 Mb, scaffold N50: 86 Mb) for haplotype2 (H2). Respective BUSCO completeness was 98.4% and 97.7% with GC content of 43.86% and 43.9%. Reference-guided anchoring and scaffolding yielded 30 super-scaffolds for each assembly (H1:2.81 Gb, scaffold N50:108.84 Mb and H2:2.60 Gb, scaffold N50:108.11 Mb) corresponding to 29 autosomes and sex chromosomes (H1:X, H2:Y). Mapping results showed significantly higher normalized read density when aligning to the H1/H2 assemblies compared to the reference (H1/Ref: +21,835 reads/Mb, p-value (p): 9.48×10^{-22}, H2/Ref: +23,412 reads/Mb, p: 7.55×10^{-22}). Additionally, H2 presented significantly higher read density than H1 (+1,576 reads/Mb, p: 9.48×10^{-20}). Variant discovery significantly improved relative to the reference with H1/H2 detecting more high-quality SNPs (H1/Ref: + 165012, $p = 3.78\times10^{-3}$, H2/Ref: +233441, $p = 7.63\times10^{-6}$, H2/H1: +68428, $p = 4.82\times10^{-2}$) and less INDELs (H1/Ref: -102108, $p = 5.35\times10^{-11}$; H2/Ref: -95316, $p = 7.63\times10^{-6}$). Both haplotype assemblies showed increased alignment relative to the reference assembly, with Hap2 presenting superior mapping and variant detection rate than Hap1. The assembled haplotype-resolved Sanga genomes enhance variant recovery, reduce reference bias and capture structural variation more effectively than the reference fostering studies on adaptation, resilience, and the genetic improvement of native African cattle.

Influence of genetics and rumen microbiome on bovine milk vitamin B2 and B12

A. J. Buitenhuis[1], L. E. Rodrigues[2], N. A. Poulsen[3], C. W. Heegaard[4], G. Gebreyesus[1]
[1] Aarhus University, Center of Quantitative Genetics and Genomics, C.F. Møllers Alle 3, DK-8000 Aarhus C, Denmark, [2] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 15, DK-1870 Fredriksberg C, Denmark, [3] Aarhus University, Department of Food Science, Agro Food Park 48, DK-8200 Aarhus N, Denmark, [4] Aarhus University, Department of Molecular Biology and Genetics, Universitetsbyen 81, DK-8000 Aarhus C, Denmark

Bovine milk is a key source of essential nutrients, providing all 13 known vitamins, including riboflavin (B2) and cobalamin (B12), which are vital for numerous biochemical processes. Because humans cannot produce these vitamins in sufficient amounts, they must be obtained through the diet, and inadequate intake can lead to various health problems. Vitamin B_2 in dairy cows originates from both dietary intake and ruminal microbial synthesis by bacteria, fungi, and protozoa, though much is modified in the rumen before absorption in the proximal jejunum via specific transporters. Vitamin B_{12}, in contrast, is synthesized exclusively by rumen microbes through a cobalt-dependent pathway involving B_{12}-producing bacteria and archaea. The hypothesis is that both host genetics and rumen microbiome composition contribute to variation in milk vitamin B_2 and B_{12} levels, with genetics expected to have significant influence. Microbial effects are anticipated to be stronger for vitamin B_{12}, as it is exclusively synthesized by rumen bacteria, whereas vitamin B_2 has both dietary and microbial origins. Vitamin B2 and vitamin B12 content were determined in 281 milk samples of Holstein cows from 3 commercial farms. These cows were genotyped (37,458 SNP markers available after filtering), and the rumen microbial composition was determined using 16S rRNA sequencing. Vitamin concentrations were transformed (square root for B_2, $\log_{10}$ for B_{12}) for normality. Mixed models estimated heritability and microbiability, with parity and days in milk (DIM) included as fixed effects, and G-matrix and M-matrix as random factors. The study evaluated predictive models using genetic, microbial, and combined data. Results showed moderate heritability for B2 (0.45 SE: 0.19) and B12 (0.37 SE: 0.22), indicating substantial genetic control. Microbiability was negligible for B2 (0.00 SE: 0.04) but modest for B12 (0.09 SE: 0.06), reflecting its microbial synthesis in the rumen. Prediction accuracy of milk vitamin B2 content based on the full model resulted in: GEBV: 0.58 and MEBV 0.51, whereas prediction accuracy of milk vitamin B12 content resulted in: GEBV: 0.68 and MEBV: 0.60. Preliminary results show that genetics plays a role in vitamin B2 and B12 content of bovine milk, and that the rumen microbiome has a larger influence on B12 compared to vitamin B2 as expected according to scientific literature.

Near teleomere-to-telomere assemblies of Swedish commercial dairy cattle breeds, Swedish red- and white, Holstein and Jersey

A. E. Lundberg[1], T. Vanhala[1], T. Klingström[1]
[1] Swedish University of Agricultural Sciences, Department of Animal Biosciences, VHC, Ulls väg 26, S-750 07 Uppsala, Sweden

The creation of reference-quality genome assemblies based on long-read platforms is now so cost-effective breed-based reference assemblies are now feasible. For this project family trios of Swedish Red and White, Holstein (with a small proportion of Swedish lowland cattle) and Jersey were sequenced with the goal of trio-binning based de novo assembly. This makes it possible to partition long reads from an offspring into haplotype-specific sets. Each haplotype is then assembled independently, resulting in a complete diploid reconstruction. Recent advances in long-read sequencing technologies have made it possible to generate near telomere-to-telomere (T2T) assemblies, although highly repetitive genomic regions still present challenges. The objective of this study was to evaluate long-read sequencing strategies for generating highly contiguous de novo genome assemblies of Swedish dairy cattle. Family trios representing the Swedish Red and White, Holstein and Jersey breeds were sequenced using PacBio Revio and Oxford Nanopore PromethION. The daughters were sequenced on the PacBio Revio platform across multiple SMRT cells, generating more than 100 Gb of HiFi reads per individual, while each parent was sequenced to approximately 60 Gb. De novo assemblies were generated using the trio-aware assembler Hifiasm version 0.25.0, producing several graph genome assemblies using different combinations of HiFi and ONT ultra-long read data, with the largest contig reaching 160 Mb, corresponding to chromosome 1. The total assembly size for the Swedish Red and White genome was approximately 3.1 Gb. This assembly consisted of approximately 1,100 contigs, with a k-mer quality score of 61 and a BUSCO completeness score of 98% for single-copy genes (0.73% duplicated genes) using the Artiodactyla dataset. To further evaluate assembly completeness, satellite repeat structure was analysed with a focus on centromeric and telomeric regions. Given the acrocentric structure of Bos taurus autosomes, repeat analyses show chromosomes remain T2T-like rather than fully telomere-to-telomere assembled. In addition, daughters were sequenced on the Oxford Nanopore PromethION platform, generating approximately 90 Gb of ultra-long reads for Swedish Red and White cattle 44 for Holstein and 51 for Jerse, Ultra-long reads (>100 kb) represented 916 Mb, 442 Mb, and 511 Mb for Swedish Red and White cattle, Holstein and Jersey respectively. Reads exceeding 300 kb comprised ~6 Mb in Swedish Red and White cattle but ~1 Mb in Holstein, indicating a substantially stronger ultra-long tail in the former dataset. These results demonstrate that current long-read sequencing strategies combined with modern assemblers such as Hifiasm can produce highly contiguous cattle genome assemblies approaching T2T quality, providing access to streamlined bioinformatics software able to generate improved genomic resources for dairy cattle research. The inclusion of Ultra Long read-data from the Oxford Nanopore will further improve the assemblies but are only likely to increase completeness by providing scaffolding in long repetitive regions. In the next step graph genomes by the addition of 8 individuals each of each breed with raw yields of 36 to 71 Gbp generated by Pacbio Revio.

Accuracy of Genomically Enhanced Breeding Values in South African Holstein Cattle for Milk Production Traits

K. Mafolo[1,2], F. Neser[1], E. Cason[1], D. Vermeulen[1], M. Macneil[1,2,3], M. Makgahlela[1,2]
[1] University of the Free State, Animal Science, PO Box 339, 9301 Bloemfontein, South Africa, [2] Agricultural Research Council, Animal Breeding and Genetics, Private Bag X2, 0062 Irene, South Africa, [3] Delta G, MT 59301, 59301 Miles City, United States

Genomically enhanced breeding values (GEBVs) derived from single-nucleotide polymorphism (SNP) markers can be estimated for animals without phenotypes. However, there is a low prediction accuracy in South Africa Holstein cattle due to the limited number of genotyped animals, furthermore, little is known about how the size of the validation population affects GEBV reliability. Therefore, the objective of this study was to evaluate the accuracy of GEBVs in SA Holstein cattle. The dataset consisted of lactation records of 354 228 Holstein cows and 541 325 pedigree records. Each cow could have up to three lactations in the dataset. Only 1 473 of these cattle were genotyped using the Illumina 50K v3 SNP chip. Breeding values for milk, protein, and fat yields, as well as protein and fat percentages were estimated using pedigree-based best linear unbiased prediction (PBLUP) and single-step genomic BLUP (ssGBLUP). Prediction accuracy was assessed as the mean of individual accuracies calculated from the prediction error variance, by excluding phenotypic records from two groups of animals consisting of the youngest genotyped individuals. The prediction accuracy for PBLUP ranged from 0.28 to 0.30 for milk yield, 0.26 to 0.29 for protein yield, and 0.27 to 0.29 for fat yield, whereas protein percentage ranged from 0.33 to 0.35 and fat percentage from 0.34 to 0.37. For ssGBLUP, accuracy for milk yield ranged from 0.58 to 0.61, for protein yield from 0.56 to 0.60, and for fat yield from 0.57 to 0.61. Furthermore, protein percentage ranged from 0.65 to 0.68, and fat percentage from 0.68 to 0.70. In conclusion, the inclusion of genomic information improves the accuracy of GEBVs relative to the use of pedigree information alone. Consequently, the size of the validation population strongly influences prediction accuracy, highlighting the need for larger genotyped reference populations in South African Holstein cattle.

Comparison of genomic evaluation models on simulated crossbred dairy cattle populations

C. A. Cunha Cambraia[1,2], P. Croiseau[1], D. Boichard[1], S. Fritz[1,3], A. A. Martin[1,3]
[1] Université Paris-Saclay, INRAE, AgroParisTech, GABI, Allée de Vilvert, 78350 Jouy-en-Josas, France, [2] Universidade Federal de Minas Gerais, Avenida Antônio Carlos, 6627 Pampulha, Belo Horizonte, Brazil, [3] Eliance, 149 Rue de Bercy, 75595 Paris Cedex 12, France

The use of crossbreeding in dairy cattle has gradually increased, reflecting breeders' interest in adopting new strategies to address current challenges in the dairy industry. However, the development of genomic predictions for crossbred populations was hindered due to limited data availability and the lack of adapted methodological tools. In France, the TransEvagenoc project, funded by APIS-GENE, aimed at developing genomic evaluation methods for crossbred dairy cattle. The objective of this study was to evaluate, using simulation, the relative performance of four genomic evaluation strategies in crossbred dairy cattle, to provide guidance on their implementation according to the available phenotypic data in crossbreds. Four methodological options were considered: (i) applying the ssGBLUP method as developed for pure breeds assuming the same SNP effects across breeds of origin, (ii) applying SNP effects estimated in each pure breed to crossbred genotypes using breed-of-origin of alleles information, (iii) adapting purebred SNP effects by incorporating crossbred information, and (iv) estimating SNP effects directly from crossbred genotypes and performances. The accuracy of models (iii) and (iv) was assessed regarding the number of crossbred information. Three simulated populations representing dairy breeds were generated using the AlphaSimR package. Five traits were simulated with genetic parameters resembling milk yield, fat yield, protein yield, somatic cell score, and interval calving to first service. Each breed underwent ten generations of selection with different trait weightings to create breed-specific trait strengths and linkage disequilibrium patterns. The simulated genome consisted of six chromosomes with 10,000 segregating sites, and 500 QTL with effects drawn from a Poisson distribution. Purebred lines were maintained under selection for ten additional generations, and a subset of purebred animals was used to supply a three-breed rotational crossbreeding system. In each generation, new F1 females were produced and introduced into the rotation, whereas crossbred females were mated to sires from a different pure breed in a rotational sequence. This design generated a continuum of crossbred individuals with varying breed contributions over ten generations. Population sizes were defined according to different scenarios, based on the targeted number of crossbred individuals made available for the genomic evaluation. Realistic genotypes and phenotypes were simulated for individuals from generations 10 to 20 and used to perform genomic evaluations. For each method, genomic prediction accuracy, i.e. correlation between true and estimated breeding values, were evaluated across increasing crossbred reference population sizes. Accuracy curves were compared to identify the most efficient strategy under different data availability scenarios. The results provide practical guidance for breeding organizations regarding the level of crossbred genotyping effort required to justify the implementation of the more advanced genomic evaluation methodologies.

Unknown Parent Groups in Turkish Holsteins: Metafounders Approach

A. Kasakolu[1,5], M. Yıldırır[2], O. Yiğit[3], F. G. Mızrak[2], E. Ünay[4], S. Koncagül[5]
[1] Ankara University, Graduate School of Natural and Applied Sciences, Faculty of Agriculture, 06110 Ankara, Turkey, [2] International Center for Livestock Research and Training, International Center for Livestock Research and Training, Ministry of Agriculture, 06800 Ankara, Turkey, [3] Cattle Breeders' Association of Türkiye, Cattle Breeders Association of Türkiye, Cattle Breeders Association of Türkiye, 06510 Ankara, Turkey, [4] Ministry of Agriculture and Forestry, General Directorate of Livestock, General Directorate of Livestock, 06800 Ankara, Turkey, [5] Ankara University, Department of Animal Science, Faculty of Agriculture, 06110 Ankara, Turkey

In the genomics era, the management of missing parental information can present significant challenges, particularly in cases involving so-called 'phantom parents' (Unknown Parent Groups; UPGs). The metafounders (MF) approach was developed, seeing UPGs as a group of interconnected bases and recognising that there could be more than one. If there are multiple relationships, the definition of relationships is done using a Gamma matrix (Γ), where diagonal elements correspond to self-relationships and off-diagonal elements amongst them. The objective of this study was to evaluate the effect of different MF grouping strategies on genomic breeding value predictions for lactation milk yield and calving interval in Holstein cattle. In the present report, a total of 11055 Holstein genotyped with 71639 variants. The pedigrees contain 234162 animals, of which 93601 and 53831 have observations of first 305-day lactation milk yield (LMY) and first calving interval (CI) records, respectively. To eliminate missing parent effects, two different grouping strategies were tested. Firstly (S1), missing parents were identified, using "Bpop", as belonging to six bases based on their origins (TR, US and others), and sex. The second strategy (S2) involved combining the previous definitions and separating the groups by considering different time spans (n = 17). The models were selected as ABLUP, ssGBLUP and ssGBLUP-MF with respect to univariate and bivariate models, conducted with "BLUPF90+". For MF models, genetic variance-covariance components were scaled, and predictions of each model were considered with consistency (ρ), bias, dispersion (β_1) and accuracy (acc) to evaluate MF effects with the focal group (born in 2018 – 2022 time span, both genotyped and phenotyped cows). The inbreeding levels of defined MFs range between 0.455 and 0.498 for Γs_1 and 0.455 to 1.997 Γs2, respectively. Among relationships of groups were observed as 0.400 – 0.460 range for Γs_1 and -0.447 – 0.904 range for Γs2, respectively. In addition, the validation results showed that ssGBLUP models provided more consistent and accurate breeding value predictions than the ABLUP model for LMY. The minimum ρ and acc were 0.86 and 0.52, respectively, for ssGBLUP models and 0.79 and 0.46, respectively, for the ABLUP model. All models exhibited slight bias (maximum of 80 kg and 0.14 days for LMY and CI, respectively) and some dispersion ($0.88 \leq \beta_1 \leq 1.00$). Based on these findings, ssGBLUP, particularly when combined with the MF approach, is recommended for routine evaluation of Holstein cattle populations affected by missing parental information. In particular, the grouping of unknown parents by both origin, sex, and time period may better capture differences among base populations, although the wider range of relationships observed in the more detailed grouping strategy suggests that careful definition of MF groups is essential. Further work is needed to optimise the definition of MF groups and to assess their usefulness for other economically important traits.

Combining sustainable poultry farming and meat quality: Insights from the intaqt project

C. Berri[1], L. Darrigade[1], M. Bourin[2], E. Baéza[1], R. Eppenstein[3], M. Petracci[4], S. De Smet[5]
[1] INRAE, Université de Tours, BOA, 37380 Nouzilly, France, [2] ITAVI, L'Orfrasière, 37380 Nouzilly, France, [3] FiBL, Ackerstrasse 113, 5070 FRICK, Switzerland, [4] University of Bologna, Piazza Goidanich 60, 47521 Cesena, Italy, [5] Ghent University, Coupure Links 653, 9000 Gent, Belgium

Chicken production and consumption today occupy a central role in global food systems. Poultry has become the most produced and consumed meat, with chicken representing nearly 90% of this production. The sector largely relies on intensive systems using fast-growing strains, which offer high technical and economic efficiency and allow the production of large volumes at low cost. However, in Europe, societal expectations regarding animal welfare, product quality, transparency, and sustainability are driving an increasing diversification of farming systems, with the development of more extensive models, lower stocking densities, and slower-growing strains. In this context, the European Horizon 2020 project INTAQT aims to better understand the relationships between farming practices and the intrinsic qualities of animal products, particularly chicken meat. The project follows an integrated approach combining the characterization of farming systems, multi-criteria evaluation of product quality (nutritional, sensory, technological, and safety aspects), and the development of authentication and traceability tools. The project is based on a network of 90 farms across five European countries (France, Italy, Belgium, Switzerland, and Poland), covering a broad continuum of systems, from the most extensive to the most intensive. The results show that the farming system strongly influences several dimensions of chicken meat quality. Intensification, notably through the use of fast-growing strains such as Ross 308, increases breast yield but also alters meat composition, with higher lipid content and lower protein levels. Concentrations of bioactive dipeptides, such as anserine and carnosine, recognized for their antioxidant properties and potential benefits for human health, also decrease as animal growth rate increases. Intensification also affects certain technological and sensory properties of the meat. Breast fillets from intensive systems generally exhibit higher water losses both raw and cooked, which can impact product appearance and processing suitability. Furthermore, the frequency and severity of muscular defects, such as white striping, wooden breast, or spaghetti meat, increase in systems using fast-growing strains, particularly for animals slaughtered at higher weights. Conversely, systems with more moderate growth rates appear to maintain good nutritional, technological, and sensory quality. The results indicate that an average daily gain below 50 g/day offers a favorable compromise between production performance and product quality. More broadly, the INTAQT project highlights the interactions between product quality, environmental sustainability, and animal welfare. It provides valuable insights to guide the evolution of production systems toward models that balance meat quality, sustainability, and economic competitiveness, in line with the "One Quality" concept.

Nutritional outcomes of high-intensity broiler farming with regard to amino acid patterns and protein digestion efficiency

V. Santé-Lhoutellier[1], L. Aubry[1], C. Selebran[1], V. Lopez[1,1], V. Lopez[1,1], L. Darrigade[2], S. De Smet[3], M. Petracci[4], R. Eppenstein[5], A. Travel[6], C. Berri[2]

Meat is widely recognized as a valuable source of high-quality protein and essential amino acids, unlike most plant-based foods, which require combination to achieve a complete amino acid profile. Among animal products, broiler chicken breast is particularly rich in protein. However, the genetic selection for fast growth in modern broiler lines has led to the emergence of muscle abnormalities such as wooden breast, white striping, and spaghetti meat, which are associated with deteriorated meat sensory, technological and nutritional quality. Within the framework of the H2020 INTAQT project, we assessed the quality of chicken breast meat from 32 farms representative of six poultry production systems in Europe. These systems vary by growth rate, slaughter age and weight, and access to outdoor areas: Indoor_Fast_Heavy, Indoor_Fast, Outdoor_Fast_Heavy, Outdoor_Medium, and Outdoor_Slow—the latter including Label Rouge and male layer hybrids. In addition to standard sensory, technological, nutritional, and sanitary assessments, our study focused on protein digestibility and amino acid composition. Breast meat samples were minced, cooked to 70 °C core temperature, and subjected to in vitro digestion. Protein content was measured before and after digestion; small and large peptides were quantified via the Kjeldahl method, and free amino acids were analyzed using HPLC. The lowest protein content and digestibility were found in meat from the Indoor_Fast_Heavy system, characterized by the highest daily weight gain (>60 g/day) and slaughter weights of 2.6–2.8 kg. Essential amino acid content was higher in meat from broiler raised in systems Outdoor_Medium (56 days) and up to 80 days than those raised in system Indoor_Fast (35 days). Leucine levels, crucial for muscle protein synthesis, were significantly higher in all systems compared to Indoor_Fast_Heavy. Arginine, histidine, and tryptophan release during digestion was also consistently lower in samples from the most intensive system. Whatever the farming practices, the sum of essential amino acids meat containing did not differ. But for specific EAA, slight differences are noticed in particular for tryptophan and histidine, which is in line with the reduced availability observed after digestion. These findings underscore the significant influence of production systems on the nutritional quality of chicken meat, particularly in terms of amino acid profiles, and raise concerns about the impact of intensive farming practices based on fast-growing genotypes. The dataset will be further enriched with complementary quality indicators, including the incidence of breast muscle myopathies, to investigate potential links between meat nutritional value and the prevalence of these muscle disorders.

Effect of outdoor enrichment and dietary supplementation with n-3 fatty acid precursors and antioxidants on meat quality of free-range chickens

M. Bordini[1], A. Cartoni Mancinelli[1], E. L. Antenucci[1], M. A. Gagliano[1], F. Soglia[1], A. Dal Bosco[2], M. Petracci[1]
[1] Alma Mater Studiorum University of Bologna, Department Agricultural and Food Sciences, Piazza Goidanich 60, 47521 Cesena, Italy, [2] University of Perugia, Department of Agricultural, Environmental, and Food Sciences, Borgo XX Giugno 74, 06121 Perugia, Italy

Growing consumer interest in animal welfare and product quality is increasing demand for products from less intensive farming systems. In poultry, dietary strategies such as supplementation with n-3 fatty acid precursors can enhance meat nutritional value. In outdoor systems, enriched pastures (e.g., grass and trees) promote locomotor activity and grass intake, facilitating the transfer of bioactive compounds into the meat. However, increased activity and higher n-3 PUFA levels may enhance oxidative processes, potentially affecting meat quality, particularly in thigh muscles, which are lipid-rich and highly involved in movement. The aim of this study was to assess the combined effects of outdoor enrichments and dietary supplementation with n-3 PUFA and antioxidants on the quality attributes and oxidative stability of thigh meat from free-range reared chickens. Four commercial chicken farms using males of a slower-growing genotype were considered in the study: two farms showing the outdoor area without pasture (NP), and two with the outdoor area enriched with grass and trees (GT). On each farm, two pens (20,000 birds each) were assigned to either a control (C) or a supplemented diet (S; 5% linseed, vitamin E and selenium). Birds were slaughtered at 56 d of age. Thigh samples were collected to assess the main meat quality traits (i.e., pHu and colour) (n=120; 15/group) and oxidative status (TBARS and carbonyl content; n=64; 8/group) after 0, 3, and 7 d of refrigerated storage (4°C). Data were analyzed by two-way ANOVA, including the outdoor enrichment and the diet, as well as their interaction in the model. The differences observed on fresh meat (0 d of storage) indicated that the outdoor enrichment have played a more prominent effect than the dietary treatment on meat characteristics. In particular, higher pHu as well as lower lightness were observed in GT samples compared to NP (6.11 vs. 5.92; $p<0.001$ and 53.6 vs. 54.8; $p<0.001$, respectively). During refrigerated storage, oxidative processes affected both the lipid and the protein fractions, regardless of pasture type and diet. In detail, the highest TBARS values observed in the GT-S group at d 0 (1.70 mg MDA/kg meat; $p<0.05$) may be attributed to the combined effect of increased locomotor activity in the birds belonging to this group that, concurrently, had higher n-3 PUFA levels in the meat (data not shown). In fact, long-chain n-3 PUFA are very susceptible to peroxidation due to their chemical structure. In the present study, GT-C group showed the highest level of carbonyls at 3 d of storage (6.69 nmol/mg of protein; $p<0.05$). This can be mainly ascribed to the high locomotor activity of birds fed the C diet, which did not receive antioxidants supplementation. In fact, it is likely that the antioxidant content of the C diet was not sufficient to mitigate the oxidation process triggered by the increased movement. In conclusion, dietary enrichment with n-3 PUFA and antioxidants can differently affect chicken meat quality depending on the presence of grass and trees, which may enhance animal movement and promote muscle oxidative processes. This study is part of the INTAQT Horizon 2020 project, which aims to establish a link between husbandry systems and the intrinsic quality of animal products.

Identifying farming practices associated with beef fatty acids, trace minerals and antioxidants across European production systems

A. Mouhanna[1], J. Hocquette[2], B. Martin[2], N. Amalfitano[3], R. Eppenstein[4], N. Scollan[5], M. Estévez[6], I. Legrand[7], S. De Smet[1]

[1] UGent, Coupure Links 653, 9000 Ghent, Belgium, [2] INRAE, UMR Herbivores, 63122 St-Genès Champanelle, France, [3] Padova University, Viale dell'Università 16, 35020 Legnaro, Italy, [4] FiBL, Ackerstrasse 113, 5070 Frick, Switzerland, [5] Queen's University Belfast, Chlorine Gardens 19, BT9 5DL Belfast, United Kingdom, [6] University of Extremadura, Avenida de la Universidad s/n, 10003 Cáceres, Spain, [7] Institut de l'Elevage, Boulevard des Arcades, 87060 Limoges Cedex 2, France

This study investigated the relationship between combinations of farming practices and variation in multiple classes of nutritional traits in beef, including fatty acids (FA), trace minerals (TM), and antioxidant compounds (AO), across diverse European production systems under commercial conditions. During two slaughter periods, samples of the Longissimus lumborum muscle were collected from 489 animals originating from 53 farms across five European countries, representing a broad production-intensity gradient. The samples were pooled by farm and slaughter period, resulting in 99 observations. Farm data were obtained via structured questionnaires and comprised 33 features describing diet, herd composition, management, and land use. A machine-learning framework combining optimized Random Forest models and Conditional Inference Trees was used to identify farming features associated with variation in beef nutritional traits. The composition of polyunsaturated FA (PUFA) showed high predictability and clear system-level patterns: n-3 PUFA were associated with grass-based diets, dual-purpose breeds, and longer finishing durations, consistent with low-input agroecological production contexts. Conversely, n-6 PUFA were associated with high concentrate use and short indoor finishing periods, which is consistent with high-input, intensive production contexts. Predictability was lower for saturated and monounsaturated FA. TM and AO traits differed in their responsiveness to farming practices. Higher concentrations of iron and heme iron were associated with heavier slaughter weights and reflected a muscle oxidative metabolic type at slaughter, which was found in low-input, slow-growing systems. In contrast, Se and Zn exhibited low predictability. The content of the bioactive dipeptide compound carnosine was associated with farming practices reflecting breed composition and finishing strategy, with the highest concentrations found in low-input fattening systems containing higher proportions of dual-purpose breeds. Anserine and α-tocopherol exhibited lower and more variable predictability. Overall, FA traits were primarily associated with feeding-related lipid metabolism, as expected. AO and TM traits reflected broader muscle metabolic characteristics associated with the structure of the production system. Traits with weaker system-level predictability likely reflect physiological homeostasis or mechanisms not captured by the recorded farm-level practices. This highlights the need to interpret system-level effects through trait-specific biological mechanisms, rather than assuming uniform responses across production system categories.

Occurrence of persistent organic pollutants, mycotoxins and heavy metals in liver of beef in different farming systems

D. Linsler[1], C. Kürbis[2], A. Lueth[2], M. Yamamoto[2], R. Pieper[2], J. F. Hocquette[3], R. Eppenstein[4], B. Martin[3], L. Darrigarde[5], M. Estévez Garcia[6], V. Caballero Fernández[6], P. Mccarron[7], F. Klevenhusen[1]

[1] University of Kassel, Faculty of Organic Agriculture; Section Sustainable Animal Nutrition, Nordbahnhofstr. 1a, 37213 Witzenhausen, Germany, [2] General Federal Institute for Risk Assessment BfR, Max-Dohrn-Str. 8-10, 10589 Berlin, Germany, [3] Clermont-Auvergne University INRAE, VetAgro Sup, UMR12133 Herbivores, 63122 St-Genès-Champanelle, France, [4] Research Institute of Organic Agriculture FiBL, Ackerstr. 113, 5070 Frick, Switzerland, [5] INRAE, Université de Tours, BOA, 37380 Nouzilly, France, [6] Universidad de Extremadura, IPROCAR Research Institute, TECAL Research Group, 10003 Cáceres, Spain, [7] Queen´s University, Institute for Global Food Security, 19 Chlorine Gardens, BT9 5DL Belfast, United Kingdom

The occurrence of contaminants in beef products can be related to cattle feeding, which generally differs among farming systems. Important contaminants in beef liver are polychlorinated dibenzo-p-dioxins (PCDDs) and dibenzofurans (PCDFs), dioxin-like polychlorinated biphenyls (PCBs), perfluorinated alkyl substances (PFAS), heavy metals and mycotoxins. These compounds were investigated in 550 beef liver samples from different farming systems collected from 55 European farms. The farms were categorized in five groups according to the age of the cattle, grazing and the proportion of concentrate feed and maize silage in the diet: Group 1 consists of grazing farms that fatten culled suckler cows (SuC) slaughtered at 90 months. Groups 2 and 3 are fattening young animals with grass-based diets and no or low concentrate feeds slaughtered at 18 (Grass18) and 28 (Grass28) months, respectively. Groups 4 and 5 are young animals (slaughtered at 15 months) that are fattened indoor with diets including medium (IndM) or high proportion (IndH) of concentrates and maize silage, respectively. None of the analysed contaminants exceeded the official maximum limits. The sum of PCDDs/PCDFs and dl-PCBs (expressed as WHO toxicity equivalent using the upperbound concentrations calculated with WHO toxicity equivalence factors 2005) showed significantly higher values for Grass18 (0.12 and 0.79 ng/kg liver, respectively) compared to IndH (PCDDs/PCDFs, 0.04 ng/kg liver) and IndM (dl-PCBs, 0.02 ng/kg liver). From 23 analysed PFAS, only Perfluorodecanoic acid, Perfluoroundecanoic acid (PFUnDA), Perfluororooctanesulfonic acid (PFOS) and Perfluorononanesulfonic acid were detected slightly above the limit of quantification. Significant differences were only found for PFOS and PFUnDA with the highest values for Grass18 (1.21 and 0.06 µg/kg liver, respectively). All of the 31 analysed mycotoxins were detected in low concentrations (<2.1 µg/kg liver) with no clear pattern among treatments. Equally, no clear pattern was found for heavy metals: for Cr there were no significant differences (mean of 20.1 µg/kg liver), for Ni and Pb, the highest values were found in Grass28 (24.7 and 12.8 µg/kg liver, respectively), for As in Grass18 (8.6 µg/kg liver) and for Cd in SuC (79.2 µg/kg liver). Overall, the highest values for the minimal amounts of persistent organic pollutants were found in farms with intensive grassland management and a low input of feed from arable land. Lower values were found in farms with suckler cows, with access to pasture and an extensive grassland management. Therefore, it can be concluded that access to pasture or more extensive green forage–based feeding do not result in an increase in food safety–relevant parameters in meat – at least in areas without known contamination with the above-mentioned contaminants. The study is part of the INTAQT project (funded by EU H2020 101000250).

Linking dairy system, breed, and welfare indicators to infrared-predicted fine milk composition and cheese-making traits in Parmigiano Reggiano cheese production area

N. Amalfitano[1], M. A. Ramirez Mauricio[1], M. Berton[1], D. Giannuzzi[1], L. F. Macedo Mota[1], M. Nocetti[2], S. Pegolo[1], L. Gallo[1], E. Sturaro[1], A. Cecchinato[1]

[1] University of Padova, DAFNAE Department, Viale dell'Università 16, 35020 Legnaro (PD), Italy, [2] Parmigiano Reggiano Cheese Consortium, Via Kennedy 18, 42124 Reggio Emilia (RE), Italy

Milk technological traits result from the interaction among dairy system, genetics, and cow welfare, factors that also shape public perception of product quality and sustainability. Fourier Transform Mid-Infrared (MIR) spectroscopy is a valid and rapid tool for monitoring milk composition and predicting technological traits, yet few studies have evaluated the combined effects of dairy systems and animal welfare (AW) within a single production system. This study investigated the effects of dairy system, breed, and AW scores based on the Italian official AW assessment (CReNBA) on fine milk composition and cheese-making traits predicted by MIR spectroscopy within the Parmigiano Reggiano production area. Data included 2,175,148 test-day records, 1,869,687 MIR spectra, and farm-level and CReNBA data from 983 farms. Clustering based on feeding and housing systems, geographical area, breed (Holstein Friesian – HF, dairy Crossbred – Cr, Brown Swiss – BS, Simmental – Si, Reggiana – Re), milk yield, and herd size identified 4 dairy systems: traditional Apennines (TA), traditional Po Plain (TP), modern without (MWTMR) or with (MTMR) total mixed ration. CReNBA indicators included management (MGT), structure and equipment (SAE), and animal-based measures (ABM), and were classified into low, medium, and high scores according to compliance with AW standards. The predicted traits, i.e. protein and macromineral profiles and cheese-making traits, were obtained using gradient boosting machine learning method developed on an external calibration population (R^2 from 0.58 to 0.88) and analyzed using mixed models with fixed effects of dairy system, breed, AW class, lactation stage, parity, month, and year, and random effects of animal and farm. Breed, dairy system, and their interaction resulted significant for almost all traits, suggesting specific breed attributes and a production context-dependent expression of breed potential. Milk yield increased from traditional to modern systems for all breeds, except Re, which performed better in TP farms. Fat content showed the opposite trend to milk yield, while protein and casein concentrations increased toward modern systems, with breed-specific proportions. Somatic cell count (SCC) was lower in TA farms, but Si showed lower values in TP and Re in MTMR. BS had higher fat, protein, and urea content. Indeed, Re and Si showed higher true protein and casein, with Re performing better in traditional systems and Si in modern ones. Minerals declined to varying extents from traditional to modern systems. Cheese-making traits were improved in modern systems with higher cheese yields and more standardized coagulation, although Si showed better performance in TA. Regarding AW, milk yield was more affected than milk composition, increasing with higher MGT and ABM scores. Higher scores in different areas were associated with higher lactose content and casein index, lower SCC, reduced urea, lower αS2-CN and α-LA, increased mineral content, improved cheese yield (mainly due to greater water retention), and slightly faster coagulation with firmer curd. Overall, breed performance was strongly linked to production context. Albeit to a limited extent, AW influenced fine milk composition and technological traits, confirming the value of routine MIR-based assessments for monitoring dairy herd performance. This research was conducted within the INTAQT project funded by the EU Horizon 2020 programme (grant No. 101000250).

A harmonized methodological framework for multi-criteria assessment of intrinsic quality in EU livestock products

L. Rey-Cadilhac[1], J. Soulat[2], F. Klevenhusen[3], J. F. Hocquette[2], C. Berri[4], B. Martin[2], V. Monteils[2], C. Laurent[2]
[1] PEGASE, INRAE, Institut Agro, 35590 Saint-Gilles, France, [2] Université Clermont Auvergne, INRAE, VetAgro Sup, UMR Herbivores, 63122 Saint-Genès-Champanelle, France, [3] University of Kassel, Faculty of Organic Agricultural Sciences, Environmentally Sustainable Animal Nutrition, 37213 Witzenhausen, Germany, [4] INRAE, Université de Tours, BOA, 37380 Nouzilly, France

Ensuring high-quality livestock products that comply with EU regulations while meeting both industry requirements and consumer expectations remains a major challenge for the livestock supply chain. The EU INTAQT project investigates how farming system intensification affects the potential intrinsic quality of milk, beef, and chicken taking these different expectations into account. This study aimed to develop three harmonized multicriteria assessments of the potential intrinsic quality of milk and meat at the farm gate for UHT milk, beef striploin, and chicken breast final products. A common methodological framework was first established by a scientific working group representing the three product sectors. Four principles, describing specific dimensions of intrinsic quality (nutritional, health, sensory, and technological) were defined, each subdivided into criteria. Conciliations between experts were then conducted to define the structure of the hierarchical assessment tree (indicators → criteria → principles) and the assessment (scoring of indicators, weighting). Theses conciliations were performed separately for each product, except for the safety indicators, which were addressed by a single cross-product expert group. Each conciliation followed a three-step process: (1) Individual elicitation, during which experts selected indicators from the list of indicators assessed in the INTAQT project to define the hierarchical assessment tree, for example; (2) Collective discussion in a three-hour online meeting to synthesize proposals and reach consensus; and (3) Validation, allowing experts two weeks to confirm or revise the written summary. An initial series of expert conciliations was organised to define the indicators characterising each criterion. For the UHT milk, two meetings were required to finalize indicators for the nutritional and health principles, resulting in 3 nutritional and 12 health indicators. A single meeting addressed the sensory and technological principles, yielding 11 sensory and 4 technological indicators. The joint meeting on safety aspects specifically identified 13 safety indicators. Equivalent procedures were implemented for beef striploin and chicken breast. A second round of expert meetings focused on defining indicator thresholds to convert raw measurements into standardized scores (1–10) based on INTAQT project databases, and on establishing the weightings used to aggregate indicators into criteria and criteria into principles. This phase required at least two meetings per product for the nutritional & health dimensions and for the sensory & technological dimensions, as well as a joint meeting for safety-related aspects. In a final step, European stakeholder groups determined the weightings of the four overarching principles for each product, through three separate meetings per product held in different countries. These multicriteria assessments will be applied to data collected through an extensive survey and sampling campaign conducted on European farms representing a gradient of intensification levels for each product. This approach will enable evaluation of how farming system intensification affects the potential intrinsic quality across the three livestock products. The study is part of the INTAQT project funded by the EU's H2020 research and innovation programme (grant agreement N°101000250).

Number of animal lives vs. quality of life in broiler, dairy, and beef production

E. Caumette[1], B. Martin[1], C. Berri[2], R. Eppenstein[3], I. Veissier[1]
[1] Université Clermont Auvergne, INRAE, VetAgro Sup, UMR H, 63122 St-Genès-Ch, France, [2] INRAE, Université de Tours, BOA, 37380 Nouzilly, France, [3] Research institute of Organic Agriculture, FiBL, 5070 Frick, Switzerland

Animal welfare is often defined as animals' quality of life, which depends on their living conditions. Conditions of death also matter, as slaughter is often accompanied by suffering, but death per se is generally not considered a welfare issue. However, animals may have interests in continued life. From an animal perspective, one should thus consider both the quality of animals' life and the number of animal lives required to produce animal products. We questioned whether it is possible to maximise the first while minimising the second, across or within livestock productions. We used data from 18 broiler, 15 dairy, and 3 suckler systems (~5 farms/system) in Europe (Horizon2020 INTAQT project). We calculated the number of lives per kg of protein from meat and milk. We approximated quality of life from the averaged percentage of time spent outdoors per life (positive experiences) and health disorders within each production (negative experiences). For cattle, cows and offspring were considered, with calves fattened in confined or pasture-based systems. Across productions, dairy production required on average 5 times fewer lives than suckler systems and over 1,000 times fewer lives than broiler systems to produce the same amount of protein (4 ± 2, 22 ± 10 and 5,000 ± 1,500 lives/t protein in dairy, suckler, and broiler systems). Suckler systems provided the highest outdoor access per life (43 ± 6 vs. 13 ± 14 and 12 ± 13% in dairy and broiler systems). In broilers, moving from standard to heavy production reduced the number of animal lives by 25-90%, but could increase morbidity. Moving from standard to outdoor systems using slow growing broilers slaughtered at a heavier live weight reduced the number of animal lives by 4-16% and improved their quality of life. However, a broiler system combining the fewest animal lives and the greatest amount of outdoor access (Ross308 genotype in an organic system) had numerous health issues such as lameness and leg deformations. In cattle, a trade-off was highlighted: the most productive dairy systems required the fewest animal lives but with low outdoor access (2.5 ± 0.3 lives/t protein, 5 ± 5% outdoor access per life with 15 ± 17% for cows and 0% for calves), whereas the most extensive dairy systems and suckler systems provided the greatest amount of outdoor access but required the largest number of animal lives (for the most extensive dairy systems: 4.9 ± 0.5 lives/t protein, 24 ± 16% outdoor access per life with 59 ± 14% for cows and 15 ± 19% for calves; for suckler systems: 43 ± 6 % outdoor access per life, with 54 ± 12 % for cows and 40 ± 7% for calves). Grass-based fattening of calves improved the average life quality and could also reduce the number of animal lives if slaughter weight is increased. Within production, minimising the number of animal lives while maximising their quality of life is not always possible, and the question of how to weigh the two objectives remains open. Both objectives can be improved by fattening animals outdoors to a higher slaughter weight in broiler and cattle but this can lead to higher morbidity in broilers if fast-growing genotypes are used. Across productions, dairy production best minimises the number of animal lives with some systems maximising quality of life. Reducing the number of animal lives while improving their quality of life would thus require a change in human diets to favour meat from dairy production and, within each livestock production, products from alternative systems that achieve higher slaughter weights while providing good living conditions to all animal categories.

Milk mid-infrared spectra potentially authenticates farming system intensification level and season of production

Braccini 2, 10095 Grugliasco, Italy, [4] INRAE, Université Clermont Auvergne, VetAgro Sup, UMR1213 Herbivores, Centre Clermont-Auvergne-Rhône-Alpes, 63122 St-Genès-Champanelle, France, [5] Walloon Agricultural Research Center (CRA-W), Chaussée de Namur, 24, 5030 Gembloux, Belgium, [6] Research Institute of Organic Agriculture FiBL, Ackerstrasse 113, 5070 Frick, Switzerland, [7] Idele, 149 rue de Bercy, 75595 Paris cedex 12, France

Food fraud is a persistent challenge in global supply chains, and authentication systems are necessary to reassure buyers that claims such as “organic,” “animal-friendly,” or “origin-certified” are truthful. This study assesses the potential of using Fourier-transform mid-infrared (FT-MIR) spectra for authentication purposes regarding farming intensification level and season of production. A total of 65 dairy farms in France, Germany, Switzerland, and Ireland were visited collecting a total of 361 samples during summer (66%) and winter (34%). Farming intensification level were categorized in 5 classes through a hierarchical clustering based on feed inputs, farm animal density, pasture stocking rate, and fertilization levels. The farm classes range from low feed input using low amount of concentrate and mainly grass from land managed extensively (17% of the farms) or intentively (21%) to farms with high feed input from concentrates and maize silage with low (32%) or high (18%) stocking rate on pastureMilk spectra from each country were standardized to build discriminant models using Principal Component Analysis (PCA) and Partial Least Squares-Discriminant Analysis (PLS-DA) for farming practices intensification and season. For the PLS-DA, the dataset was split into 70:30 (training set:testing set). Models’ performance was evaluated via balanced accuracy. Results revealed that the PCA explained 82% of the variance (PC1, 65%; PC2, 17%) but showed no apparent clustering by season or intensification level, indicating that this unsupervised method was insufficient for sample authentication. Better results were obtained with the PLS-DA, as this supervised method was able to discriminate samples. In particular, excellent classification was observed for the season, with a high accuracy of the model (testing set balanced accuracy, 0.91) confirming that MIR spectra capture compositional changes linked to seasonal feeding strategies, such as pasture-based diets in summer versus conserved forage in winter. However, prediction performance for farm intensification level varied widely, with the best results for discriminating extensive farms (testing set balanced accuracy, 0.78), while most intensive farms revealed the lowest discriminatory potential (testing set balanced accuracy, 0.52). This lack of specificity suggests that MIR detects diet-related changes but cannot fully capture nuances of management, such as partial grazing or mixed feeding strategies. In conclusion, FT-MIR spectroscopy can effectively authenticate the season milk was produced, which could be a proxy for fresh grass consumption. However, further refinement and larger datasets are needed to improve the classification based on farming intensification.

Infrared spectroscopy for farming system classification and beef quality assessment: a multi device chemometric approach

A. Lopez[1,2], B. Martin[1], J. F. Hocquette[1], I. Constant[1], O. Joubert[1], V. M. Moretti[2], D. Andueza[1]
[1] Université Clermont Auvergne, INRAE, VetAgro Sup, UMR Herbivores, Saint-Genès-Champanelle, 63122 Theix, France, [2] Università degli Studi di Milano, Department of Veterinary Medicine and Animal Science, Via dell'Università, 6, 26900 Lodi, Italy

One of the aims of the EU INTAQT project was to develop innovative and cost-efficient analytical tools for the rapid prediction of intrinsic quality traits and the authentication of husbandry systems across Europe. We evaluated and compared the performance of two portable spectroscopic devices, the IndiGo Vis (visible region, 400-700 nm) and the FlameNIR (NIR region, 935-1665 nm), with that of a benchtop reference instrument (NIRS™ DS2500, combined Vis/NIR region) for authentication and quality assessment in the beef production chain. The first objective of this study was to classify beef samples according to the intensification level of the farming system, previously defined based on farming input data. For this purpose, we used a linear discriminant analysis with previous variable selection algorithm based on covariance among wavelengths. The IndiGo Vis and FlameNIR devices showed classification abilities comparable to the NIRS™ DS2500, achieving testing accuracies of 0.72-0.78 when considering the farm as the experimental unit and 0.82-0.90 when considering the animal as the experimental unit. The second objective was to predict a wide range of beef biochemical quality attributes, including proximate composition, fatty acids profile, oxidation products, B-group vitamins (and others), using partial least squares regression. In this context, the NIRS™ DS2500 achieved the highest overall performance (R^2 = 0.65-0.93, depending on the trait), whereas the portable devices generally produced lower prediction accuracy. Among the latter, only the IndiGo Vis yielded reliable prediction models for total and heme iron (R^2 = 0.69 and 0.77, respectively), likely because these traits are linked to fresh meat colour and therefore detectable within the visible spectral region. As part of this objective, we also compared spectral data collected on pooled samples (Pooled) with those obtained on individual samples and subsequently averaged (Ind_Aver). Prediction accuracy differed significantly between the two strategies ($p<0.001$), with consistently higher R^2 values for Ind_Aver (0.65) compared to Pooled (0.22) across all traits. The third objective was to predict beef carcass characteristics measured at the slaughterhouse, such as pH and marbling score, plus meat tenderness (shear force) and sensory attributes. Although the NIRS™ DS2500 again outperformed the portable devices, the resulting prediction equations were unsatisfactory ($R^2 < 0.30$), regardless of the instrument used. However, some classification approaches might provide more robust results than exact value prediction (analysis ongoing). The studies showed that the tested portable devices could support specific applications for authentication and for prediction of some biochemical traits, offering promising perspectives for practical field use. Nevertheless, developing robust calibrations for a broader set of quality traits remains challenging and further methodological refinement will be necessary to improve prediction accuracy and expand the applicability of portable spectroscopic tools.

Evaluating the Impact of Traditional Montanera vs. Intensive Feeding Systems on Technological Meat Properties in Iberian Pigs: Implications for System Resilience

M. Freire[1], J. Garcia-Gudiño[2], A. Ortíz[1], L. León[1], A. I. Del Rosario[1], D. Tejerina[1]
[1] Finca La Orden/ Cicytex, Meat and Meat Quality, , Ctra, A-V, Km372,, 06187 Guadajira,, Spain, [2] Veterinayr Faculty / University of Extremadura, Department of Animal Production and Food Science, Avenida de la Universidad s/n, 10003 Cáceres, Spain

Climate-driven declines in acorn availability during Montanera compromise the resilience of the traditional Iberian pig system, forcing producers to adjust stocking rates and increasingly rely on standard compound feed with no acorn inclusion. This dietary shift may modify essential meat-quality attributes, influencing texture parameters such as hardness, adhesiveness, springiness, cohesiveness, gumminess, chewiness and resilience, together with physicochemical traits including dry matter, fresh protein, total fat, water-holding capacity (WHC)and pH. These changes pose challenges to maintaining the technological and sensory characteristics historically linked to acorn-based finishing. Evaluating how standard feed affects these indicators is essential for designing adaptive strategies that enhance robustness in European livestock systems facing continuous environmental variability. A total of 40 purebred 100% Iberian Retinto pigs were selected for the trial. Ten of them were fed under traditional Montanera conditions (extensive free-range system, stocking density 0.75 pigs ha^{-1}) with exclusive access to naturally available acorns and pasture, until the end of the finishing phase, while another ten were assigned to an intensive feeding regime, although maintained under extensive conditions with a stocking density of 100 m² per animal and fed a high oleic commercial compound feed. Both production systems were carried out in accordance with the Iberian Quality Standard (RD 4/2014). After slaughter, the longissimus thoracis et lumborum (LTL)-loin– and Serratus ventralis -presa– muscles were removed from the carcasses and analyzed fresh. Different quality parameters were evaluated, including the texture profile at 80% compression, WHC, and proximate analysis. The results revealed significant differences between production systems across several quality parameters. Compared with Montanera, pigs raised under intensive conditions and fed a high-oleic commercial diet exhibited significantly higher ($p < 0.05$) maximum force and hardness (N; ~30 points higher), at least 10-point increases in gumminess and chewiness, and lower WHC and higher moisture in both presa and loin cuts. Moreover, a strong correlation was observed among texture parameters, WHC, and moisture in both cuts, indicating a consistent relationship between structural integrity and water retention. Finally, a significant interaction effect between production system and muscle type was detected in the nutritional composition ($p<0,005$), suggesting that the response of each cut to the feeding regime differed in magnitude and direction. The production system significantly influences the technological properties of meat, particularly hardness and chewiness, whereas proximate composition parameters (moisture, dry matter, fat, and protein) are primarily determined by muscle type and its interaction with the production regime. WHC constitutes a structural mediator between composition and texture, indicating that the effect of the production system on mechanical properties is partially driven by modifications in muscle microstructure and water–protein interactions. This research was funded by the Regional Government of Extremadura and the European Regional Development Fund (FEDER), Project " IBERCAL " The registration and attendance have been co-financed—85%—by the E.U., through FEDER Fund, and by the Regional Government of Extremadura. GR24147.

Factors influencing the phospholipid profile and concentration in cow milk: A study in commercial European dairy farms varying in intensification level

V. Menoury[1], B. Martin[1], L. Rey-Cadilhac[2], A. Ferlay[1]
[1] Université Clermont Auvergne, INRAE, VetAgro Sup, UMR Herbivores, Route de Theix, 63122 Saint-Genès-Champanelle, France, [2] PEGASE, INRAE, Institut Agro, , 35590 Saint-Gilles, France

Phospholipids (PL) are amphiphilic lipids located in the membrane of milk fat globules and milk exosomes. Phospholipids can be grouped into 5 classes according to their structure: phosphatidylethanolamine (PE), phosphatidylcholine (PC), sphingomyelin (SM), phosphatidylserine (PS), and phosphatidylinositol (PI). A higher intake of PL may provide beneficial health effects for consumers by supporting brain development, promoting gut health, regulating plasma cholesterol, and reducing inflammation. Therefore, the PL profile and concentration can be considered as a health quality trait of milk. A limited number of previous studies have shown that some farming factors can influence the PL concentration in milk and milk fat (g/100 g of milk and g/100 g of total lipids, respectively). These factors include cow breed (Holstein vs. Jersey), lactation stage (early vs. late), diet (linseed supplementation, forage-to-concentrate ratio), season (summer vs. winter), and management (conventional vs. organic farming). Our objectives were: (1) to characterise the variability of milk PL concentration and profile according to farm intensification level in Europe, and (2) to identify factors influencing milk PL profile and concentration. Milk samples were collected in summer, on three occasions, from 80 commercial European dairy farms located in France, Germany, Ireland, Italy, and Switzerland. Milk samples were pooled per farm on a weight basis before freeze-drying. Phospholipids were extracted using the modified Folch method, separated using high-performance thin-layer chromatography, and quantified using densitometry. Results were expressed as % of total PL and as g/100 g of total lipids. Questionnaires completed at each farm visit were used to characterise farm intensification (Caumette, 2025) as well as management, including herd composition and diet, during the 7 days before each sampling. Results showed variability between farms in both PL profile (coefficient of variation ranging from 16.0 to 29.8%) and concentration (coefficient of variation ranging from 7.9 to 36.1%). However, the intensification level did not appear as a major factor in explaining the observed variability. Preliminary descriptive statistics highlighted a negative correlation between maize intake and total PL concentration ($r = -0.23$, $P = 0.047$). No evidence of correlation was found between the dietary phosphorus content and PL profile or concentration. Among major milk PL (PE, PC, and SM), fresh grass intake (grazing or zero-grazing) was positively correlated with PE ($r = +0.25$, $P = 0.031$) and SM ($r = +0.29$, $P = 0.012$) concentrations, whereas maize intake was negatively correlated with PC ($r = -0.23$, $P = 0.048$) and SM ($r = -0.35$, $P = 0.002$) concentrations. The dietary content of C18:3 n−3 was positively correlated with SM concentration ($r = +0.35$, $P = 0.002$), whereas the dietary contents of C18:2 n−6 and C18:1 were negatively correlated with SM concentration ($r = -0.27$, $P = 0.019$ and $r = -0.31$, $P = 0.005$, respectively). Higher milk fat yield was correlated with lower PC ($r = -0.32$, $P = 0.005$) and SM ($r = -0.35$, $P = 0.021$) concentrations. Milk somatic cell count was negatively correlated with PE concentration ($r = -0.25$, $P = 0.032$). Overall, the observed correlations were weak. Future work will use multivariate statistical analyses, including random forest models, to investigate factors influencing milk PL profile and concentration.

Early-life antimicrobial treatment have long-term effects on the fecal microbiota of dairy calves

A. Ortiz Chura[1], M. Popova[1], A. Bachelet[2], D. P. Morgavi[1]
[1] Université Clermont Auvergne, INRAE, VetAgro Sup, UMR Herbivores, 63122 Saint-Genès-Champanelle, F-63122 Clermont Ferrand, France, [2] UEP, INRAE, 2019. Unité Expérimentale du Pin, L'Ermite, La Cochère, 61310 Gouffern-en-Auge, France

Early-life antimicrobial therapy is widely used in calf management to control gastrointestinal diseases, yet its long-term effects on the gut microbiota remain poorly understood. Host genetics and management practices may influence the microbiota response to these interventions. This study aimed to evaluate the long-term effects of early-life antimicrobial treatments on the fecal microbiota of calves. Twenty animals were selected from a cohort of 63 based on health records. Two breeds were included, Holstein (n=10) and Normande (n=10), with equal representation of calves that experienced diarrhea (n=5) and calves that were healthy throughout the experimental period (n=5). Samples were collected at birth, at 1 week, at 3 weeks, at weaning, at 2 weeks post-weaning, and at 8 months of age. A total of 120 fecal samples were sequenced using bacterial 16S rRNA gene amplicons. As most of the digestive disorders occurred within the first 6 months of age, the potential long-term effects of antimicrobial treatments were evaluated at 8 months of age, when all calves were clinically healthy. All calves were raised indoors, but the etiology and, therefore, the treatment strategies differed between breeds. Holstein calves that developed diarrhea received broad-spectrum antibiotics administered intramuscularly before weaning. In contrast, Normande calves were treated orally with coccidiostats after weaning. At 8 months of age, both alpha and beta diversity differed significantly between Holstein and Normande calves ($P<0.05$). Diversity also differed between calves with a history of digestive disorders vs healthy calves ($P<0.05$), and a significant interaction between breed and health status was detected ($P<0.05$). The abundance of most prevalent families, including Prevotellaceae, Lachnospiraceae, Oscillospiraceae and Ruminococcaceae, did not differ between breeds or health status. However, the families Atopobiaceae, Flavobacteriaceae, Eggerthellaceae, and Desulfovibrionaceae were more abundant in Normande calves compared with Holstein calves ($q<0.1$). Conversely, Nocardiaceae, Microbacteriaceae, Pirellulaceae, and Victivallaceae were more abundant in Holstein calves than in Normande calves. Calves that received antimicrobial treatments following diarrhea episodes showed increased relative abundances of several bacterial families, including Marinifilaceae, Victivallaceae, Eggerthellaceae, Bacteroidaceae, Peptostreptococcaceae, Christensenellaceae and Pirellulaceae, compared with non-treated calves, which were characterized by higher abundances of Fibrobacteraceae and Desulfovibrionaceae. These results suggest that calves showed breed-dependent fecal microbiota responses, and these differences interact with prior health status history and with antimicrobial treatments. These findings underscore that, despite calves differed in breed, management conditions, antimicrobial compounds, and the timing of treatment, a long-term effect on fecal microbiota composition was observed. This suggests that early-life therapeutic interventions can induce persistent microbial shifts that extend well beyond the treatment period. Further studies are needed to determine whether these microbiota shifts influence later animal performance in dairy cattle.

The effect of transitioning from low energy to high energy diets, and vice versa, on viruses and their hosts in the rumen fluid and faeces of Holstein dairy cows

D. A. Linde[1,2], J. S. Saenz[1,2], M. Bakiasi[1,2], J. Seifert[1,2]
[1] University of Hohenheim, Institute of Animal Science, Emil-Wolff-Str. 8, 70599 Stuttgart, Germany, [2] University of Hohenheim, 2HoLMiR – Hohenheim Centre for Livestock Microbiome Research, Leonore-Blosser-Reisen Weg 3, 70599 Stuttgart, Germany

The rumen microbiome, which consists of various microorganisms, will change when the diet of the ruminant changes. High-energy or high-concentrate diets have been reported to have a lower bacterial diversity compared to low-energy or high-roughage diets. However, little is known about the effect of the change from one energy diet to another, and vice versa, on the prokaryotic and viral community. The aim of this study was to determine the effect of transitioning cows from a low energy diet to a high energy diet and vice versa on the viral community and their hosts. Twenty first lactation Holstein cows were divided into two groups: one group received a low energy diet and thereafter a high energy diet (LE~HE) while the other group received a high energy diet at first and then a low energy diet (HE~LE). The animal experiment and sampling was done in the collaborative research project WiMiQ (https://gepris.dfg.de/gepris/projekt/202989534). Rumen fluid and faecal samples were collected three times across 6 weeks and subjected to DNA extraction and shotgun metagenomic sequencing. In total, 427 metagenome assembled genomes (MAGs) were assembled, and 4112 viral operational taxonomic units (vOTUs) were identified. Alpha and beta diversity of each community were determined, and functional annotation was performed on the generated contigs. In the rumen fluid, little variation was found in the alpha diversity of the viral community when the animals transitioned from HE~LE. A significant decrease in alpha diversity was observed in the group where the animals transitioned from LE~HE, which was also observed in the prokaryotic community. The Beta diversity clustered according to energy shift in both the prokaryotic and viral communities. After the transition from LE~HE, the evenness of the viral community decreased indicating that some vOTUs became dominant. The majority of these vOTUs were associated with an unknown host, but 4 vOTUs were linked to uncultured members of the Succinivibrionaceae family. High concentrate diets favour Succinivibrionaceae, where it rapidly ferments starch to produce succinate among others. When considered together, this might indicate that a bloom of specific phages occurred when the animals transitioned from LE~HE, possibly driven by the presence of Succinivibrionaceae. In contrast, there was no significant change in the abundance of Succinivibrionaceae and its phages when the animals were transitioned from HE~LE. The changes in bacterial and viral compositions need to be elucidated further to improve our understanding of the host-phage interaction and the possible consequences for the animal.

Metaproteomic Insights into Energy-Driven Microbial and Protozoal Functional Shifts Across the Ruminant Gastrointestinal Tract

M. Bakiasi[1,2], J. S. Saenz[1,2], J. Seifert[1,2]
[1] merzai.bakiasi@uni-hohenheim.de, 1Institute of Animal Science, Emil-Wolff-Str. 8, 70599 Stuttgart, Germany,
[2] University of Hohenheim, HoLMiR – Hohenheim Centre for Livestock Microbiome Research, Leonore-Blosser-Reisen Weg 3, 70599 Stuttgart, Germany

Ruminants rely on a symbiotic rumen and intestinal microbiome including bacteria, archaea, fungi, and protozoa. Current functional and genomic knowledge remains biased toward prokaryotes, leaving eukaryotes insufficiently characterized. Because diet and dietary energy shifts are major drivers of microbial restructuring in the gastrointestinal tract (GIT), this study used spatially resolved metaproteomics to investigate how changes in dietary energy alter the microbiome composition and functional activity across the GIT in dairy cows. The animal experiment and sampling was done in the collaborative research project WiMiQ (https://gepris.dfg.de/gepris/projekt/202989534). A total of 48 mid-lactation Holstein dairy cows (178.2 ± 23.5 days in milk; primiparous and multiparous) were randomly assigned at week −1 to two dietary energy levels—high energy (HE; 11.45 MJ ME/kg DM) and low energy (LE; 10.85 MJ ME/kg DM). From week 1 onward, dietary energy levels were reciprocally exchanged between groups to induce a controlled dietary energy shift, while all cows were offered a common diet supplemented with fava beans and ad libitum access to a partial mixed ratio consisting of 66% maize silage, 32% grass silage and 2% barley straw. Diet formulation and nutrient supply followed GfE (2023) recommendations. The trial lasted 7 weeks. At week 7, 20 animals (n = 10 per energy group) were slaughtered under standard welfare regulations. Mucosal and digesta samples were collected along the GIT to enable spatially resolved metaproteomic analysis. Proteins were extracted, digested, and analysed by LC–MS/MS. The MGnify cow rumen database, supplemented with protozoal SAG-derived sequences, was used as the search database in MetaLabMAG, while the UniProt bovine database served as the host reference. The obtained data suggest that dietary energy level influenced microbiome composition including protozoal species across GIT compartments. Beta diversity of animal- and section-specific metaproteomic samples differed significantly between dietary treatments, revealing a clear separation of microbiomes under HE and LE diets, consistent with energy-driven restructuring. Differential abundance analyses highlighted compartment-specific genera contributing to these compositional differences. Functional profiling further indicated diet-related differences in pathway expression, suggesting that dietary energy modulates microbial and protozoal activity as well as community structure. These findings underscore the importance of integrating spatial metaproteomics to better understand energy-driven microbial dynamics in ruminants.

Plasma Extracellular Vesicle Proteomics Reveals Systemic Metabolic Adaptation to Dietary Energy Transition in Dairy Cows

A. Malik[1], M. H. Ghaffari[1,2], N. Ranjbar[1], F. Shakeri[3], A. Buness[3], M. Sylvester[4], H. Sauerwein[1]
[1] University of Bonn, Institute of Animal Sciences, Physiology Unit, Katzenburgweg 7 - 9, 53115 Bonn, Germany, [2] Research Institute for Farm Animal Biology (FBN), Nutrition and Metabolism/ WG Metabolic Health, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [3] University of Bonn, Core Unit for Bioinformatics Analysis, Venusberg-Campus 1, 53127 Bonn, Germany, [4] University of Bonn, University Hospital Bonn, Institute of Biochemistry and Molecular Biology, Core Facility Analytical Proteomics, Nussallee 11, 53115 Bonn, Germany

Extracellular vesicles (EV) are nanosized lipid bilayer-enclosed particles that transport proteins, lipids and nucleic acids between cells, coordinating intercellular communication. Because their molecular cargo reflects the metabolic and physiological state of their cell of origin, circulating EV may serve as indicators of systemic metabolic adaptation. Dietary energy transitions are known to influence rumen microbial composition and host metabolism; therefore, we hypothesized that altering the concentrate-to-roughage ratio would modulate the plasma EV proteomics profile in dairy cows. The animal experiment and sampling were done in the collaborative research project WiMiQ (https://gepris.dfg.de/gepris/projekt/202989534). Twenty primiparous German Holstein cows (182 ± 15 days in milk) were assigned to either a high-energy diet (HE; 45% concentrate, n = 10) or a low-energy diet (LE; 25% concentrate, n = 10). At Week 1, diets were switched: HE cows received a low-energy diet (20% concentrate; HE/LE), and LE cows received a high-energy diet (50% concentrate; LE/HE). Plasma samples were collected before the transition (TP-1) and after six weeks (TP6). EV were isolated by differential centrifugation followed by size exclusion chromatography. Particle concentration and size distribution were measured by nanoparticle tracking analysis. EV-associated proteins were identified by LC–MS/MS (Orbitrap Fusion Lumos) and processed against the Bos taurus UniProt database at 5% FDR. Statistical analysis in R (v4.4) included variance stabilization, missing value imputation, and differential abundance testing using Limma. Functional enrichment analyses were performed using STRING (v12), g:Profiler, and ClueGO (v2.5.10). Plasma EV particle number and size distribution did not differ between dietary groups or time points. Proteomic profiling identified 404 plasma EV-associated proteins, 27 of which overlapped with the top 100 Vesiclepedia EV proteins. STRING analysis revealed a highly enriched protein–protein interaction network (PPI enrichment $p < 1.0 \times 10^{-16}$), indicating strong functional connectivity among EV-associated proteins. Differential abundance analysis showed that proteomic remodeling was primarily driven by time rather than dietary group, suggesting a coordinated systemic response to dietary transition rather than a passive temporal change. In the HE/LE group, 43 proteins were significantly regulated, while 27 proteins were differentially abundant in the LE/HE group at TP6 compared to TP-1. Enrichment analyses consistently identified pathways related to lipoprotein particle remodeling, complement activation, antioxidants, and endosomal trafficking. Although partial co-isolation of lipoproteins cannot be excluded, the strong network connectivity and consistent pathway-level enrichment support coordinated biological regulation rather than random contamination. In conclusion, dietary energy transition induced coordinated remodeling of the plasma EV proteome, reflecting dynamic systemic adaptation to altered energy supply. This study demonstrates that plasma EV proteomic profiling can provide novel insights into metabolic responses to dietary modulation in dairy cows.

Industry-level value and welfare consequences of methane-reducing feed additives in EU ruminant value chains

A. Ait-Sidhoum[1], F. Bedoin[2], J. K. Niemi[1]
[1] Natural Resources Institute Finland (Luke), Latokartanonkaari 9, 00790 Helsinki, Finland, [2] Institut de l'Elevage, 43 avenue Albert Raimond, 42272 Saint Priest en Jarez, France

Methane-mitigating feed additives are among the most promising near-term options to reduce greenhouse gas emissions from ruminant production, yet their deployment depends on incentives, feasibility across production systems, and how costs and benefits are shared along the value chain. This paper assesses the industry-level value consequences of alternative feed additives by linking farm-level effects to market and welfare outcomes "from farm to fork". We develop a scenario-based socio-economic framework that combines comparative static analysis with participatory modelling to quantify how additive adoption affects production costs, productivity, emissions intensity, prices, quantities, and surplus distribution across farmers, processors, retailers, and consumers. Empirically, we examine three additive pathways; 3-nitrooxypropanol (3-NOP), linseed oil, and extruded linseed; to quantify and compare their value-chain consequences under alternative uptake scenarios First, we parameterize additive-specific farm-level impacts (changes in unit costs, output, and emissions per unit of product) and upscale them using EU baseline market data. Second, we translate partial adoption into sector-level supply shifts and estimate resulting changes in market equilibrium under alternative assumptions on demand responsiveness and cost pass-through. Third, we extend the analysis beyond pure cost effects by allowing for demand-side mechanisms where verified low-methane products can attract price premia or secure market access. Scenario design is co-developed with value-chain stakeholders and structured as policy–market narratives that reflect plausible uptake pathways: (i) a reference regime with limited adoption driven by private profitability; (ii) incentive-supported regimes (e.g., eco-schemes, advisory support) that lower adoption barriers and broaden uptake; (iii) a high-regulation regime (e.g., carbon pricing or mandatory intensity targets) that accelerates adoption but may increase compliance costs and risk import substitution; and (iv) a coordinated value-chain regime based on contracts, certification/labeling, and premium-sharing arrangements that can shift incentives and redistribute value. The study delivers scenario-based estimates of (a) sector-wide emissions reductions, (b) changes in producer and consumer surplus, (c) distribution of gains and costs along the chain, and (d) the conditions under which mitigation becomes both scalable and economically robust. By comparing incentive-, regulation-, and market-pull pathways, the analysis provides actionable guidance on policy and contractual designs that support adoption while safeguarding competitiveness and fairness across ruminant value chains.

Enabling Methane Mitigation with Standardized Rumen Microbiome References and Pipelines

Z. Cai[1], M. A. Satti[1], M. Maigaard[2], I. Farhana[1], S. Zhang[1], T. D. E. Rozada[2], A. Schönherz[2], S. J. Noel[2], M. R. Weisbjerg[2], G. Sahana[1]

[1] Aarhus University, Center for Quantitative Genetics and Genomics, C. F. Møllers Alle 3, 8000 Aarhus, Denmark, [2] Aarhus University, Department of Animal and Veterinary Sciences, AU Viborg–Research Centre Foulum, 8830 Tjele, Denmark

Mitigating enteric methane is an urgent priority for sustainable cattle production. Assessing the level of mitigation achievable via changes in feed, microbiome modulation, and genetic selection depends on accurate, standardized rumen microbiome measurements, as methane is produced by methanogenic archaea from fermentation-derived substrates. Yet current bioinformatic practice limits precision and comparability: incomplete rumen microbiome references, modest strain-level resolution, functional annotation gaps, and sensitivity to wet-lab and Bioinformatics pipeline choices. Closing these gaps is critical for reliable microbiome–methane associations and scalable mitigation strategies. We addressed these challenges through three objectives: (1) benchmarking current sequencing technologies for taxonomic and functional quantification of the rumen microbiome; (2) developing a reproducible, modular pipeline for multi-purpose metagenomic analysis and construction of a non-redundant rumen gene catalog; and (3) curating high-quality rumen metagenome-assembled genomes (MAGs) into a versioned, queryable database. We generated 1232 Illumina short-read whole-metagenome sequencing (WMS) datasets, 52 Oxford Nanopore long-read WMS datasets, and 459 short-read 16S rRNA amplicon sequencing (16S) datasets, and publicly available datasets. We benchmarked platforms using metrics spanning community profiling accuracy, strain resolution, absolute quantification and functional annotation fidelity. To streamline analyses, we designed and released a modular pipeline covering read QC, assembly, polishing, binning/refinement/dereplication, taxonomy, and gene catalog construction. Finally, we present a curated rumen MAG database with standardized abundance estimates and taxonomic annotations to enable robust and comparable rumen microbiome analyses. In standard mock communities, both short-read and full-length 16S sequencing exhibited PCR-driven distortion and bias from inter-genome variation in 16S rRNA operon copy number, affecting quantitative accuracy. Full-length 16S nevertheless yielded more accurate abundance estimates. WMS approaches were limited in detecting and accurately quantifying low-abundance taxa. Across methods, we observed non-trivial rates of taxonomic misclassification—predominantly among closely related clades and under-represented lineages— which is expected to decrease with the use of curated, niche-specific reference resources. The consistent patterns were observed in ~450 samples profiled both by WMS and 16S. To put these findings into practice and support community-wide standardization, we developed MetaMAG Explorer (for database augmentation and multi-purpose metagenomic analysis) and MetaGene (for non-redundant gene-catalog construction and functional annotation). These pipelines yield a rumen-niche resource comprising 21667 non-redundant MAGs, a non-redundant gene catalog with standardized annotations, and harmonized 16S reference and annotation files, enabling reproducible abundance estimation for both WMS and 16S data. We benchmarked different sequencing strategy, mapped resolution–bias trade-offs, and released MetaMAG Explorer/MetaGene with curated rumen MAG, gene-catalog, and 16S resources to standardize rumen-relevant profiling. This study provides a robust measurement foundation for rumen microbiome studies and further accelerates the development of methane mitigation strategies for sustainable cattle production.

Response of primary mammary epithelial cells to pathogen challenge in dairy cows

T. Iso-Touru[1], F. Panitz[1], D. Fischer[1], S. Taponen[2], Z. Cai[3], G. Sahana[3], K. Kondrotienė[4], M. Malakauskas[4], I. Tapio[1], J. Vilkki[1]

Møllers Allé 3, 8000 Aarhus C, Denmark, [4] Lithuanian University of Health Sciences, Tilzes 18, 47181 Kaunas, Lithuania

Mastitis is the major health and welfare challenge in dairy cattle, and a deeper understanding of the early molecular responses in the mammary gland is essential for developing sustainable prevention and breeding strategies. Using primary bovine mammary epithelial cells (pbMECs) derived non-invasively from milk, we characterized the genomic mechanisms underlying the early host response to Escherichia coli by in vitro challenging of pbMECs with E. coli. In addition, as new treatment options are needed to prevent further emergence of antimicrobial resistance, we tested the effect of lactic acid bacteria (LAB) on the host response during the pathogen challenge. Metabolites from LAB are reported as potential candidates as alternative therapeutic agents for bovine mastitis. To investigate how host genetics modulate functional responses, pbMECs from cows with divergent genomic breeding values for udder health were compared under identical E. coli challenge conditions. Transcriptome profiling at 3 h and 24 h post E. coli challenge revealed a rapid, robust activation of innate immune pathways, dominated by strong upregulation of chemokines, cytokines, and inflammatory signaling cascades, including TNF, NF-κB, NOD-like receptor, and cytokine–cytokine receptor interaction pathways. Antigen presentation pathways became prominent at later time points, indicating a progression toward adaptive immunity. When pbMECs were challenged simultaneously with LAB and E. coli, gene function of the host was adjusted compared to the challenge with E. coli only, as more genes were both up- and downregulated at early stages of challenge. On the other hand, when pbMECS were challenged with LAB alone, only very few host genes were differentially expressed. Cells from cows with lower genomic breeding values for udder health displayed markedly higher numbers of differentially expressed genes and stronger modulation of metabolic and cell-cycle pathways, whereas cows with higher breeding values for udder health showed a more focused and regulated inflammatory response. Despite these extensive transcriptional differences, early epithelial responses did not overlap known mastitis associated genomic regions, suggesting that the initial molecular response of epithelial defense may not directly capture the loci underlying phenotypic resistance. Nevertheless, several well-established immune-related genes, such as CXCL8, LTF, TLR2, and BOLA-DRB3, were consistently induced, confirming their relevance in mammary epithelial immunity. These findings prove that milk-derived pbMECs are a powerful non-invasive tool for dissecting functional host responses and complement ongoing efforts toward functional understanding of host–microbe interactions in ruminants. Work contributes functional genomic insights that can be integrated with broader multi-omics frameworks to improve our understanding of mastitis susceptibility and to support future breeding strategies for healthier, more resilient dairy cattle.

Mapping Tryptophan-Derived Metabolites along the Bovine Small Intestinal Tract: An Evolutionarily Distinct Host–Microbiota Adaptation in Ruminants?

A. Veshkini[1], S. Bes[1], J. Tournayre[1], A. Imbert[1], M. Bonnet[1]
[1] INRAE, VetAgro Sup, UMR Herbivores, Rte de Theix, 63122 Saint-Genès-Champanelle, France

The spatial distribution of metabolites across the gut segments may indicate digestive or microbiota-related specificities, which impact local gut physiology and endocrine functions but also the overall performance and health of ruminants. Gut microbiota extensively metabolizes tryptophan (Trp) into a diverse group of indole metabolites, such as Indole-3-propionic acid (IPA), which act as key signaling molecules regulating epithelial barrier integrity, mucosal immunity, and endocrine regulations. In non-ruminants, indole production is dominant in the distal intestine, whereas in dairy cows, rumen microbial fermentation may severely alter this pattern, which has yet to be elucidated. This study aimed to characterize the spatial distribution of indole metabolites across the small intestine of dairy cows. Intestinal tissue samples were collected from six Holstein ruminant calves (3.5 months old). Metabolome profile of small intestinal segments (duodenum, jejunum, ileum) was measured using MxP® Quant 1000 kit (Biocrates Life Sciences AG, Austria) and liquid chromatography mass spectrometry (LC-MS/MS). Indole-related metabolites, including tryptamine, IPA, Indole-3-acetic acid (IAA), Indole-3-acetamide (IAM), Indole-3-carboxylic acid (I3CA), Indole-3-ethanol (I3E), indoxyl sulfate (Ind-SO4), and Indoleacetaldehyde (IAAld), were selected according to the compound classifications provided by the Biocrates website (https://biocrates.com/). Indole metabolites values below the limit of detection (LOD) were imputed using a 1/5 of the minimum positive values. Differences in indole metabolite abundance across intestinal segments (duodenum, jejunum, ileum) were assessed using a general linear model (GLM) in the MetaboAnalyst V6 platform. Multiple testing was adjusted using the false discovery rate (FDR), and metabolites with FDR < 0.05 were considered statistically significant. IPA (0.06 μM) and Indole-3-acetic acid (0.15 μM) were significantly higher in the duodenum, whereas in the jejunum and ileum their concentrations were below LOD. The concentration of Indoleacetaldehyde (~ 0.003 μM) and indoxyl sulfate (~ 0.11 μM) remained unchanged across intestinal segments. Tryptamine, Indole-3-acetamide (IAM), Indole-3-carboxylic acid (I3CA), and Indole-3-ethanol were detectable across intestinal segments, although at very low concentrations (<LOD), and no significant differences were observed between segments. Metabolomic profiling revealed that indole metabolites are distributed across the entire intestinal tract in dairy cows with certain members showing peak concentrations in the duodenum. The proximal enrichment of indoles represents a distinctive feature compared with non-ruminants where indoles are usually detectable in the distal part and likely reflects a ruminant–specific host–microbiota regulatory mechanisms. Interestingly, IAA and IPA, which were predominant in the duodenum, are well-known for playing a crucial role in strengthening barrier integrity by promoting tight junction expression, also have the ability to enter circulation and impact peripheral tissues. Future studies need to investigate whether indole metabolites function as adaptive signals that fine-tune host regulatory networks such as immune and endocrine responses.

Deciphering the Bovine Nasal Microbiome by reconciling 16S rRNA sequencing and culturomics

S. Méndez Barroso[1,2], G. Pot[3], M. Monié-Ibanes[3], H. Robert[3], D. Bars-Cortina[3], X. Laurent Nouvel[3], C. Citti[3], K. Kochanowski[1,2], N. Mach[3]

[1] Unitat mixta d' Investigació IRTA-UAB, Edifici CReSA,, 08193 Bellaterra, Spain, [2] IRTA-CReSA, Edifici CReSA, 08193 Bellaterra, Spain, [3] École nationale vétérinaire de Toulouse, Interactions Hôtes-Agents Pathogènes, 23 Chem. des Capelles Entrée n°1,, 31300 Toulouse, France

The bovine nasal microbiota is a key line of defense against respiratory pathogens, and numerous studies indicate that its composition can influence the success of pathogen colonization. Yet, the mechanisms underlying the interactions among commensals, pathogens, and the host remain largely unclear. Addressing these knowledge gaps requires not only a refined description of the commensal bovine nasal microbiota but also experimental approaches that enable controlled in vitro investigation of commensals and pathogens' interactions. To tackle these issues, we followed a two-step approach combining large-scale analysis of in vivo nasal microbiota datasets with cultivation of swab-derived microbial communities. First, to generate a comprehensive compositional map of the (healthy) bovine nasal microbiota, we assembled a diverse collection of 654 nasal-swab 16S rRNA sequencing samples. These in vivo datasets span multiple production systems, ages, geographical locations, and diets, allowing us to classify microbial genera based on abundance and prevalence. Despite high overall diversity (> 2,200 detected bacterial genera), the nasal microbiota was dominated by a core set of 10 highly abundant and prevalent genera, including Moraxella, Mycoplasma and Psychrobacter among others. These core genera accounted for ≈ 45% of cumulative abundance across datasets and represent the most stable and consistent members of the bovine nasal microbiota. Beyond this core, we identified two layers of accessory genera: 253 high-prevalence accessory members (HPA), consistently detected and suggesting ecological persistence despite low biomass; and 1,886 low-prevalence accessory members, characterized by sporadic occurrence and low abundance. These findings point towards a layered structure of the bovine nasal microbiota, in which rare taxa may nonetheless contribute to ecological stability, resilience, and host interactions. Second, to assess the feasibility of studying these different taxa in vitro, we cultivated swab-derived communities under multiple growth conditions and used 16S rRNA sequencing to evaluate taxonomic recovery. Under aerobic conditions, core genera exhibited the highest recovery rates (up to 33%), while HPA showed intermediate recovery (up to 17%), and LPA were rarely recovered (typically < 4-6%) across media types. Strictly anaerobic conditions yielded lower recovery rates across all groups. These findings support the hypothesis that dominant taxa are more readily cultivable, while many accessory members likely require specific conditions not reproduced in conventional media. Together, this work provides an updated, high-resolution view of the bovine nasal microbiota and establishes tractable in vitro tools for studying interactions among its members. This integrated framework lays the groundwork for mechanistic studies of how commensals influence pathogen behavior and respiratory health in cattle under in vitro tractable conditions.

Dietary supplementation with buffer and protected amino acids improves milk production and modulates microbiota in heat-stressed primiparous dairy goats

E. Romera-Recio[1], E. Ramos[1], M. Romero-Huelva[1], I. Rivelli[1], J. Barroso[2], A. Gomez-Mesonero[1], D. R. Yanez-Ruiz[1]
[1] CSIC, C/ Profesor Albareda, 1, 18658 Granada, Spain, [2] CAPRIGRAN, Cortijo Peinado, 18340 Fuente Vaqueros, Spain

Background and objective: Heat stress compromises dairy goat productivity and metabolic homeostasis. We hypothesized that dietary supplementation with magnesium oxide buffer and hydroxy analogue of methionine in commercial conditions would improve energy metabolism and modulate microbiota, enhancing milk production under heat stress. Materials and methods: Ninety Murciano-Granadina dairy goats (15 ± 4 DIM) were enrolled in a four-month trial (June-October 2024) at a commercial farm in Granada, Spain. Goats were assigned to either a control diet (CTL, n=45) or a treatment diet supplemented with buffer and protected amino acids (TRT, n=45). Temperature-humidity index (THI) was monitored continuously. Blood samples were collected during heat stress (July, THI=75.6) and thermoneutral (October, THI=66.8) periods. Milk yield and composition were recorded biweekly. Faecal and raw milk samples from primiparous goats (N=19; CTL=11, TRT=8) were analysed for bacterial composition using 16S rRNA gene sequencing. ASVs were identified with DADA2 and taxonomy assigned using Greengenes2 database. Results from blood metabolites were analysed using generalized linear mixed models. Microbiome data underwent quality filtering and rarefaction. Alpha diversity was compared using Wilcoxon tests, beta diversity using PERMANOVA, differential abundance using DESeq2, and discriminant analysis using sPLS-DA. Spearman correlations assessed microbiota-production relationships stratified by treatment. Results: Environmental monitoring confirmed severe heat stress during July-August (THI>80). In primiparous goats, TRT animals produced significantly more milk (+1 kg/day), fat (119.1 vs. 101.1 g/day), and protein (+20 g/day) compared to CTL ($P<0.05$). Blood parameters analyses revealed higher glucose (53.2 vs. 42.9 mg/dL, $P<0.001$) and lower non-esterified fatty acids (NEFA; 0.46 vs. 0.61 mmol/L, $P<0.05$) in TRT goats, indicating improved energy balance. Milk microbiome analysis showed trends toward reduced alpha diversity in TRT (Pielou evenness: $P=0.051$; phylogenetic diversity: $P=0.062$), while beta diversity did not differ significantly between groups. DESeq2 identified seven genera less abundant in TRT milk (FDR<0.05), predominantly Actinobacteria (Pseudonocardiaceae family: Prauserella, Saccharopolyspora; and Nocardiopsis), suggesting reduced environmental contamination or altered mammary ecology. Notably, treatment moderated microbiota-production relationships: Staphylococcus-protein yield correlation was positive in CTL ($\rho=0.66$) but negative in TRT ($\rho=-0.49$), while Stenotrophomonas-fat yield shifted from negative in CTL ($\rho=-0.47$) to positive in TRT ($\rho=0.89$), indicating treatment-dependent host-microbiome interactions. Faecal microbiota showed significant community separation by sPLS-DA, with 12 differentially abundant taxa including decreased Akkermansia, Alistipes, and Cryptobacteroides; and increased Ruminococcus_E and Bifidobacterium in TRT goats. Conclusion: Dietary supplementation with buffer and protected amino acids improved milk production and energy metabolism specifically in primiparous dairy goats under heat stress. These improvements were associated with distinct shifts in both mammary and faecal bacterial composition, with milk microbiota showing reduced environmental taxa and treatment-dependent correlations with production traits. These findings support the hypothesis that nutritional supplementation improves productive performance through enhanced energy balance and microbiota modulation, with effects most pronounced in primiparous goats.

Exploring Bacterial Defluorination of Sodium Fluoroacetate in Rumen Fluid

E. D. Cason[1], R. Kaputjaza[1], G. C. Josling[1], J. B. Van Wyk[1], P. D. Vermeulen[2], F. W. C. Neser[1]
[1] University of the Free State, Animal Science, 205 Nelson Mandela Drive, Park West, 9301 Bloemfontein, South Africa, [2] University of the Free State, 2Department of Groundwater Studies, 205 Nelson Mandela Drive, Park West, 9301 Bloemfontein, South Africa

Livestock mortality associated with sodium fluoroacetate (SF)-producing plants, particularly Dichapetalum cymosum, remains a major constraint to sustainable livestock production in southern Africa. Conventional mitigation strategies, such as veld management and herbicide application, are often economically and logistically impractical across extensive rangelands. Although symptom-reversal therapies and genetically modified SF-detoxifying bacteria have been developed, their effectiveness is constrained by treatment timing and regulatory limitations. Recent evidence indicating the presence of naturally occurring SF-degrading rumen bacteria offers a promising, biologically based alternative. This study evaluated the feasibility of developing a natural ruminal detoxification strategy combining SF-degrading bacterial isolates with tricarboxylic acid (TCA) cycle intermediates to enhance detoxification efficiency. Using an in vitro Daisy II incubation system, teff hay was subjected to four treatments: (T1) control; (T2) basal diet + Pigmentiphaga kullae and Ancylobacter dichloromethanicus (probiotic treatment); (T3) basal diet + sodium citrate and arginine (TCA intermediates); and (T4) basal diet + probiotics + TCA intermediates. Rumen fluid from cattle served as inoculum. Samples were collected at 0, 12, 24, and 48 h to determine dry matter degradability (DMD) and rumen pH. Bacterial community composition was characterised by targeted 16S rRNA metagenomics. Rumen pH remained within the physiological range (6.0–7.0) across all treatments, indicating no adverse effects on ruminal fermentation conditions. However, DMD differed significantly ($P < 0.05$) among treatments. TCA supplementation alone slightly reduced degradability relative to the control, whereas the combined probiotic and TCA treatment (T4) mitigated this decline. Microbial profiling revealed treatment-specific shifts in community structure, with Bacillus, Pseudomonas, Ruminobacter, and Lysinibacillus among the dominant genera. Notably, the combined treatment enhanced microbial diversity and promoted greater community stability compared to TCA supplementation alone. Collectively, these findings support the potential of integrating naturally occurring SF-degrading rumen bacteria with targeted nutritional supplementation as a complementary strategy to mitigate SF toxicity. Further optimisation of inoculum dosage, substrate composition, and in vivo validation is warranted to advance practical application under field conditions.

Influence of post-birth management and milk replacer feeding level on early life performance, health and behaviour of dairy calves

G. Scoley[1], K. Lawther[2], S. Huws[2], C. Ferris[1]
[1] Agri-Food and Biosciences Institute, Sustainable Livestock Systems, Large Park, BT26 6DR Hillsborough, United Kingdom, [2] Queen's University Belfast, University Road, BT7 1NN Belfast, United Kingdom

The early life of a calf involves a complex mix of environmental and management factors that can influence long-term production efficiency, growth, resistance to disease, and phenotypic resilience to changing environmental conditions. This study aimed to determine the impact of divergent early life management practices on calf behaviour during the first week of life and performance during the first 10 weeks of life. Biological samples collected at key times will be further used to characterise the establishment of microbiomes as well as determine their influence on key performance indices. Forty-eight Holstein heifer calves were allocated in a 2 × 2 factorial design (n = 12 calves per treatment), with 2 birthing protocols (Remain vs Remove) and 2 × milk replacer (MR) feeding levels (Low vs High). Calves were balanced on each of the four treatments, as far as possible, for birthweight, sire, dam production parameters and dam genetics. Remain calves stayed with their dam in the calving pen for 24 h (22-26 h) following birth while Remove calves were taken from the dam immediately and placed in an individual pen. Low MR calves received 4 L/day MR, with High MR calves offered a maximum of 8L/day until weaning at 56 days of age. Calves were individually penned from 24h post birth until the end of the study and provided with ad lib access to water and starter concentrate feed from 5 days of age. Liveweight was recorded at 24 h of age and weekly according to individual calf age between 7-70 days of age. Activity monitors were affixed to calves throughout the experimental period. Data was analysed using GenStat (version 21.1, VSN International Ltd). Feed intake, liveweight and activity data were analysed using a repeated measures model with birthweight, time point, birthing protocol and MR feeding level along with associated interactions fitted as fixed effects where applicable. Average daily gain (ADG) was subject to REML variance components analysis using a linear mixed model with fixed effects of birthing protocol, MR feeding level and associated interactions. Probability of $P<0.05$ was selected as the level of significance, and data was then subject to Fisher's protected least significant difference test where applicable. Daily MR intake was increased in Remove compared to Remain calves ($P<0.001$), however, at a practical level this only represented an average increase of 52 ml/day. Calves offered 4 L/day of MR consumed an average of 111 g DM/day more starter than High MR calves during the pre-wean period ($P=0.002$), however this effect was not evident in the post-wean period ($P=0.770$). Birthing treatment had no effect on starter intake during the pre-or post-wean periods, or on liveweight ($P=0.404$), or ADG over the first 10 weeks of life ($P=0.142$). Both lying time and motion index in calves were significantly impacted by birthing treatment in the first 24 hours following birth, whereby motion index was increased and average lying time for each 15-minute period was reduced in Remain calves compared to Remove calves ($P<0.001$). However, no further differences in lying behaviour parameters were observed during the pre-wean period ($P>0.1$). Removal at birth compared with allowing the calf to remain with the dam for 24 h had limited impact on calf behaviour after the initial 24 h period. Future work should examine the impact of extended periods of cow-calf contact in the days following birth. Results highlight that calves can be offered higher volumes of milk replacer in the pre-wean period without affecting post-wean starter intake and with a positive impact on growth.

Is the Pig Faecal Microbiota Shaped by Host Genetics?

C. Engelking[1,2], A. Camarinha-Silva[1,2], M. Rodehutscord[1,2], J. Bennewitz[1,2], V. P. Haas[1,2]
[1] University of Hohenheim, Institute of Animal Science, Garbenstraße 17, 70599 Stuttgart, Germany, [2] HoLMiR - Hohenheim Center for Livestock Microbiome Research, Leonore-Blosser-Reisen Weg 3, 70599 Stuttgart, Germany

A key aspect for understanding the variability in gut microbial composition is estimating the host genetic component associated with it. Therefore, this study aimed to estimate the heritability of faecal bacterial genera abundances at the genus level, and of α-diversity indices derived from amplicon sequence variant (ASV) profiles in pigs. Based on these findings, regional heritability mapping (RHM) was applied to identify genomic regions that are associated with pigs' bacterial genera. The study design included 450 Pietrain × Landrace F1 crossbred pigs with a defined family structure. The animals were kept under standardised individual housing and feeding conditions from the 11th week of life onwards. All animals were genotyped for 48,525 SNPs and faecal microbiota composition was characterised by 16S rRNA gene amplicon sequencing. Faecal microbiota were profiled at 16 weeks of age. Relative abundances were initially summarised across 325 bacterial genera; following prevalence filtering (minimum 20% of animals), 150 genera were retained for analysis. ASV-level data were subjected to quality and minimum occurrence filtering, yielding 6,344 ASVs for subsequent analyses. Genomic mixed linear models were used to estimate variance components for heritability estimation for individual bacterial genera and α-diversity indices. To assess α-diversity, richness was calculated as the count of genera with non-zero relative abundance, while the Shannon index was calculated to assess overall community diversity. Seventy-six of 150 genera revealed significant heritability estimates ($p < 0.05$) ranging from 0.11 (SE = 0.07) to 0.45 (SE = 0.10). For 14 genera, a heritability greater than 0.30 was estimated. Results for the α-diversity showed a heritability of 0.11 (SE = 0.07) for richness and 0.11 (SE = 0.08) for the Shannon index. These findings indicate that a subset of faecal bacterial genera is substantially influenced by host genetics. Genera that showed a stronger genetic component were further selected and RHM was conducted to identify genomic regions contributing to host genetic control of these genera. The separation of genetic and non-genetic factors shaping the pig faecal microbiota is crucial when the microbiota is considered as biomarker or target in breeding programmes. This study demonstrates a pipeline for assessing heritability in the microbiome and reports initial estimates to be substantiated in larger cohorts.

Comprehensive analysis of rumen-derived bacteriocin-producing Lactococcus lactis for Streptococcus biofilm control strategies

A. Elnar[1], M. A. Batican[1], J. Jeong[1], G. Kim[1], R. Kang[1], T. Park[1]
[1] Ruminant Nutrition and Physiology Laboratory, Department of Animal Science and Technology, Chung-Ang University, 4726 Seodong-daero, Daedeok-myeon, 17546 Anseong, South Korea

The rumen is a highly complex microbial ecosystem composed of interlinked ecological niches that collectively drive ruminant nutrition and health. Within this system, lactic acid bacteria (LAB) act as crucial facultative anaerobes that ferment carbohydrates into lactic acid, serving as an intermediate substrate for propionate-producing bacteria—providing a primary energy source for ruminants. Beyond their metabolic roles, several LABs, including Lactobacillus, Streptococcus, and Enterococcus, produce bacteriocins that influence microbial community structure and suppress opportunistic pathogens. However, the diversity and functional relevance of rumen-derived bacteriocin-producing LABs remain insufficiently characterized. In this study, ten strains of Lactococcus lactis subsp. lactis were isolated from rumen fluid of Hanwoo cows (Anseong, South Korea), fed a 50:50 (DM) rice straw-concentrate diet. Bacteriocin characterization included stability assessments across a range of temperatures (60°C – 121°C), pH levels (2 – 10), and proteolytic enzyme treatments (proteinase K, pepsin, and trypsin), determination of minimum inhibitory activity via checkerboard assay, and subsequent evaluation of biofilm inhibition, with statistical significance analyzed using one-way and two-way ANOVA with post hoc multiple comparisons tests ($p < 0.05$). All isolates exhibited inhibitory activity against Streptococcus equinus KCTC 21172 (MIC $\geq$ 400 AU/mL) and Listeria monocytogenes strains (MIC $\geq$ 100 AU/mL). Lactococcal bacteriocins significantly inhibited S. equinus KCTC 21172 biofilm formation ($p < 0.05$) and effectively disrupted pre-formed streptococcal biofilms (46.54 ± 7.37% to 83.50 ± 1.40%), highlighting their potential applications in biofilm prevention of specific rumen-microbial consortia, associated with subacute ruminal acidosis (SARA) and opportunistic pathogenesis. Biochemical characterization revealed properties consistent with nisin-like bacteriocins. Complementary meta-analysis of publicly available lactococcal genomes ($n = 99$) revealed substantial bacteriocin diversity for L. lactis subsp. cremoris (i.e., lactococcins, garvicin, and enterolysin) and subsp. lactis (i.e., lactococcins, nisin, and enterocin), likely reflecting ecological adaptation. Statistical analysis of bacteriocin gene distribution using Fisher's exact test (two-tailed) with Benjamini–Hochberg correction for multiple comparisons revealed that garvicin Q and lactococcin A were significantly enriched in L. lactis subsp. cremoris, whereas nisin and sactipeptides were significantly associated with subsp. lactis ($q < 0.05$), supporting subspecies-specific bacteriocin profiles. Collectively, these findings demonstrate that rumen-derived lactococci are potent producers of antimicrobial peptides and represent promising candidates for modulating rumen microbiota, controlling opportunistic pathogens, and mitigating biofilm-associated rumen disorders.

Effects of selected rapeseed meal cultivars in low-protein diets on performance and oxidative stress in dairy cows and their calves during the periparturient period

S. Lemosquet[1], H. Quesnel[1], Y. Le Cozler[1], B. Graulet[2], J. C. Martin[3], F. Gondret[1]
[1] UMR PEGASE, INRAE, 16 le Clos, 35590 Saint-Gilles, France, [2] INRAE, UMRH, 63122 Saint-Genès Champanelle, France, [3] INRAE, AMU, C2VN, 27 bd Jean-Moulin, FAC Méd La Timone, 13385 Marseille, France

Dairy cows and calves experience acute oxidative stress and inflammation around the calving. A previous study showed that two rapeseed (R) cultivars 00 (M: Mambo; B: Bonanza) improved the redox status of Ob-Ob mice through specific polyphenols and glucosinolates. This study aimed to evaluate the effects of rapeseed meals of these two cultivars, on the performance, immunity, and oxidative stress of dairy cows and their calves from week (wk) 4 before to wk 5 after calving. Multiparous Holstein cows (n = 45) were assigned to 4 groups of 10-12 cows. Each group was fed a maize silage-based diet containing fixed amounts of dry matter (DM, kg pre/post-partum) of toasted lupin (L: 0.88/1.2), overheated (140°C) M meal to alter specific metabolites (HM: 1.5/2.3), or low-temperature (110°C) M or B meals (1.5/2.1). The Protein Digestible in the Intestine (PDI) of the HM diet was higher than in L, M, B diets (81.6 vs. 70.9 / 96.6 vs 87.8, respectively). Net energy was similar across the diets (1.44 Mcal/kg DM). Calves (12/diet) received maternal colostrum (2.9 ± 0.8 kg) and milk for 2 days (d), then fixed amounts of pooled milk from cows in matched dietary groups. until wk 5. Blood was collected 2 wk before calving (cows), and after calving, on d1 (cows) or d2 (calves, wk 1), and wk 3 and 5 (cows and calves). Data were analysed by ANOVA with diet, wk and diet × wk as main effects and animal as a random effect, wk as a repeated measure and covariates for milk parameters. Orthogonal contrasts were performed: L vs. R, M&B vs. HM, and M vs. B. DM intake (DMI) of prepartum cows was 12.6 ± 0.4 kg/d (fixed offers). During lactation, DMI was lower for L vs. R diets (21.7 vs. 23.9 kg; $P < 0.05$), which led to lower yields of milk (36.3 vs. 39.1 kg/d), protein (1096 vs. 1241 g/d), fat (1461 vs. 1623 g/d) and plasma concentrations of most essential amino acids (AA). Despite the lower PDI supply in M&B vs. HM diets, cows fed M&B or HM produced similar milk and protein yields resulting in a greater PDI efficiency (0.79 vs. 0.72; $P < 0.05$) in the M&B diets. This suggests reduced AA catabolism and urinary N losses. Milk somatic cell scores were the lowest for M cows (M vs. B: 1.3 vs. 2.5, $P= 0.07$) and lactose concentration was the highest in M&B cows (47.5 g/kg vs 46.5 g/kg; M&B vs. HM: $P = 0.08$), suggesting reduced mammary inflammation associated with feeding M and B diets. Calves' total milk intake (247 ± 9 kg) and BW gain (0.76 ± 0.13 kg/d) were not influenced by treatments. Similar amounts of α and γ-tocopherols (600 and 757 ± 50 mg/d) were ingested for L vs. R diets. Cows fed L vs. R tended ($P < 0.1$) to have lower plasma hydrogen peroxides (dROM) and reduced glutathione reductase activity (antioxidant enzyme) at wks 3 and 5 ($P < 0.05$). Calves receiving L vs. R milk also had lower plasma dROM ($P = 0.02$) and greater total antioxidant capacity (FRAP, $P = 0.06$). This suggested lower oxidative stress in both L cows and calves. Cows fed M&B vs. HM diets had lower ($P < 0.06$) plasma dROM, and plasma glutathione was higher in their calves ($P = 0.01$). Calves fed with M vs. B milk had higher plasma haptoglobin, and lower activity of superoxide dismutase ($P < 0.05$). Plasma concentrations of immunoglobulins G and M in calves were unaffected by maternal diets. In conclusion, in low PDI diets, functional metabolites in toasted lupin or rapeseed cultivars have only subtle effects on oxidative stress in cows and calves but low heated meals from rapeseed cultivars maintained DMI and milk production.

Supplementing a Bacillus-based probiotic to mitigate acidosis in beef cattle consuming a high-concentrate diet

R. Cooke[1], B. Cappellozza[2]
[1] Texas A&M University, Animal Sciences, 2471 TAMU, 77843 College Station, United States, [2] Novonesis, Animal Business Unit, Biologiens Vej 2, 2800 Lyngby, Denmark

Bacillus-based direct-fed microbials are proposed to modulate ruminal fermentation and microbial ecology, but their effects on ruminal responses to an acidosis-inducing diet are not fully understood. This experiment compared ruminal fermentation, nutrient degradability, and performance responses of beef heifers receiving an acidosis-inducing diet and supplemented with a Bacillus-based probiotic (BAC; Bacillus licheniformis + B. subtilis; Bovacillus™; Novonesis, Lyngby, Denmark). Fifteen ruminally-cannulated heifers were ranked by pre-trial body weight (BW) and assigned to 3 groups of 5 heifers each. Groups were enrolled in a replicated 3 × 3 Latin square design containing 3 periods of 21 days, and a 14-day washout interval between periods. During each period, heifers had ad libitum access to water and were offered a forage-based diet from day 0 to 6 and an acidosis-inducing diet from day 7 to 21 at 2% of BW (DM basis), in equal proportions at 0700 and 1600 h. Groups were assigned to receive no BAC supplementation (CON; n = 15), BAC supplementation at 3 g/heifer daily from day 7 to 21 (BAC; n = 15), or BAC supplementation at 3 g/heifer daily from day 0 to 21 (BACPRE; n = 15). The BAC dose was mixed with dried distillers' grain and manually blended into the diet at each feeding. Heifer unshrunk BW was recorded on days -3, -2, and -1 relative to the beginning of each period and averaged for initial BW. Final BW was calculated by averaging heifer BW on days 19, 20, and 21. Rumen fluid samples were collected on days 0, 7, 14, and 21 of each period, immediately prior to (0 h) and at 3, 6, and 9 h relative to the morning feeding. Results obtained on day 0 were averaged and used as independent covariate in each respective analysis. Dietary dry matter and nutrient degradability in the rumen were evaluated from day 17 to 20 using Ankom bags. No treatment differences were detected ($P \geq 0.20$) for heifer BW gain, feed intake, or gain:feed ratio. No treatment effects or interactions containing the treatment effect were detected ($P \geq 0.33$) for rumen pH. No treatment differences were detected ($P \geq 0.15$) for concentrations of individual or total volatile fatty acids on day 7. On day 14, heifers assigned to BAC had less ($P = 0.03$) butyrate concentration compared with BACPRE and CON heifers, whereas no other differences were detected ($P \geq 0.41$) for individual or total volatile fatty acids. On day 21, heifers assigned to BAC and BACPRE had greater ($P = 0.03$) valerate concentration compared with CON heifers, whereas no other differences were detected ($P \geq 0.36$) for individual or total volatile fatty acids. Heifers assigned to BAC and BACPRE had greater ($P \leq 0.02$) diet dry matter disappearance rate (4.15 and 4.02 vs. 2.99 %/h, respectively; SEM = 0.33) and effective degradability (61.1 and 60.0 vs. 57.6%, respectively; SEM = 0.10) compared with CON heifers. In summary, supplementing BAC to beef heifers receiving an acidosis-inducing diet increased ruminal dry matter disappearance rate and effective degradability, but did not modify rumen pH or overall volatile fatty acid concentrations.

Effects of inoculation of corn silage with Lactobacillus buchneri and Lactococcus lactis on silage quality and stability, and production performance and efficiency in beef cattle

S. Grossi[1], C. A. Sgoifo Rossi[1]
[1] Università degli Studi di Milano Statale, DIVAS, Via dell'Università, 6, 26900 Lodi, Italy

This study evaluated the effect of a novel silage inoculant based on Lactobacillus buchneri and Lactococcus lactis on corn silage quality, conservation, and aerobic stability, as well as its impact on beef cattle performance, production efficiency, and health. At harvest, corn silage from the same fields was evenly divided into two bunker silos and either treated or not with the inoculant (SiloSolve® FC, Chr. Hansen A/S, Hørsholm, Denmark) at 2g/ton of fresh silage. After a 60-days ensiling period, the two silages were fed to 292 Charolais beef bulls, blocked by arrival weight and divided evenly in two groups: i) Control (146 bulls), receiving basal diets containing control untreated silage; ii) Treatment (146 bulls), receiving basal diets containing the inoculated silage. The trial covered the entire fattening period of 186 days. Silage samples were collected monthly and analyzed for chemical composition, fermentative profile, mycotoxins content, and biogenic amines (putrescin, cadaverine and histamine). Individual weights were taken at the beginning and end of the trial to calculate the average daily gain (ADG). The feed intake was measured monthly, and the feed conversion ratio (FCR) was calculated. Health was monitored daily, with particular attention to digestive disorders and nutrition-related lameness. Apparent total tract digestibility (aTTD) was evaluated monthly per pen using a portable near-infrared system by comparing diet and fecal composition. Slaughtering performances were also recorded. The data were analyzed using SAS software with specific models applied to each parameter. No differences were observed in the chemical composition of the two silages. Conversely, the fermentative profile was improved in treated silage, showing lower pH (3.65 vs 3.93), butyric acid (0.01 vs 0.23 % on dry matter), ammonia (NH3) (929.71 vs 1640.43 ppm), and higher lactic and acetic acids (7.23 and 3.73 vs 5.95 and 2.46 % on dry matter) ($P < 0.0001$). Mycotoxin concentrations and biogenic amine levels were also significantly reduced in treated silage ($P < 0.0001$). Those trends were also stable over time. Treatment improved ADG (1.528 vs 1.475 kg/head/day) ($P < 0.0001$) and showed a tendency toward higher final body weight (722.25 vs 716.17 kg) ($P = 0.064$) and carcass weight (429.9 vs 425.94 kg) ($P = 0.055$). Feed intake was not affected, whereas FCR was significantly improved in the Treatment group (7.58 vs 8.10) ($P < 0.0001$). Carcass fatness score was also improved, with a higher proportion of carcasses classified as fatness score 3 in the Treatment group (33.33 vs 19.05%) ($P = 0.004$). The average aTTD of NDF (52.18 vs 50.79%) ($P=0.0001$), cellulose (54.06 vs 50.01%) ($P = 0.045$) and starch (96.75 vs 95.68%) ($P<0.0001$) were significantly improved by the Treatment, with also stable results over time. A tendency toward a reduction in nutrition-related non-traumatic lameness was also observed (1.59 vs 5.56%) /$P = 0.068$). The inclusion of the inoculant improved significantly the stability and safety of corn silage, leading to enhanced digestibility at the rumen and potentially contributing to a more stable ruminal environment, ultimately supporting improved production performance in beef cattle.

Effects of Biochar Supplementation on Milk Yield, Milk Composition, Milk Fatty Acids and Health in Dairy Cows

A. N. Rückert[1], D. Dannenberger[1], A. Eggert[1], M. Oster[1], H. Reyer[1], A. Vernunft[1]
[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

In dairy cows, biochar supplementation has been linked to improved health, better feed conversion, and higher milk yield. However, previous studies often relied on small sample sizes or limited observation periods providing only a snapshot of short-term effects. In this study, we investigated the long-term effects of variable biochar supplementation on milk yield, milk composition, milk fatty acid concentrations and health parameters of dairy cows. A feeding trial was conducted from May to November in 2024 on a conventional dairy farm located in eastern Germany. The biochar feeding was divided into three consecutive phases. One group of dairy cows (n = 132–194 per phase) received biochar in increasing concentrations (0.5%, 1%, 2% of feed), whereas the control group (n = 144–185 per phase) received the same feed without added biochar. Daily milk yield of each cow was recorded by a milking robot. In each phase, the milk composition (fat, protein, lactose, urea) was analysed in a routine milk inspection. On day 43 of the second phase and on day 4 of the third phase during the feeding period, milk samples were collected to determine milk fatty acid concentrations using gas chromatography. Health data, including the number of affected cows, disease incidence, and administered medications (analgesics and antibiotics), were recorded throughout the study period. The data was analysed using R version 4.5.1 (R Core Team, 2025). A linear mixed-effects model was fitted to account for repeated measurements within animals and including treatment, lactation group, lactation stage, and individual baseline values as fixed effects. Considering milk yield, significant effects were observed only in the first phase. Cows in their first lactation produced an estimated 1.06 kg/d more milk in late lactation (days in milk ≥ 105; $P = 0.04$), and cows in their fourth or higher lactation produced an estimated 2.78 kg/d more milk in early lactation (days in milk < 105; $P = 0.03$) compared with the control animals. Regarding milk composition, protein content was affected only in the last phase, when 2% biochar was added to the feed. In this phase, the biochar fed group showed an estimated 0.10% higher milk protein content than the control group ($P < 0.01$). For evaluation, the analysed milk fatty acids were grouped by degree of saturation and carbon chain length. Differences were detected only on the first sampling day, when the biochar group showed higher estimated concentrations of monounsaturated fatty acids (1074 ± 49 vs. 878 ± 55 mg/100g milk, $P < 0.01$) and polyunsaturated fatty acid (134 ± 6 vs. 121 ± 6 mg/100g milk, $P = 0.04$) than the control group. Additionally, linoleic acid ($P = 0.01$) and alpha-linolenic acid ($P = 0.04$) were higher in the biochar group, again only on the first sampling day. Apart from more frequent analgesic treatment in the biochar group during the first phase ($P = 0.03$), and a higher estimated somatic cell count of the biochar group in the second phase ($P < 0.01$), no effects of biochar on health parameters were observed. In summary, the results suggest that biochar supplementation had no consistent significant effect on milk yield, milk composition or health indices. Minor changes in milk fatty acid concentrations were observed, but no clear overall pattern emerged. Although a temporary increase in milk protein content in the third phase indicates a possible effect on rumen microbiota and amino acid supply for milk production, this was not yet investigated further. At the same time, biochar does not appear to compromise milk production either.

Effects of supplementing 25 OH vitamin D3 on immune markers and colostrum quality in Holstein cows during the transition period, and on plasma vitamins and metabolites in their newborn calves

S. Lashkari[1], M. Vestergaard[1], N. B. Kristensen[1], T. D. Turner[2], S. K. Jensen[1]
[1] Aarhus University, AU Viborg, Foulum,, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark, [2] dsm-firmenich, Kirkebjerg Allé 88, 2605 Brøndby, Denmark

This study investigated impact of dietary supplementation of 25-OH-D3 (HyD) on (I); plasma acute-phase proteins, cytokines, and immunoglobulin (Ig) concentrations in colostrum of multiparous Holstein cows from three weeks before calving through 21 days in milk, and (II); plasma levels of fat-soluble vitamins, Ig, minerals, and metabolites in their newborn calves. A total of forty-two cows were allocated to one of two treatments: vitamin D3 (D3) or HyD supplementation. From −21 d relative to expected calving until parturition, cows in the D3 group received 0.475 mg/d (19,000 IU/d; 0.035 mg/kg DM) of vitamin D3, whereas HyD cows received 1.45 mg/d (58,000 IU/d; 0.108 mg/kg DM) of HyD. From calving to 21 DIM, D3 cows continued to receive 0.625 mg/d of vitamin D3 (25,000 IU; 0.024 mg/kg DM). During the same period, HyD cows received the same D3 dose plus 1.0 mg/d (40,000 IU of HyD; 0.056 mg/kg DM). Blood samples were collected from the tail vein on days −7 (6 ± 2 d), −3 (2 ± 1 d), 0 (13 ± 8 h after calving), 1 (36 ± 11 h after calving), 10 (9 ± 2 d), and 20 (16 ± 2 d) relative to parturition. These samples were analyzed for plasma concentrations of acute-phase proteins (haptoglobin [HAP] and serum amyloid A [SAA]), and cytokines including tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), and interleukin-10 (IL-10). After calving, cows were milked in the calving pen, and a colostrum sample was collected (2.2 ± 1.9 h after calving; mean ± SD). Calves were then immediately fed colostrum from their own dam. A blood sample was also collected from each calf via jugular vein at 48 ± 3 hours of age (mean ± SD). For maternal plasma TNF-α concentrations, a treatment × time interaction was detected ($P < 0.01$), and cows receiving HyD showed reduced TNF-α levels before calving compared with those given D3, but this difference diminished around parturition and the two groups reached comparable concentrations by 20 days in milk. No treatment effect was observed for plasma Hap (0.54 g/L), SAA (17.8 pg/mL), IFN-γ (333 pg/mL), or IL-10 (177 pg/mL; means across treatments). Newborn calves from cows supplemented with HyD showed greater plasma 25-OH-D3 concentrations compared with calves from the D3 group (13.9 vs. 8.9 ng/mL; $P < 0.01$). In contrast, plasma levels of 25-OH-D2 (1.7 ng/mL), vitamin A (0.16 µg/mL), and vitamin E (2.2 µg/mL; means across treatments) in the calves did not differ between treatments. A positive linear association was observed between the calves' plasma 25-OH-D3 concentrations and those measured in their dams ($Y = 6.8 + 0.06 X$). Colostrum volume (4.1 L), Brix value (20.7%), and colostrum concentrations of IgA (1,113 µg/mL), IgM (5,614 µg/mL), and IgG (101 mg/mL; means across treatments) did not differ between cows receiving D3 and those supplemented with HyD. Consistent with these findings, the calves' plasma levels of IgA (326 µg/mL), IgM (25 µg/mL), and IgG (23 mg/L; means across treatments) also showed no treatment differences between the two groups. In conclusion, HyD supplementation had minimal effects on acute-phase proteins and cytokine responses in transition cows. Supplementing HyD during close-up period led to enhanced 25-OH-D3 levels in calves at birth; however, no associated influence on immunoglobulin concentrations in colostrum or calf plasma was noted. Significance of elevated 25-OH-D3 in calf plasma in relation to active immune development remains to be investigated.

Effects of a rumen-protected choline prototype on milk yield and composition, liver triglyceride, and blood parameters for early lactation Holstein cows exposed to feed restriction

C. Bradford[1], N. Hogan[1], T. Mutsvangwa[1], G. Penner[1]
[1] University of Saskatchewan, 51 Campus Drive, S7N 5A8 Saskatoon, Canada

During early lactation, dry matter intake (DMI) lags behind milk production, causing cows to enter a negative energy balance. This deficit necessitates mobilization of adipose reserves as non-esterified fatty acids (NEFA) to promote milk production. Although NEFA can be fully or partially oxidized for energy, excessive mobilization rates can exceed metabolic capacity of the liver and export of NEFA as very low-density lipoproteins (VLDL), resulting in triglyceride (TG) accumulation in the liver. Choline is a precursor for phosphatidylcholine, a key component of VLDL. Greater VLDL production enhances hepatic clearance rates of NEFA, limiting the risk for TG deposition. As dietary choline supply is often inadequate during early lactation, dietary supplementation with rumen-protected choline (RPC) may be of use for dairy cows. The objective of this study was to determine the effect of a RPC prototype on DMI, milk yield and composition, liver TG concentration, and blood metabolites in 16 early-lactation Holstein cows (DIM = 44 ± 5 d, initial milk yield = 45.6 ± 8.8 kg/d) undergoing a feed restriction challenge. The study used a randomized complete block design consisting of 14 d of adaptation to RPC, 5 d of baseline (BASE), 5 d of feed restriction (FR; 40% of ad libitum intake), and 10 d of recovery (REC). Treatments included a negative control (CON; n = 8) or a daily RPC dose (RPC; 27 g/d, providing 12 g/d of choline ion; n = 8) mixed with 1 kg of the TMR 30 min prior to feeding. All cows were fed the same barley silage-based TMR. Blood samples were collected on d 1, 19, 21, 23, 25, 26, 27, 29, 31, and 34 relative to the start of the study. Liver biopsies were performed on d 17, 25, and 34. Cows were milked 3× daily and milk yield from d 15 to 34 were used for statistical analysis. Composite milk samples from four time-points (d 17-19, 22-24, 25-27, and 32-34) were analyzed for composition. Data were analyzed using the GLIMMIX procedure in SAS v9.4, with treatment, time, and treatment × time as fixed effects, and block and cow as random effects. Milk, DMI, and liver data were analyzed by phase (BASE, FR, REC) with REC further split into two components (REC1 and REC2) for milk and DMI. Blood data were analyzed by day, with d 1 of study (before treatment offered) as a covariate. There were no treatment × time interactions detected for any variables ($P \geq 0.14$). As imposed, DMI was greatest during BASE (29.0 kg/d), was 39% of BASE during FR (11.0 kg/d), and gradually increased during REC (24.5 kg/d; phase, $P < 0.01$). There was no effect of treatment on DMI ($P = 0.52$), but RPC numerically increased DMI during REC. While milk yield did not differ by treatment ($P = 0.35$), cumulative yield was numerically greater for RPC than CON. Milk yield was greatest during BASE (49.4 kg/d), least during FR (34.0 kg/d), and increased during REC (38.8 kg/d; phase, $P < 0.001$). Milk fat percentage increased during FR (5.1%) compared with BASE (3.6%) and REC (4.1%; phase, $P < 0.01$), with no effect of RPC ($P = 0.40$). Blood concentrations of NEFA were lowest in BASE (355 µEq/L), increased during FR (1,710 µEq/L), and decreased during REC (769 µEq/L; day, $P < 0.01$). Liver TG concentrations were lowest during BASE (14.1 µM), highest during FR (486.6 µM), and decreased during REC (41.3 µM; phase, $P < 0.001$). There was no treatment effect on blood NEFA ($P = 0.96$) or liver TG ($P = 0.93$). Supplementation with the RPC prototype to cows exposed to a FR challenge did not affect DMI, milk yield and composition, liver TG, or NEFA. It is possible that the RPC evaluated could not overcome the metabolic stress imposed with severe FR.

Breed impacts voluntary intake of hydroxychloride and sulphate sources of trace minerals in beef heifers

D. Brito De Araujo[1], K. V. Z. Augusto[2], M. A. F. Porcionato[2], J. L. M. Vasconcelos[3], P. Moriel[4]
[1] Nutreco Nederland, Selko, Stationstraat 77, 3811MH Amersfoort, Netherlands, [2] Trouw Nutrition Brazil, Avenida Rocha Bonfim, 241, 13080-000 Campinas, Brazil, [3] Sao Paulo State University, School of Veterinary Medicine & Animal Science, Rubiao Junior, s/n, 18618-970 Botucatu, Brazil, [4] University of Florida, IFAS - Range Cattle Reseach & Education Center, 3401 Experiment Station Rd, 33865 Ona, United States

This study investigated the influence of breed (Bos taurus vs. Bos indicus) on the preferential choice and voluntary selection of two different sources of Cu, Mn, and Zn when incorporated into a white salt-based trace mineral supplement (day 0 to 55; Exp. 1) and a protein-based trace mineral supplement (day 56 to 112; Exp. 2). On day 0, Nellore and ½ Angus × ½ Nellore heifers (n = 20/breed) were categorized by breed, body weight (347 ± 82 kg), and age (12–30 months) and assigned to individual drylot pens. Each experiment included a 28-day washout phase followed by a 28-d evaluation of voluntary intake phase. During the preferential intake phases, heifers were given simultaneous access to sulphate (SUL) and hydroxychloride (HYD) sources of Cu, Mn, and Zn, which were blended into salt-based trace mineral supplements from day 28 to 55 (Exp. 1) and protein-based trace mineral supplements from day 84 to 112 (Exp. 2). From day 0 to 112, heifers had unrestricted access to Tifton 85 (Cynodon sp.) hay. A breed × source × day interaction was observed ($P \leq 0.05$) for daily trace mineral intake from day 28 to 56 and day 84 to 112. Angus × Nellore heifers consumed more SUL than HYD supplements between days 31 and 33 ($P = 0.02$) but preferred HYD over SUL from days 37 to 42 ($P \leq 0.02$). Conversely, Nellore heifers exhibited a higher intake of HYD compared to SUL between days 31 to 33 and 43 to 51 ($P \leq 0.05$). Across both breeds, intake of protein supplements containing HYD was greater ($P \leq 0.05$) than those with SUL from day 84 to 112, with the difference being more pronounced ($P \leq 0.04$) in Nellore than in Angus × Nellore heifers. Overall, Nellore heifers strongly preferred mineral and protein supplements containing hydroxychloride compared to sulphate sources. Regardless of breed, hydroxychloride supplementation promoted greater voluntary intake and minimized variability in consumption compared to sulphate-based minerals.

Post-weaning optimization by using fibrous concentrate and essential oils supplementation in lambs

A. H. Chekikene[1], J. Muñoz-Grein[1], N. Ghallabi[1], A. Belanche[1]
[1] University of Zaragoza, Department of Animal Production and Food Science, Miguel Servet 177, 50013 Zaragoza, Spain

Improving rumen fermentation and health during the post-weaning (PW) period while maintaining animal performance and reducing feeding costs represents major challenges in intensive ruminant productions. This study hypothesized that the use of a forage-free fibrous concentrate diet and supplementation with a commercial essential oil (EO) blend (Agolin® Ruminant; 200 mg/kg DM) could optimize the PW process in lambs. A total of 56 weaned male lambs (40 days-old) were randomly distributed into 28 pens and allocated to four experimental treatments according to a 2 × 2 factorial design: a conventional concentrate plus barley straw without (CTL−) or with EO supplementation (CTL+), and a fibrous concentrate without straw supplementation without (FIB−) or with EO supplementation (FIB+). Rumen fermentation and microbiota were evaluated at 2 weeks PW; blood health indicators were measured at 1, 3, and 10 weeks PW; feeding behavior was recorded during week 5; and animals were slaughtered at 11 weeks PW in a commercial abattoir. Results indicated no differences in DMI during the PW period. The FIB diets resulted in a more homogeneous DMI throughout the day, whereas CTL lambs showed higher DMI during the morning. The FIB diet increased total VFA concentration (+33%) and reduced rumen pH, promoting a shift toward propionate production (+6%) during PW. Microbiologically, the FIB diet was associated with the absence of rumen protozoa, reduced methanogen abundance (−4%), and increased abundance of propionate producers such as the family Selenomonadaceae (+98%), while decreasing several fiber-degrading taxa within the phyla Bacillota_A and Bacillota_I. Lambs fed the FIB diet exhibited higher blood β-hydroxybutyrate concentrations (+32%), a lower glucose-to-β-hydroxybutyrate ratio, and reduced urea-N concentration (−29%), indicating increased rumen fermentative activity and improved nitrogen utilization. Anatomically, lambs fed the FIB diet had a lighter rumen epithelium color ($P = 0.036$), suggesting a lower degree of keratinization than CTL lambs at 11 weeks PW. The EO supplementation promoted favorable changes in rumen fermentation during PW, including a tendency to increase propionate concentration (+11%) and the D/L lactate ratio, while decreasing NH_3-N concentration (−52%). EO supplementation exerted antimicrobial effects characterized by a reduction in rumen bacterial richness (−22 ASVs), along with decreases in low-abundance taxa, including the phylum Spirochaetota. Moreover, EO supplementation decreased methanogen richness and the relative abundance of methanogen reads, but only in lambs fed the FIB diet. EO supplementation had no effects on blood health indicators or feeding behavior. Average daily gain, feed efficiency, carcass weight, and diarrhea index were not affected by the experimental treatments. During the entire experiment, concentrate intake was similar across treatments; however, CTL lambs additionally consumed straw (7% of total DMI), resulting in greater total DMI and higher feeding costs (+2.05 EUR/lamb). Overall, this study demonstrates that the post-weaning period can be optimized through targeted nutritional interventions. EO supplementation shifted rumen fermentation toward a potentially more efficient profile, whereas the forage-free FIB diet boosted the rumen fermentation and reduced feeding costs without compromising health or productivity. The combination of these strategies may therefore represent a synergistic approach to enhancing rumen function and profitability in intensive lamb production.

Effects of oilseed supplementation on organoleptic and nutritional quality of Rubia Gallega veal

C. Montes[1], S. Crecente[1], C. García[2], R. Alonso[2], T. Moreno[1]
[1] Mabegondo Agricultural Research Centre, Betanzos–Santiago Road, km 7, 15318 A Coruña, Spain, [2] Meat Technology Centre, San Cibrao das Viñas, 32900 Ourense, Spain

Dietary supplementation with essential oils derived from hydrolysed R. communis oilseed (Bovino Plus ®) was evaluated as a nutritional strategy to modulate Longissimus th. muscle on physicochemical and fatty acid analyses. Twenty-four Rubia Gallega male calves from Mabegondo Agricultural Research Centre herd were randomly assigned to one of three treatment groups for 90 days: control (G0), 10 mL/animal/day of essential oils supplement (G1) or 20 mL/animal/day of essential oils supplement (G2). Animals were fed indoors with concentrate and hay ad libitum. The intake of concentrate was calculated daily for each group as the difference between the amount offered and the amount refused (mean daily intake 6.08 kg DM /calve/day). Animals were slaughtered at 312 days of age, with mean slaughter live weights of 449.25 kg (G0), 437.25 kg (G1), and 465.87 kg (G2), and a mean carcass weight of 250 kg (G0), 243 kg (G1) and 272 kg (G2). Carcasses were classified according to the EUROP system as R+2+ for G0, U−2+ for G1, and U2+ for G2. At 48 h postmortem, the Longissimus th. was dissected from the left half-carcasses and transported to the Meat Technology Centre. Subsequently, pH, L*, a*, b* and the percentages of moisture, fat, protein, and ash were determined. Finally, the extraction, derivatization, methylation, and chromatographic analysis of fatty acids present in the Longissimus th. were carried out. All statistical analyses were performed using R Commander for Windows, version 4.3.2. High oil supplementation (G2) increased significantly ash (G0: 1.10 ± 0.07 vs. G2: 1.16 ± 0.03, $P < 0.05$) and protein contents (G1: 21.40 ± 0.53 vs. G2: 22.06 ± 0.29, $P < 0.05$) and reduced intramuscular fat compared with G0 (G0: 1.95 ± 0.68 vs. G2: 1.00 ± 0.55; $P < 0.01$). Muscle $pH_{(24)}$ was higher in G2 but remained within acceptable technological ranges. Significant differences in trichromatic coordinates were observed between G2 and the G0 and G1 treatment group. L* value was significantly higher in G2 than in G1, with no appreciable differences compared with G0 (G1: 42.95 ± 3.87 vs. G2: 48.38 ± 5.12, $P < 0.05$). Similarly, a* value was higher in G2 than in G1, while no significant differences were detected between G0 and the supplemented groups (G1: 12.46 ± 0.85 vs. G2: 14.15 ± 1.08, $P < 0.01$). The value of b* was significantly higher in G2 compared with both G0 and G1 (G0: 13.71 ± 1.08 and G1: 14.09 ± 1.45 vs. G2: 16.56 ± 2.51, $P < 0.05$).Total PUFA content was significantly higher in G2 than in G0 (G0: 12.19 ± 2.42 vs. G2: 17.87 ± 4.72; $P < 0.05$), with increased n-3 PUFA, including EPA (G0: 0.40 ± 0.11 vs. G2: 0.80 ± 0.31, $P < 0.01$), DHA (G0: 0.12 ± 0.02 vs. G2: 0.19 ± 0.05, $P < 0.01$) and DPA (G0: 1.01 ± 0.20 vs. G2: 1.63 ± 0.46, $P < 0.05$). The PUFA/SFA ratio improved in G2 (G0: 0.26 ± 0.09 vs. G2: 0.39 ± 0.11, $P < 0.05$), while total SFA did not differ among treatments. C14:0 decreased in G2 (G0: 2.71 ± 0.61 vs. G2: 1.98 ± 0.19, $P < 0.01$). The n-6/n-3 ratio remained below recommended thresholds in all groups (G0: 3.93 ± 0.46, G1: 3.78 ± 0.50 and G2: 3.78 ± 0.30, n.s.). In conclusion, supplementation with 20 mL/animal/day of hydrolysed R. communis oilseed improve meat physicochemical quality. In general, meat colour improved significantly in G2, with higher L*, a* and b* values, suggesting enhanced oxidative stability associated with bioactive compounds naturally present in R. communis oilseed. Finally, the treatment resulted in a more favourable nutritional lipid profile through increased PUFA deposition, supporting its potential as a functional feed additive in Rubia Gallega veal production.

Immune-activating PhytoComplex solution reduces cryptosporidiosis severity in neonatal calves through Interleukin-18–mediated host defense

M. De Kock[1], Y. Han[2], E. H. Wall[2], M. M. Mia[3], A. R. Azam[3], W. H. Witola[3]
[1] Trouw Nutrition B.V., Gut Health and Resilience, 77 Station Street, 3811MH Amersfoort, Netherlands, [2] Nutreco Explorations, Nutreco Switzerland, Amriswilerstrasse 50, 9320 Arbon, Switzerland, [3] University of Illinois Urbana-Champaign, Department of Pathobiology, College of Veterinary Medicine, 2001 S Lincoln Ave, 61802 Urbana, Illinois, United States

Cryptosporidiosis, caused by Cryptosporidium parvum, is one of the most common causes of neonatal calf diarrhoea worldwide and leads to impaired growth, intestinal damage, and substantial economic losses. Due to the absence of effective vaccines or curative treatments for calves, nutritional strategies that enhance early-life immune readiness are of increasing scientific interest. A proprietary PhytoComplex solution (PC15, Selko US, Indianapolis) containing green tea, cinnamon, and pomegranate extracts has shown potential in a cryptosporidiosis mouse model to support innate immune activation, particularly via interleukin-18 (IL-18)–mediated antimicrobial peptide (AMP) production. Two randomised challenge trials involving male Holstein calves were conducted to investigate whether PC15 supplementation improves clinical outcomes, reduces oocyst shedding, and enhances innate immune responses in neonatal calves experimentally infected with C. parvum. In the first trial, fifteen calves were assigned to three groups: uninfected controls, infected controls, and infected calves receiving 25 mg PC15/kg BW (equivalent to 1333 mg/kg CMR). All infected calves received 5×10^5 C. parvum oocysts orally on day 3. Faecal oocyst shedding (qPCR), faecal scores, body weight, and intestinal IL-18 expression (day 14) were recorded. In the second trial, twenty-five calves were allocated to uninfected controls, infected controls, or infected calves receiving 3.75, 7.5, or 11.25 mg PC15/kg BW (200–600 mg/kg CMR). Study duration was 10 days. Methods matched the first trial. In both studies, infected control calves exhibited typical cryptosporidiosis symptoms, including diarrhoea, reduced body condition, and progressive oocyst shedding. In the first trial, PC15-supplemented calves showed no clinical signs of disease, gained 778 g/day more weight ($P < 0.0001$), and exhibited 99% lower oocyst shedding on day 14 ($P = 0.0013$) compared with infected controls. IL-18 expression was significantly elevated ($P < 0.0001$), and intestinal structure remained intact. In the second trial, PC15 produced clear dose-dependent effects: calves receiving the highest inclusion rate achieved 478 g/day greater weight gain ($P < 0.0001$) and up to a 201-fold reduction ($P = 0.009$) in oocyst shedding compared with infected controls. PC15 significantly reduced the severity of cryptosporidiosis across two independent challenge studies. The findings support an immune-mediated mode of action, whereby PC15 enhances IL-18-driven antimicrobial peptide production and strengthens intestinal defence mechanisms. These results indicate that PC15 may contribute meaningfully to early-life resilience against enteric parasitic infections in calves. Keywords: Cryptosporidiosis, neonatal calves, phytogenics, PhytoComplex solution, IL-18, intestinal immunity, oocyst shedding

Supplementing a Bacillus-based probiotic to mitigate frothy bloat in beef cattle receiving a high-concentrate diet

R. Cooke[1], B. Cappellozza[2]
[1] Texas A&M University, Animal Sciences, 2471 TAMU, 77843 College Station, United States, [2] Novonesis, Animal Business Unit, Biologiens Vej 2, 2800 Lyngby, Denmark

Bacillus-based direct-fed microbials are proposed to modulate ruminal fermentation and microbial ecology, but their effects on physicochemical factors associated with frothy bloat are not fully understood. This experiment compared the incidence of frothy bloat, as well as ruminal, physiological, and performance responses of beef heifers receiving a bloat-provoking diet and supplemented with a Bacillus-based probiotic (BAC; Bacillus licheniformis + B. subtilis; BovacillusTM; Novonesis, Lyngby, Denmark). Sixteen ruminally-cannulated yearling Angus-influenced heifers were ranked by pre-trial body weight (BW) and assigned to 2 groups of 8 heifers each. Groups were enrolled in a 2 x 2 Latin square design containing 2 periods of 28 days, and a 14-day washout interval between periods. Groups were assigned to receive no BAC supplementation (CON; n = 16) or BAC supplementation at 3.0 g/heifer daily (n = 16) from day 0 to 28. During each period, heifers (n = 16/treatment) were housed in individual pens, and fed a sorghum-based bloat-provocative diet at 2% of their BW. Diet and treatments were individually fed to heifers, twice daily in equal proportions (0700 and 1600 h). Heifer unshrunk BW was recorded on days -3, -2, and -1 relative to the beginning of each period and averaged for initial BW. Final BW was calculated by averaging heifer BW on days 26, 27, and 28 of each period. Heifers were assessed for bloat score (0 to 5 scale, increasing according to bloat severity) 3 h after the morning feeding. Rumen fluid samples were collected via rumen cannula on days 0 and 28 of, immediately prior to (0 h) and at 3, 6, and 9 h relative to the morning feeding. Results obtained on day 0 were averaged and used as independent covariate in each respective analysis. No treatment differences were detected ($P \geq 0.45$) for heifer BW gain or gain:feed ratio. No treatment differences were detected ($P \geq 0.59$) for mean bloat score during the experiment (1.15 vs. 1.16 for BAC and CON heifers, respectively; SEM = 0.95) and rumen pH on day 28 (5.83 vs. 5.80 for BAC and CON heifers, respectively; SEM = 0.06). Heifers assigned to BAC had less ($P = 0.04$) rumen fluid viscosity (3.15 vs. 3.89 mPa.s.; SEM = 0.32) and less ($P = 0.05$) ruminal protozoa count on day 28 compared with CON heifers (8.53×10^5 vs. 1.02×10^4 cells/mL; SEM = 7.0×10^4). Heifers assigned to BAC had less ($P = 0.03$) valerate concentrations in the rumen fluid compared with CON heifers (4.41 vs. 5.21 mM, respectively; SEM = 0.55), whereas no other treatment effects were detected ($P \geq 0.14$) for concentrations of individual and total volatile fatty acids in the rumen fluid. In summary, supplementing BAC to beef heifers consuming a sorghum-based bloat-provocative diet decreased viscosity and protozoa population in the rumen fluid, but did not improve rumen fermentation responses nor mitigated the incidence of frothy bloat.

Effects of vitamin D_3 on cell viability, myogenic regulatory factors, and antioxidant responses in bovine skeletal muscle cells under heat stress

J. H. Lee[1], X. C. Jin[1], B. M. Kim[1], H. J. Oh[1], J. S. Lee[1], H. G. Lee[1]
[1] Konkuk University, Department of Animal Science and Technology, College of Life Science, 120 Neung-dong-ro, Gwangjin-gu, 05029 Seoul, South Korea

Heat stress is a major environmental challenge that impairs skeletal muscle development and redox homeostasis in cattle. Vitamin D_3 (1,25-dihydroxyvitamin D_3) is known to regulate muscle metabolism and oxidative balance. However, its role in bovine skeletal muscle cells under heat stress remains unclear. This study aimed to evaluate the effects of vitamin D_3 on cell viability, myogenic regulatory factors, antioxidant gene expression, and heat shock proteins in heat-stressed bovine skeletal muscle-derived cells (BSMCs). BSMCs isolated from Korean native cattle (Hanwoo) were treated with vitamin D_3 (0, 1, 10, and 100 nM) and exposed to heat stress at 41 °C for 48 h. Cell viability was evaluated using a CCK-8 assay in a separate experiment. For gene expression analysis, cells were exposed to heat stress (41 °C) for 48 h during mid-differentiation (d 2–4), and samples were collected immediately after heat exposure (d 4). The expression of myogenic regulatory factors (Myf5, MyoD, MyoG, Myf6), antioxidant enzymes (GPX1, GPX4, SOD1, SOD2, NRF2), and heat shock proteins (HSPB1 and HSP70) was analyzed by qPCR. Data were analyzed using the MIXED procedure of SAS, and significance was declared at $p < 0.05$. Heat stress significantly reduced cell viability ($p < 0.01$). Vitamin D_3 treatment improved cell viability under heat stress. The 1 nM group restored viability to a level comparable to the normothermic control, whereas the 10 and 100 nM groups did not fully restore viability to the control level. Heat stress significantly increased HSPB1 ($p < 0.01$) and HSP70 ($p < 0.05$), and this increase remained high across all heat-exposed groups. Heat exposure altered myogenic regulatory factors, with significant changes observed in Myf5 and Myf6 ($p < 0.01$), whereas MyoD and MyoG were not significantly different. Antioxidant-related genes showed heat-responsive changes. GPX1 and SOD1 were significantly increased under heat stress ($p < 0.01$). SOD2 expression was increased by heat stress and decreased with increasing vitamin D_3 concentration ($p < 0.01$). NRF2 was significantly increased only in the 100 nM group under heat stress ($p < 0.05$), whereas GPX4 was not significantly different ($p = 0.0625$). In conclusion, vitamin D_3 improved cell viability under heat stress and modulated myogenic and antioxidant gene expression, whereas heat shock protein induction remained robust under heat exposure. These findings indicate the potential of vitamin D_3 as a nutritional strategy to support muscle cellular stability during thermal stress in cattle.

Targeted cis-9, trans-11 CLA bioconversion in in vitro rumen fermentation catalyzed by Bifidobacterium-based probiotic and postbiotic supplementation

A. Elnar[1], J. Jeong[1], G. Kim[1], R. Kang[1], G. B. Kim[2], T. Park[1]
[1] Ruminant Nutrition and Physiology Laboratory, Department of Animal Science and Technology, Chung-Ang University, 4726 Seodong-daero, Daedeok-myeon, 17546 Anseong, South Korea, [2] Laboratory of Dairy Technology and Microbiology, Department of Animal Science and Technology, Chung-Ang University, 4726 Seodong-daero, Daedeok-myeon, 17546 Anseong, South Korea

Conjugated linoleic acid (CLA) is a bioactive lipid widely consumed as a dietary supplement due to its reported health promoting properties. Commercial CLA is typically derived from plant oils via chemical synthesis; however, this process generates a heterogenous isomer mixture, reducing biological efficacy due to poor isomer specificity. Microbial biosynthesis offers a superior alternative, as microbial enzymes preferentially convert linoleic acid (LA) into a single CLA isomer, most commonly cis-9, trans-11 isomer. In this study, Bifidobacterium breve JKL2022, a potent producer of cis-9, trans-11 CLA, was investigated for potential applications beyond conventional probiotic use. Probiotic and postbiotic preparations of JKL2022 were evaluated as biocatalysts for CLA production in two systems: in vitro vegetable oil fermentation and in vitro rumen fermentation. Under a controlled one-step in vitro digestion of grapeseed oil with CRL lipase and JKL2022 linoleic acid isomerase, preferential conversion to cis-9, trans-11 CLA was achieved at high efficiency (87.71 ± 1.45% – 91.27 ± 0.79%). Efficient conversion of conjugated linolenic acid (CLnA) from perilla seed oil was also observed, highlighting the feasibility of valorizing low-cost plant oils into high-value bioactive lipids. Under in vitro rumen fermentation conditions, supplementation of either probiotics or postbiotics preparation of JKL2022 (10^{10} CFU/mL) resulted in early CLA production. Addition of 0.5 – 1.0 mg/mL of LA lead to detectable cis-9, trans-11 CLA within the first 3 h of fermentation, catalyzed by probiotic (21.76 ± 3.33 µg/mL) and postbiotic (16.84 ± 2.08 µg/mL) preparations. Further fermentation shifted the lipid profile from CLA toward vaccenic acid (C18:1), consistent with rumen microbial biohydrogenation. Importantly, early CLA production may enhance mammary uptake of CLA and vaccenic acid, potentially increasing milk CLA content. Overall, B. breve JKL2022 exhibits a unique capacity for highly specific CLA biosynthesis in both food and rumen-simulated systems. These findings support its development as a probiotic or postbiotic strategy for targeted bioactive lipid production, with potential application in functional feeds, dairy quality enhancement, and sustainable lipid bioprocessing.

The effect of lowering the crude protein of dairy diets with the addition of either a molasses based liquid feed (Regumix) alone or with Regumix + methionine supplementation on production performance and efficiency

G. Chapman[1], P. Holder[1]
[1] ED&F Man Liquid Products UK, Alexandra House, Regent Road, L20 1ES Liverpool, United Kingdom

Excess dietary protein increases urinary and faecal urea excretion, contributing to environmental load. Providing rapidly fermentable carbohydrates, such as sugars, can improve ruminal nitrogen capture and reduce nitrogen losses with a recent trial showing a 7.6% reduction in urinary nitrogen when feeding Regumix, a 27% protein molasses-based liquid feed. Research on sugars in lower-CP diets and their effects on performance and health remains limited. Methionine is typically the first limiting amino acid in UK dairy diets, and overfeeding CP to supply essential amino acids is inefficient. Targeted amino acid supplementation offers a more sustainable approach amid pressure to cut carbon, nitrogen, and soya use. This study aimed to assess whether the nitrogen efficiency benefits of fermentable carbohydrates persist under reduced CP diets and whether methionine supplementation offers additional advantages on protein efficiency, milk production, and environmental sustainability in dairy cows. A continuous 11-week experiment was conducted with 42 lactating Holstein cows, including a 2-week covariate period followed by 9 weeks of measurement. Cows were assigned to one of three diets—Control (FD), Regumix (LF), or Regumix + MetaSmart methionine supplement (PLF)—with CP levels of 17.5%, 16.3% and 16.1%, respectively, and 14 cows per treatment. Blocking was based on covariate milk yield, stage of lactation and parity; cows were >35 L/day yield, targeted at 40 L, and 100–140 DIM at study start. Diets consisted of grass silage, maize silage, concentrate blend and molasses-based liquid feeds, fed ad libitum as a TMR via Calan gates. Diets were formulated to be isoenergetic by adjusting the blend and adding 1.4 kg of each liquid feed to LF and PLF. Measurements included daily DMI and weekly milk yield, milk composition, liveweight and BCS. Data was analysed using the Mixed procedure of SAS® and a model testing fixed effects of treatment, week, their interaction, and the random effect of cow within block, using covariate measurements and blocking variables (parity, days in milk) as fixed effects. Results found no statistical difference in milk yield across the 3 treatments despite lower dietary protein levels. When dietary CP was analysed and calculated, the actual CP feeding levels were 17.4%, 15.4% and 15.4% for the FD, LF and PLF respectively. Cows on the PLF diet exhibited higher milk protein percentages and improved BCS in late lactation, showing greater resilience and indicating better energy balance and metabolic health. Total Protein Efficiency (TPE) was calculated as follows TPE = (milk yield×milk protein %)/(DMI×CP%), and showed a 17% improvement with the PLF diet, demonstrating more effective conversion of dietary protein into saleable milk protein. Lower milk urea concentrations in both treatment groups suggested enhanced nitrogen metabolism. In conclusion, precision liquid feeding offers a viable and sustainable alternative to traditional high CP diets enhancing protein efficiency and supporting cow health through maintenance of BCS through lactation. By reducing the CP feeding level by 1.4% in a ration, this could, for example, equate to a removal of around 300g of high-protein soybean meal per cow per day, equating to a potential saving of over 185,000 tonnes annually across the UK dairy herd helping meet environmental goals in the industry.

Dietary Polyphenols Modulate Milk Production and Udder Inflammation in Commercial Dairy Herds

G. H. M. Marcelino[1], W. V. B. Soares[2], B. Hortolani[3], L. C. Roma Junior[2]
[1] Instituto de Zootecnia, Pos Graduaçao, Rua Heitor Penteado 56, 13380011 Nova ODessa, Brazil, [2] Instituto de Zootecnia, Divisao de Pesquisa e Desenvolvimento de Bovinos Leiteiros, Rua Heitor Penteado 56, 13380011 Nova ODessa, Brazil, [3] Autonoma, Zootecnista, Rua Pedro Leonardi 60, 13920000 Pedreira, Brazil

The use of polyphenols in dairy cows nutrition has gained attention due to their antioxidant and anti-inflammatory properties and their potential to modulate the ruminal microbiota, favoring metabolic efficiency regarding nutrient utilization and mammary gland health. These bioactive compounds have been investigated as sustainable alternatives capable of improving productive performance and reducing losses associated with subclinical mastitis. Considering such benefits, it becomes relevant to study its application in commercial herds and to determine the effects of the polyphenolic bioactive on milk production and udder health, at different stages of lactation and classes of somatic cell count. Therefore, this study was conducted on 10 commercial dairy farms in the State of São Paulo, Brazil, totaling 429 lactating cows, whose objective was to evaluate the effect of the polyphenolic compound extracted from sugarcane (Polygain™, The Product Makers, Australia) on milk production and mammary gland health. Supplementation was provided for 28 days, at 50 g/animal/day dosage, incorporated into the diet and without any changes in feeding or milking protocols. Individual data on milk yield (kg/cow/day) and somatic cell count (SC $\times 10^3$/mL) were collected on days 0 (D0) and 28 (D28). SCC analyses were performed in a reference laboratory, and the values were log-transformed for statistical analysis. For the purpose of SCC classification, cows were categorized into three categories: class 1 (≤200 thousand cells/mL), class 2 (201–500 thousand cells/mL), and class 3 (>501 thousand cells/mL). Lactation stage was also categorized into three phases: early (≤100 days), mid (101–200 days), and late (201–305 days). Data normality was verified by the Shapiro-Wilk test. Comparisons between D0 and D28 were performed using the paired Wilcoxon and KruskalWallis tests, adopting a statistical significance level of 5%. The polyphenol supplementation showed specific effects according to lactation stage and SCC class. For cows in class 1 and in early lactation, a significant increase in milk yield was observed, from 41.5 to 42.8 kg/day (P=0.0133), although this effect is more associated with the production peak of the period than with the bioactive. Regarding SCC, a significant reduction was observed only in animals in class 3. For the early stage, SCC decreased from 1,891 to 139 thousand cells/mL (P=0.0078), while for late lactation it decreased from 2,551 to 1,835 thousand cells/mL (P=0.0234), indicating a better response of the product in cows with more pronounced inflammation. Supplementation with polyphenols derived from sugarcane extract demonstrated potential to improve mammary gland health indicators, especially in cows with elevated SCC, in which expressive reductions were observed. The effect on milk yield was limited and mainly influenced by lactation stage. These results suggest that the use of polyphenolic compounds may be a complementary strategy to support udder health, particularly in animals with greater inflammatory challenge, contributing to more efficient and sustainable production systems.

Effect of a phytogenic ingredient mixture on rumen degradability of soybean meal protein

F. Gadeyne[1], J. Jeyanathan[2], V. Fievez[2]
[1] Royal Agrifirm Group, Landgoedlaan 20, 7325 AW Apeldoorn, Netherlands, [2] Ghent University, Department of Animal Sciences and Aquatic Ecology, Coupure Links 653, 9000 Ghent, Belgium

Improving nitrogen (N) efficiency is of utmost importance for farmers to lower their N emissions while maximizing farm profits. Phytogenic ingredients (PHY) can be used to decrease rumen degradability of dietary protein, thereby nutritionally optimizing cattle diets in an economic way and allowing farmers to comply working within tighter environmental constraints. An in vitro experiment was designed to evaluate the effect of Nsure, a mixture of PHY, on rumen degradability (DM and CP), NH3-N accumulation and fermentability (CH4 and volatile fatty acids; VFA) of soybean meal (SM). Therefore, 500 mg, consisting of 475 mg SM (449 g CP/kg), Nsure (0, 3.125, 6.25, 12.5 or 25 mg) and limestone as filler, was placed into sealed nylon bags (pore size 37 µm) and incubated in triplicate in sealed CO2-flushed 250-ml flasks for 24h in a shaking incubator with 50 ml CO2-saturated phosphate/bicarbonate-buffer (0.8 v/v) and inoculum (0.2 v/v) derived from 3 rumen fistulated dairy cows. A linear decrease in degradability of SM was observed with increasing Nsure inclusion for DM (70.0, 69.5, 68.1, 67.2 and 65.3 % of DM0h, resp.; -0.93% per % Nsure, SE=0.374, R^2=0.32, P=0.027) and CP (49.6, 52.1, 49.4, 43.2 and 37.4 % of CP0h, resp.; -2.90% per % Nsure, SE=0.698, R^2=0.57, P=0.001). Protection against ruminal degradation seemed specific to the protein fraction of SM, as there was no linear effect (P=0.684) on the degradability of the non-CP DM fraction (83.9, 81.5, 80.6, 82.7 and 83.2 % of non-CP DM0h, resp.). Furthermore, NH3-N accumulation linearly decreased with increasing Nsure inclusion (311, 289, 282, 230 and 187 mg/L, resp.; -25.1 mg/L per % Nsure, SE=4.99, R^2=0.66, P<0.001). Also absolute CH4 and total VFA was linearly impacted (P=0.006), presumably because less degradable CP was available for microbial fermentation, without affecting relative CH4 production (mol/mol CH4/VFA; P=0.721). Molar proportions of iso-butyrate and -valerate, being indicators of CP degradation, were linearly decreasing as well (P<0.001), underlining the protective effect against ruminal protein breakdown. Further in vivo research is needed to validate the effect of Nsure on N efficiency in real life conditions.

Optimizing amino acid supply in early lactation cows improves production performance in commercial farm conditions

A. Vigh[1], M. Müller[1], J. Guyader[1]
[1] Evonik Operations GmbH, Rodenbacher Chaussee 4, 63457 Hanau, Germany

Optimizing amino acid supply, particularly methionine, during the early stages of lactation is a key strategy to enhance metabolic efficiency and milk production in high-yielding dairy cows. This study aimed at evaluating the effects of rumen-protected methionine (RP-Met) supplementation on production performances of early and peak lactating cows. A total of 140 Holstein cows from a German commercial farm were divided at calving into two experimental groups fed either a basal diet alone (CON) or supplemented with 15 g/day/cow of RP-Met (RPM, Mepron®, 85% DL-methionine, Evonik Industries, Germany). The supplementation lasted 14 weeks, but performance were evaluated for another 4 weeks to assess the carry-over effect of RP-Met. Individual milk yield (MY) was registered daily with an automated milking system (AMS) and milk composition were assessed monthly via the official milk recordings national agency. Statistical effects were analyzed based on a linear model using treatment and period (week) and their interaction as fixed effects. Least square means were compared using Tukey's test. Significance was declared when $P \leq 0.05$ and tendency with $0.05 < P \leq 0.10$. Milk yield significantly increased by +1.7 kg/day during the supplementation period with RPM in comparison to CON ($P<0.001$), while milk fat and protein content were not affected. Energy corrected milk (ECM) was significantly higher for the RPM group ($P<0.001$; 34.7 and 33.1 kg/day for RPM and CON, respectively) mainly driven by the higher milk fat yield ($P=0.017$; 1.37 and 1.30 kg/day for RPM and CON, respectively) and protein yield ($P=0.043$; 1.20 and 1.16 kg/day for RPM and CON, respectively). After finishing RPM supplementation, MY remained significantly higher for RPM in comparison to CON ($P<0.001$; 33.1 and 31.9 kg/day, respectively). The significant carry-over effect on MY after RP-Met supplementation highlights the importance of optimal methionine supply in improving the lactation persistency in high producing dairy cows. These results confirm the value of RP-Met as a practical tool for amino acid balancing and metabolic optimization in modern dairy production systems.

Microalgae supplementation enhances omega-3 PUFA in lamb meat and its consumption improves blood fatty acid status in consumers

L. Perkins[1], O. Cristobal Carballo[2], F. Godoy Santos[1], S. Morrison[2], A. Aubry[2], E. Lewis[3], T. Yan[2], N. Scollan[1], S. Huws[1]
[1] Queen's University Belfast, School of Biological Sciences, 19 Chlorine Gardens, BT95DL Belfast, United Kingdom, [2] Agri-Food and Biosciences Institute, Large Park, BT26 6DR Hillsborough, United Kingdom, [3] Devenish Nutrition, 122-126 Duncrue Street, BT3 9AR Belfast, United Kingdom

Long-chain omega-3 (n-3) polyunsaturated fatty acids (FA), including eicosapentaenoic acid (C20:5 n-3; EPA) and docosahexaenoic acid (C22:6 n-3; DHA), are essential for optimal human health and well-being. Traditionally, n-3 in lamb is derived from grass-based diets, but alternative strategies are needed to further enhance its nutritional profile. Microalgae finishing also offers sustainability benefits, including the potential to reduce methane emissions from livestock. The aim of this study was to investigate the impact of consuming microalgae finished lamb meat, compared to a control, on blood FA response and cardiovascular risk factors among healthy consumers. Lambs were supplemented with microalgae supplemented (1.62% DM) or control diets (0% DM) for 11 weeks until slaughter. Healthy participants then consumed two portions per week of these lambs in a six-week, single-blinded, dietary intervention. Blood samples were taken at baseline (week 0), mid-way (week 3) and post-intervention (week 6) for FA and cholesterol analysis. Weight, body mass index (BMI) and blood pressure measurements were also taken. FAs from blood plasma, plasma phospholipids and red blood cells were extracted using a chloroform: methanol method. Fatty acid methyl esters (FAMEs) were analysed by GC-FID. Repeated measures ANCOVA, with baseline values as covariates, was used to evaluate the effects of lamb treatment (microalgae-finished vs. control) over time, including treatment, time, and treatment X time interactions ($p < 0.05$). Microalgae finishing increased the n-3 content of the lamb, and consumption of this meat led to detectable changes in blood FA profiles. Changes in cholesterol fractions were observed, while BMI and blood pressure remained unchanged. Regular consumption of microalgae-finished lamb, as part of a balanced diet, increases blood n-3 FA levels, which is associated with improved health and well-being.

Grape pomace silage in the finishing diet of beef steers

L. Forte[1], M. Santoro[1], G. Calzaretti[1], F. Rosalia[2], R. Roma[2], P. De Palo[1], A. Maggiolino[1]
[1] University of Bari Aldo Moro, Department of Veterinary Medicine, Strada Provinciale per Casamassima km 3, 70010 Valenzano, Italy, [2] University of Bari Aldo Moro, Department of Soil, Plant and Food Science, Via Amendola 165/a, 70126 Bari, Italy

Vitis vinifera L. is one of the most widely cultivated fruit crops, with an annual production exceeding 67 million tons and generating up to 200 kg of solid waste per 750 liters of wine. Approximately 60% of these by-products is grape pomace, a mixture of skins, seeds, stems, wastewater, and lees. Incorporating grape pomace into animal diets is a promising strategy to reduce feed costs, disposal expenses, and competition for food resources between humans and livestock. This study evaluated the inclusion of grape pomace silage (GPS) at two different inclusion levels in the finishing diet of beef steers and its effects on body weight, blood biochemical and oxidative profiles, and meat quality during dry aging. Finally, this study aimed to compare the cradle-to-farm gate environmental sustainability of two different inclusion levels of GPS. A total of 48 crossbred Holstein × Belgian Blue steers were enrolled in the trial. The experiment was conducted in three replicates, spaced two weeks apart. Within each replicate, the 16 animals were randomly assigned to one of three dietary treatments: a control group (C) receiving 150 g/kg DM of wheat straw, a low grape pomace group (LGP) receiving 50 g/kg DM of grape pomace replacing straw, and a high grape pomace group (HGP) receiving 100 g/kg DM of grape pomace replacing straw. The feeding period lasted 60 days prior to slaughter. Body weights and blood samples were collected at the start of the feeding trial and after 60 days. Blood samples were analyzed to assess clinical biochemical and oxidative profiles. 24 h after slaughter bone-in loins from the thirteenth thoracic vertebrae to the sixth lumbar vertebrae were collected from the left side of each carcass and subjected to dry aging for 42 days. At each experimental time point (0, 14, 21, 28, 35, and 42 days), a 30 mm steak was cut from each loin for the analyses. Meat samples were evaluated for instrumental color, water-holding capacity, cooking loss, and oxidative profile, including both oxidation products and antioxidant potential (FRAP assay). Life cycle assessment (LCA) was used for environmental impact assessment. The functional unit was 1 kg of live weight gain. The studied environmental profile was applied to three categories of impact: global warming potential (GWP, kg CO2 -eq), water depletion (WD, m3 eq), and abiotic depletion of fossil fuels (ADP fuel, MJ), by using the SimaPro 10.1 PhD, PRé Consultants. Data were analyzed using SAS statistical software. Normality and homogeneity of variance were checked prior to analysis. An ANOVA (GLM) was then applied, considering diet, time, and their interaction as fixed effects. Preliminary results showed no significant effect of diet on blood clinical biochemical or oxidative profiles. Similarly, meat quality parameters were not significantly affected by diet, with the exception of TBARS. Notably, meat from animals fed GPS showed significantly lower TBARS concentrations during the dry aging period ($P<0.001$). These preliminary results suggest that GPS can be incorporated into finishing diets without compromising animal health, growth performance, or meat quality of beef steers. LCA results showed that LGP has the lowest GWP (1.8 kg CO2 eq,) WD (3.81 m3 eq). and ADP fuel (2.13) depletion compared with C and HGP. Moreover, this study also used the ratio between product value and environmental impact as an indicator of eco-efficiency: results highlighted that the eco-efficiency for main categories is most effective with LGP.

Multivariate relationships between carcass, muscle, and beef eating quality traits in Limousine cull cows

Y. Cui[1], A. Neveu[2], M. Kombolo[1], J. Liu[3], I. Legrand[4], F. Noel[4], P. Faure[1], D. Pethick[5], M. P. Ellies-Oury[1,6], J. F. Hocquette[1]

[1] INRAE, UMRH, Route deTheix, 63122 Saint-Genès Champanelle, France, [2] 2Birkenwood Europe, 960 route de Lanon, 03240 Saint-Sornin, France, [3] Teagasc, Department of Food Quality and Sensory Science, Teagasc Food Research Centre, D15 DY05 Dublin, Ireland, [4] Institut de l'Elevage, Service Qualité des Carcasses et des Viandes, Boulevard des Arcades, 87060 Limoges Cedex 2, France, [5] Food Futures Institute, Murdoch University, 6150 Perth, Australia, [6] Bordeaux Sciences Agro, CS40201, 33175 Gradignan Cedex, France

Adopting a grading scheme inspired by the Meat Standards Australia (MSA) system is considered an effective way to strengthen consumer confidence in beef across Europe. However, differences between Europe and Australia in cattle breeds, production systems, and consumer dietary habits require a re-examination of the links among carcass traits, muscle traits, and beef eating qualities. In France, cull cows constitute a major beef source, with Limousine cattle being one of the predominant breeds. Accordingly, this study evaluated 102 French Limousine cull cows (mean age 125.8 months) to investigate the relationships among carcass, muscles, and beef eating quality traits, and to explore the predictive value of key biological indicators for beef palatability. A comprehensive dataset integrating carcass grading traits assessed using the EUROP grid and the MSA protocol, muscle laboratory measurements, and consumer sensory score of beef was analyzed using correlation analysis, principal component analysis (PCA), and linear mixed-effects modelling. Carcass yield-related traits (carcass weight, conformation, and eye muscle area) were highly intercorrelated ($r > 0.8$) and moderately associated with consumer-evaluated eating quality. In contrast, indicators of intramuscular fat deposition (marbling and intramuscular fat content) showed no direct correlation with eating quality. PCA revealed a clear structural opposition between eating quality traits and compression force, highlighting compression force as a more informative structural indicator than Warner–Bratzler shear force (WBSF) in beef from older Limousine cull cows. When classifying carcasses based on the MSA grades, high consumer-graded samples clustered with multiple carcass traits related to yield and fat deposition, whereas low-graded samples were primarily associated with older age, higher compression force, elevated pH, and greater SFA content. Linear mixed-effects models demonstrated that marbling showed minimal contribution to eating quality prediction across muscles (marginal $R2 \leq 0.01$). In contrast, traits related to muscle development, including age, carcass conformation, and compression force, played a dominant role in determining eating quality ($P < 0.05$). Model performance differed between MSA grade groups. High-MSA grade samples exhibited more comprehensive biological features and achieved higher predictive accuracy. However, low-MSA grade samples showed reduced model performance, likely due to narrower sensory variation and higher trait homogenization. These findings indicate that predictors of beef eating quality depend on animal type and age. In older cull cows, predictors of eating quality are likely to be more specific, particularly those related to muscle structure and maturity, at least in part. Overall, these findings provide practical guidance for the beef industry in predicting beef eating quality and improving grading systems for cull cows.

The effect of post-slaughter time on marbling scores in beef carcasses

H. Shand[1], S. Connaughton[1], G. Gardner[1]
[1] Murdoch University, Meat Science, 90 South Street, Murdoch, 6150 Perth, Australia

Marbling is used throughout the beef industry to describe the visual fat characteristics of a specific cut, commonly the rib eye. Establishing a reliable and accurate grading method is imperative as international markets pay a premium for highly marbled products. At present, the standard practice for grading marbling involves the use of trained professionals who visually score the cuts, referencing the AUS-MEAT and MSA scoring system. AUS-MEAT scores range from 0-9, considering the amount of fat, whereas the MSA system scores range from 100 – 1190, which additionally takes into account the fineness and distribution of fat. However, recent imaging technologies such as the Q-FOM camera have been developed, allowing a much higher level of objective measurement and accuracy. Marbling scores are expected to increase over time, but to what extent and how rapidly remains undetermined. This is potentially beneficial to the meat processing plant as graded product may not be expressing the potential maximal marble score. Therefore, the objective of this research is to establish the optimal grading time post-slaughter, using Q-FOM grading technology. It was hypothesised that marble scores from both grain and grass-fed cattle will not increase after 24h and up to 96h post-slaughter. It is also hypothesised that grain-fed cattle will have greater marble scores compared to grass-fed cattle. A total of 120 carcasses (n = 60 grass-fed, n = 60 grain-fed) were graded visually and using the Q-FOM, from 24 h post-slaughter, up to 96 h. These 5 separate timepoints were taken from 6 individual chillers at the collaborating processing plant, and carcasses ranged from 210-980 MSA marble score. Samples from each animal were chemically analysed in a laboratory to determine intramuscular fat percentage (IMF%). Statistical analysis was conducted in RStudio, using a linear mixed effects model to test the interactions between IMF%, time and diet on marbling score. This helped to predict the change in marbling over time and how this differs between diets. It was determined that marble scores increase up until 47 hours post-slaughter, with no further increase in marble score beyond this time point. Between 24 and 36 hours, the exact rate at which marbling develops needs further investigation. As hypothesised, the grain-fed animals did produce greater marble scores compared to the grass-fed. Current practice of delaying the grading of grain-fed beef is maximising marble scores; grass-fed animals are not typically graded following the same protocols. These carcasses are graded at a maximum of 24 hours post-slaughter, which may not be sufficient time for the optimal marble score to be achieved. By extending this time to grading, there will be operating costs associated, as well as storage space, however this may be plausible for processing facilities. Further research is required to determine this potential return on investment.

Physicochemical quality differentiation of European beef cuts by retail price category, sex, and region reared

Y. Singh[1], M. Pozza[1], D. Martini[1], M. De Marchi[1]
[1] University of Padova, aDepartment of Agronomy, Food, Natural Resources, Animals and Environment, Viale dell'Università 16, Stecca 1, 35020 Legnaro, Italy

European beef production is highly fragmented, characterised by heterogeneous genetics, feeding regimes, and processing conditions that influence meat quality. Unlike unified carcass grading systems, the European beef market relies heavily on retail cut-based pricing, yet the relationship of these commercial price categories and physicochemical traits remains largely unquantified. This study tested whether retail price-based cut categorisation differentiates physicochemical quality, with sex and European region reared providing independent variation for market segmentation. Commercial beef cuts (n=83) were classified into Low (n=22; topside, brisket), Medium (n=39; rump, knuckle, flat iron), and High (n=22; tenderloin, picanha, cube roll, striploin) Price categories. Samples were sourced from Western (n=17; France, Holland, Ireland, Spain), Central (n=34; Austria, Czech Republic, Hungary, Slovakia), and Eastern (n=32; Poland, Latvia) Europe, and stratified by Sex (male, female). Assessed traits included colour, pH, cooking loss, water holding capacity (WHC), shear force (SF), and proximate composition. The obtained data were analysed using the GLM procedure of SAS. The model included the fixed effects of Price, Cut nested within Price, Sex, Region reared, and their 2-way interactions. The Price effect was tested using Cut nested within Price as the error term, whereas the other fixed effects were tested on the residual error. Model R^2 ranged from 0.27 to 0.70, indicating robust model fit for key traits. Price category significantly affected SF (F=7.04, P=0.027). The nested contrast confirmed a systematic tenderisation gradient scaling directly with price: Low (57.2 N), Medium (44.4 N), and High (23.3 N) (all pairwise P<0.05). Conversely, the Cut (Price) nested effect dominated compositional and colour traits (water F=9.94, protein F=4.03, fat F=7.08, collagen F=7.44, WHC F=6.62; P<0.01), reflecting how muscle-specific physiology drives biochemical composition within broader commercial price brackets. Sex independently influenced quality and functionality trade-offs. Compared to males, females exhibited higher fat (4.90% vs. 3.57%; P=0.038), elevated nutrition scores (129 vs. 117 kcal/g; P=0.026), greater fat-to-protein ratios (0.23 vs. 0.17; P=0.046), and significantly more tender meat (lower SF: 35.6 vs. 47.6 N; P=0.007). However, female beef displayed slightly lower WHC (40.7% vs. 41.2%; P=0.037). Region reared systematically shaped appearance and hydration profiles. Western beef presented superior lightness (L* 35.4 vs. 32.3 Central and 32.3 Eastern; P=0.003); chroma (C* 26.2 vs. 24.6 Central and 23.6 Eastern; P=0.036), alongside the highest salt content (1.10% vs. 0.76% Central and 0.82% Eastern; P=0.002). Eastern beef retained the highest overall water content (69.0% vs. 68.9% Western and 68.3% Central; P=0.012) but the lowest WHC (40.2% vs. 41.4% Western and 41.0% Central; P=0.005), suggesting fundamental variations in post-mortem chilling, aging, or processing practices across regional supply chains. All two-way interactions were non-significant (P>0.05), proving these three main effects operate independently. In conclusion, retail price categorisation serves as a reliable predictor of tenderness in the European beef market, successfully validated when isolating cut effects. Furthermore, sex differentiates energy density and tenderness, while rearing region shows distinct processing and hydration signatures. Integrating these independent parameters provides a comprehensive, scientifically validated framework for quality assessment, product valuation, and targeted consumer communication in the meat industry.

REIMS-based metabolic fingerprinting discriminates animal categories across muscle types, and ageing regimes in beef loin

Y. Cui[1], A. B. Ross[2], C. Realin[3], R. Zhang[3], D. Mou[2], V. Ruppert[2], J. F. Hocquette[1]
[1] INRAE, UMRH, Theix, 63122 Saint-Genès Champanelle, France, [2] New Zealand Institute for Bioeconomy Science Limited, Smart Foods and Bioproducts, Tuhiraki, 7608 Lincoln, New Zealand, [3] New Zealand Institute for Bioeconomy Science Limited, Smart Foods and Bioproducts, Private Bag 11008, 4442 Palmerston North, New Zealand

Meat ageing is a complex biochemical process influenced by multiple biological and processing factors. Rapid evaporative ionization mass spectrometry (REIMS) is a minimally invasive analytical technique with direct measurement times <10 seconds, that has shown potential for monitoring quality changes during meat ageing. The ability of REIMS to discriminate meat samples from different backgrounds and ageing conditions remains underexplored. We hypothesised that REIMS can discriminate beef samples across animal categories, muscle types, and ageing conditions, and that its performance depends on the magnitude of biochemical changes induced during ageing. In this study, REIMS was applied to a multiclass dataset including aged meat samples from multiple animal categories (adult cattle, yearling cattle, heifers, and steers) across three beef cuts (loin, chuck, and topside). Loin samples from different categories were further subjected to either wet-ageing to test the effects of ageing time (0, 5, and 21 d) or to ageing regimes (unaged, in-bag dry ageing, stepwise ageing) for 28 d. Stepwise ageing refers to wet-ageing for 14 d followed by in-bag dry-ageing for 14 d. Multivariate classification was performed using orthogonal partial least squares – hierarchical discriminant analysis (OPLS-HDA), and multivariate modelling with unbiased variable selection in R (MUVR) was applied for model validation. REIMS fingerprinting exhibited robust discrimination of muscle cuts across adult and yearling beef with an accuracy of 80.5%, indicating that muscle-specific structural and metabolic characteristics represented the dominant source of variation compared with animal category. Discrimination of wet-ageing time of beef loins achieved an overall accuracy of 70.8%, with a clear difference in performance between animal categories. Pronounced class separation was observed in 21 d aged samples from adult cattle compared with unaged samples and aged for 5 d. In contrast, loin samples from yearling calves showed no clear discrimination in REIMS fingerprints across ageing time. In-bag dry-ageing was the primary factor distinguishing between ageing regimes, producing the greatest cluster separation from stepwise-aged and unaged samples, which partially overlapped. However, beef from heifers and steers could not be reliably distinguished under either dry or stepwise ageing, with a classification accuracy <50%. Overall, these results support the potential of REIMS as a rapid tool for discriminating animal age and muscle types, and evaluation of changes during ageing processes.

Growth performance in Chianina cattle: a 10-year database comparison between PGI production scheme and EU mandatory beef labelling system

A. Fioroni[1], L. Seri[2], R. Fioroni[2], V. Bolletta[3], M. Pauselli[3]
[1] Soc. Coop. Bovinitaly, Quality, Development, and Research, Via Delle Fascine 4, 06132 San Martino, Perugia, Italy, [2] Galileo Galilei Scientific High School, Cambridge International, Via Carlo Manuali 12, 06122 Perugia, Italy, [3] University of Perugia, Department of Agricultural, Food and Environmental Sciences, Borgo XX Giugno, 06121 Perugia, Italy

The production of the native Italian beef cattle breed Chianina is characterized by the coexistence of two management systems. The first is the mandatory Regulation (EC) No. 1760/2000 labeling system (ETQ-Ch), generally adopted by specialized fattening centers and characterized by standardized rations and greater use of non-local feed ingredients. The second is the PGI "Vitellone Bianco dell'Appennino Centrale" system (PGI-Ch), a voluntary scheme which imposes stricter requirements on geographical area, animal genealogy and feeding practices to strengthen the link between meat characteristics and territory. Quantitative evidence on how these different management strategies affect animal growth performance remains limited, despite their practical relevance for farm management. Therefore, we hypothesized that the PGI-Ch and ETQ-Ch production systems would differ in animal growth performance. The study was conducted using data obtained from the Italian National Cattle Database (BDN, Teramo). Male cattle recorded as Chianina in the BDN, aged between 600 and 750 days and slaughtered between 2012 and 2022 at the Perugia Meat Slaughtering Centre were included. Age at slaughter, carcass weight and average daily carcass gain (ADG) were evaluated. Animals with incomplete records for any of the analysed variables were excluded. The dataset comprised PGI-Ch (n = 17,415) and ETQ-Ch (n = 3,557) animals, for a total of 20,972 records. Differences between the systems were analysed using a general linear model including the fixed effect of the identification system (PGI-Ch vs ETQ-Ch). The relationship between age at slaughter and ADG was evaluated using simple linear regression. Normality and homoscedasticity assumptions were verified through residual analysis and variance tests. Outliers were identified through graphical inspection of residuals and evaluated based on biological plausibility. Results were considered significant when $P \leq 0.05$ and a tendency when $0.05 < P \leq 0.10$. Statistical analyses were performed using SAS® 9.4. Average slaughter age was 649.82 ± 74.62 days (SD) and 623.11 ± 86.71 days (SD) for PGI-Ch and ETQ-Ch, respectively, although the difference was not statistically significant. Average carcass weight was 480.24 ± 75.54 kg (SD) for PGI-Ch and 477.84 ± 72.19 kg (SD) for ETQ-Ch, showing a tendency towards heavier carcasses in the PGI-Ch group ($P = 0.07$). The ADG was higher in ETQ-Ch animals than in PGI-Ch animals (0.774 vs. 0.745 kg/day) ($P < 0.001$). This difference may reflect the feeding strategies adopted in ETQ-Ch, which often involve higher energy density. Moreover, this result may partly reflect genetic selection and the search for phenotypic standardization in the Chianina breed over time, contributing to more homogeneous production performance even among non-PGI animals. For both groups, a negative relationship was observed between age at slaughter and ADG, consistent with the physiological growth of the animals ($R^2 = 0.32$). In conclusion, the results suggest that animal performance parameters are influenced by the rearing system, with higher ADG for ETQ-Ch animals. Further research integrating farming management (feed ingredient origin, environmental conditions, etc.) and meat quality traits is needed to define sustainable production strategies while supporting the valorisation of native breeds and typical products.

When beef turns brown: a cross-country comparison of consumer preferences in Germany and USA

B. A. Altmann[1], E. López-Escalante[1], A. Thies[2], N. Kemper[1], M. N. Nair[3]
[1] University for Veterinary Medicine Hannover, Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] Johann Heinrich von Thuenen Institute, Institute of Market Analysis, Bundesallee 63, 38116 Braunschweig, Germany, [3] Colorado State University, Department of Animal Sciences, 350 W. Pitkin St., 80523 Fort Collins, United States

In the USA, 197 million kg of beef is wasted annually due to discoloration at retail. To reach the Sustainable Development Goal (SDG) 12.3 of halving per capita food waste by 2030, an understanding of consumer preference for beef color is needed to tailor market strategies. Our research compares consumers' willingness-to-pay (WTP) for beef strip loin (longissimus lumborum) steak stored for up to 9 days under retail conditions. Photos of steaks during retail display at days 0, 4, 7, and 9 were incorporated into a discrete choice experiment including 4 levels of real market country-specific prices, and a sale sticker (30% off). Consumers in Colorado, USA (n=297; June – August 2023) and Lower Saxony, Germany (n=154; September – December 2025) completed the choice task programmed in Qualtrics running on an iPad. Choice data were analysed using multinomial logit models; price was a fixed effect variable and all other attributes were random variables. Discolored, i.e. steaks stored 4 – 9 days, were heavily discounted by consumers compared to day 0. USA consumers were more sensitive to price and discoloration than German consumers. Differences in German WTP between day 7 and day 9 were minimal, whereas USA estimates show a 100% decrease in their WTP from day 7 to day 9. Differences across gender were similar across countries, with females being more sensitive and discounting discolored steaks almost twice that of men. Although sale stickers on meat could be perceived as signaling reduced intrinsic quality, the sale sticker in our study had a positive coefficient across all models regardless of gender and/or country, and as such was perceived positively. This is most likely due to the perceived utility gains of saving money. However, according to the models' results, a 30% discount would not be sufficient for enticing consumers to purchase discolored steaks, even after day 4. We initially anticipated that USA consumers who are more familiar with beef steaks are less likely to discount discolored steaks; however, our results show otherwise. Although BBQ culture is growing in Germany, beef steak is considered a luxury cut and often consumed out of home; the reduced familiarity with a raw product may explain their reduced sensitivity to discoloration. Due to current consumer preferences based on our WTP estimates, technological innovation, e.g. packaging or freezing, strategies to improve color stability as well as educational marketing measures directed at meat color formation are required to reduce beef waste at retail. Shorter term mitigation measures could include color sorting in retail counters, to hinder the consumer's ability to compare across-product color.

Can bone mineral density by dual-energy X-ray absorptiometry predict age, shear force, and collagen in cull cows' carcasses?

P. G. Vilas Boas[1,2], S. L. Connaughton[2], C. L. C. Nunes[1], L. K. E. S. Jesus[1], G. E. Gardner[2], M. L. Chizzotti[1]
[1] Universidade Federal de Viçosa, Department of Animal Science, Av PH Rolfs, s/n, Campus Universitário, 36570900 Viçosa, Brazil, [2] Murdoch University, 90 South Street, Murdoch, 6150 Perth, Australia

Cull cow carcasses often show high variability in eating quality, largely driven by maturity-related changes in connective tissue and their interaction with carcass composition. Dual-energy X-ray absorptiometry (DEXA) has been increasingly explored in livestock to predict carcass composition, and its bone outputs may also provide objective maturity-related information. We hypothesised that bone mineral density (BMD) measured by medical DEXA could predict chronological age, collagen traits, and tenderness in cull cows, particularly when combined with hot carcass weight (HCW). The objective was to evaluate the predictive capacity of regional and whole-carcass BMD for age (months), collagen content (mg/g), collagen solubility (%) and Warner–Bratzler shear force (WBSF, kgf) at 0 and 14 d post-mortem (SF0, SF14). Twenty-one Nellore cull cow carcasses (92.9 ± 35.5 months; 132.3 ± 19.0 kg) were used. The carcasses were chilled (4 °C, 24 h), and then the right side was divided into five anatomical regions (R1: longitudinal cut after the second rib; R2: longitudinal cut after the eighth rib; R3: longitudinal cut after the last rib; R4: longitudinal cut after the sacrum; and R5: remaining caudal section). Each region was DEXA scanned, and regional BMD (g/cm²), bone mineral content (BMC, g), and area (cm²) were recorded. Whole-carcass BMD was calculated as ΣBMC/ΣArea across the five regions. Collagen content and collagen solubility were determined by hydroxyproline-based assays, and WBSF was measured on longissimus lumborum samples. Data were analysed using SAS software (PROC GLM), individually testing regional BMD variables and their interactions with HCW. Models using only BMD explained a moderate proportion of variation in age ($R^2 \leq 0.30$, RMSE ≤ 34.8 months). Prediction improved when HCW was included ($R^2 \geq 0.71$, RMSE ≤ 22.0 months), and interaction models provided the best fit ($R^2 = 0.79$, RMSE = 17.8 months for BMD2×HCW) for age. Collagen content was not predicted by any models. In contrast, interaction models showed moderate explanatory power for collagen solubility and SF14, with the best being BMD5×HCW ($R^2 = 0.47$ and 0.55, RMSE = 1.6 % and 1.0 kgf, respectively). Single BMD models did not predict SF0 or SF14, whereas inclusion of HCW improved prediction for SF14. These results partly support the hypothesis that BMD has limited ability to predict age in cull cows, likely reflecting a plateau in bone mineralisation in mature animals. When HCW was included as a co-predictor, model performance improved substantially. The lack of association with collagen content is consistent with tenderness in mature animals being more influenced by connective tissue maturity (e.g., thermally stable collagen crosslinks and/or collagen solubility) than by collagen quantity. Overall, DEXA-derived BMD combined with HCW may complement conventional carcass measures as an objective maturity descriptor and provide moderate prediction of age, collagen solubility and aged tenderness (SF14) in cull cows.

Effect of breed and post-mortem aging time on beef eating quality assessed by untrained Brazilian consumers

N. Mendes[1,2], W. Baldassini[3,4], M. Coutinho[5], G. Rovadoscki[5], T. Oliveira[2], L. Chardulo[3,4], J. F. Hocquette[1]
[1] INRAE, Saint-Genès Champanelle, 63122 Theix, France, [2] UFG, Rodovia Goiânia-Nova Veneza Km-0, 74690-900 Goiânia, Brazil, [3] UNESP, São Paulo, 14884-900 Jaboticabal, Brazil, [4] UNESP, São Paulo, 18618-681 Botucatu, Brazil, [5] Brazil Beef Quality, São Paulo, 13414-157 Piracicaba, Brazil

The Brazil Beef Quality (BBQ) program, adapted from the Meat Standards Australia (MSA) grading scheme, has emerged as a promising national framework to predict beef eating quality. The objective of this study was to evaluate the capacity of the BBQ grading framework to predict beef eating quality across major Brazilian regions by assessing consumer sensory responses to Nellore and F1 (Angus × Nellore) beef aged for different post-mortem periods, and to study genotype, aging, and regional effects on consumer perception of palatability. This study provides the first large-scale sensory assessment of beef eating quality in seven states representing the Southeast, Midwest, and South of Brazil. A total of 672 untrained consumers (96 per state) from São Paulo, Goiás, Minas Gerais, Paraná, Rio de Janeiro, Mato Grosso do Sul, and Rio Grande do Sul evaluated meat sensory traits (tenderness, flavor, juiciness, and overall liking) from 12 Nellore and 12 F1 (Angus × Nellore) cattle aged for 5 and 15 days, allowing the identification of patterns of preference and regional differences in consumer perception. Data were processed using the Clipped method to reduce outliers. A Generalized Linear Mixed Model (GLMM) assuming a Gamma distribution was used to analyze fixed effects: the sample tasting sequence, breed (F1 Angus × Nellore, Nellore), aging time (5 and 15 days), consumer region (7 levels), and the interaction between breed and aging time. Consumer and animal were included as random effects to account for within-individual dependence and biological variability. The mixed-model analysis revealed that the interaction between breed and aging time was highly significant for all sensory attributes ($P<0.001$). Increasing aging time from 5 to 15 days induced a significant improvement in scores for both genotypes ($P<0.001$). While F1 (Angus × Nellore) beef consistently received higher scores, the gain observed for Nellore beef aged between 5 and 15 days was substantial. Notably, extended aging time effectively reduced the gap between Bos indicus and crossbred meat, with 15-day aged Nellore achieving sensory scores comparable to 5-day aged F1 (Angus × Nellore) beef. Regarding regional effects, consumer regions did not significantly influence tenderness perception ($P=0.062$). However, a significant regional effect was observed for flavor, juiciness, and overall liking ($P<0.05$), with consumers in Paraná generally assigning higher scores compared to those in Rio Grande do Sul and Mato Grosso do Sul, with differences ranging from 4 to 12 points (on a 0-100 scale). This study demonstrated that Brazilian consumers were able to perceive differences in eating quality between beef from Nellore and F1 (Angus × Nellore) cattle. Crossbred beef consistently received higher scores for all attributes, confirming the superior palatability typically associated with taurine genetics. In addition, post-mortem aging significantly improved the sensory attributes of Nellore beef. These results highlight that controlled aging is a practical and efficient strategy to enhance tenderness and increase consumer acceptance of zebu beef. Despite differences in absolute scoring levels across regions, the relative ranking of genotypes remained consistent across the evaluated states. These findings reinforce the feasibility of adopting a consumer-driven beef grading scheme, such as the BBQ system, to predict and guarantee consistent beef eating quality throughout Brazil.

Bovine appeasing substances before and after transport reduce beef stress

M. D. M. Campo[1], J. Vieira Romero[1], N. Huanca Marca[1], G. Miranda De La Lama[1]
[1] Instituto Agroalimentario IA2, Miguel Servet 177, 50013 Zaragoza, Spain

Dark, Firm, Dry (DFD) meat is a quality defect that reduces sustainability due to its shorter shelf life and consumer rejection, causing important losses to the beef industry. It is characterised by an ultimate pH>6.0, caused by depletion of muscle glycogen prior to slaughter, mainly as a result of stressful conditions experienced by the animal. Reduced glycogen availability leads to an abnormal post-mortem acidification process, resulting in a high ultimate pH. Prior to the slaughter, animals are subjected to transport and lairage, two particular stressful events that may increase energy expenditure and, therefore, contribute to low glycogen reserves in the muscle. Pheromones are substances produced by animals transported through the air that provide communication between individuals. Synthetic pheromones are being used to calm animals in stressful conditions, but their effects on meat quality have been little explored. Therefore, the aim of this study was to assess the effect of applying bovine synthetic appeasing substances (BAS), before and after transport to the abattoir, on the final pH of the meat and on blood stress markers. A total of 144 crossbred entire young bulls from two farms were used. Both farms were located at a similar distance from the same abattoir, and the same lorry and driver transported the animals. Using a syringe, 5 mL of Secure Cattle® was applied to the neck of each animal. A 2×2 factorial design was used, resulting in four treatments: with or without BAS applied on the farm before entering the lorry, and/or applied upon arrival at the abattoir before distribution into the pens. Animals on each sampling day could be assigned only to only one treatment due to the volatile nature of BAS. Transport lasted between 30-40 min. Lairage lasted 14 h, with 13-17 animals kept together in the same pen. After stunning with a captive bolt, blood was collected in tubes during exsanguination and centrifuged 15‘ at 3500 rpm. Serum was stored at -18 $_{o}$C. Cortisol, glucose, creatine kinase, lactate, NEFA and oxytocin were analysed. After 24 h, pH was measured using a penetration probe (XS Instruments). A GLM was applied using SPSS 29.0 with treatment as a fixed effect, and Tukey’s test was used to differentiate significant mean values. The average meat pH when BAS was administered only after transport was significantly higher (P<0.001) than when BAS was applied before transport, either alone or in combination with BAS at the entrance to the abattoir (5.97 vs 5.76/5.82, respectively). This high pH value was associated with a 33.9% incidence of DFD meat, whereas DFD meat was observed only in 13.8% of animals from the control group without BAS, 7.41% in the group receiving BAS only before transport, and 3.70% in the group receiving BAS in both stages. This suggests that applying BAS only before lairage could have a negative effect, possibly due to a reduced ability of animals to adapt to stressors during this period. In the group with the highest DFD incidence, creatine kinase levels were significantly higher (P=0.007) than in the group receiving BAS before transport (608 vs 426 U/L, respectively). Higher creatine kinase levels were associated with lower lactate concentrations, whereas cortisol, which can be considered an indicator of acute stress, glucose and oxytocin were significantly higher in animals from the control group without BAS. NEFA concentrations did not different significantly between groups. Under short-distance transport conditions, BAS may have a positive effect in reducing the incidence of DFD meat when applied on the farm, but may have a negative effect if applied only before lairage. BAS may also improve animal welfare, as indicated by lower blood glucose and cortisol levels.

Authentication of dry and wet aging in Angus beef steaks by means of near-infrared spectroscopy

L. León[1], A. Ortiz[1], M. Freire[1], D. Tejerina[1]
[1] Scientific and Technological Research Centre of Extremadura, Meat Quality, Ctra. A-V, Km372, 06187 Guadajira, Spain

In recent years, the Aberdeen Angus breed has been widely adopted due to its ability to improve beef quality, particularly through its high intramuscular fat deposition. Beyond genetics, technological processes such as post-mortem aging play a key role in defining final meat quality. Beef aging is mainly determined by the type of process—dry or wet aging—and its duration. Dry aging is carried out under controlled aerobic conditions of temperature, relative humidity, and airflow, whereas wet aging is performed under vacuum packaging and refrigerated conditions. Despite the higher costs and yield losses associated with dry aging, the aging process is not required to be declared on product labelling. This lack of regulatory protection increases the risk of mislabelling, especially when beef is commercialised as vacuum-packaged steaks, highlighting the need for reliable authentication tools. Therefore, the objective of this study was to evaluate the potential of near-infrared spectroscopy (NIRS), using a portable MicroNIR™ 1700 OnSite-W device, to discriminate between dry- and wet-aged vacuum-packaged Angus beef steaks (picanha, Biceps femoris muscle). A total of 16 picanha cuts (Biceps femoris; 2.52 ± 0.31 kg) from Aberdeen Angus × Charolais heifers slaughtered at 450–500 kg live weight (<12 months) were used. Half of the cuts were subjected to carcass dry aging for 7 days under controlled conditions (2 °C, 80% relative humidity, and 0.35 m/s airflow), then sliced into 2.5 cm-thick steaks and vacuum-packaged. The remaining cuts were directly sliced, vacuum-packaged, and stored under refrigerated conditions for 7 days (wet-aged). In total, 48 vacuum-packaged steak samples were analysed (24 dry-aged and 24 wet-aged). Near-infrared spectra were acquired non-destructively through the packaging using a handheld MicroNIR™ 1700 OnSite-W spectrometer (908–1676 nm). Measurements were performed in direct contact with the packaging film using a zigzag scanning pattern to capture sample variability. Discrimination models between dry- and wet-aged beef steaks were developed using partial least squares discriminant analysis (PLS-DA) with leave-one-out cross-validation. The PLS-DA model showed good discrimination ability between dry- and wet-aged beef steaks, achieving a coefficient of determination in cross-validation (1-VR) of 0.91. Model performance was further supported by the two-dimensional score plot of the first two PLS-DA components, which together explained 99% of the total spectral variability. The score distribution revealed a clear clustering of samples according to aging type, with limited overlap likely attributable to similarities between both aging methods. Overall, these results indicate that portable NIR spectroscopy provides a reliable approach for authenticating the aging process of beef. This approach has strong potential for implementation along the value chain and at the retail level as a rapid, non-destructive tool for the authentication of premium beef steaks.

Evaluation of texture in dry- and wet-aged beef at different pH under various packaging: a preliminary assessment

J. V. Romero[1], M. P. Lierta[1], J. L. Olleta[1], M. Bueno[1], M. M. Campo[1]
[1] Instituto Agroalimentario de Aragón–IA2 (CITA-Universidad de Zaragoza), Departamento de Producción Animal y Ciencia de los Alimentos, C/. Miguel Servet 177, 50013 Zaragoza, Spain

Abnormally high-pH meat is associated with an increased risk of developing dark, firm and dry (DFD) meat, which negatively affects quality and consumer acceptance. Tailoring post-mortem ageing strategies according to meat pH at 24 h to identify the most appropriate packaging system could improve meat quality as assessed by instrumental texture. Such optimization is expected to enhance consumer-perceived quality and increase economic returns for producers while reducing losses along the supply chain. This study evaluated instrumental texture in meat with different pH values after dry- or wet-ageing and under different display times. Thirteen carcasses were selected at an abattoir: 8 with normal pH (<5.8) and 5 with high pH (≥6.0). From each carcass, the Longissimus dorsi muscle was excised from both sides. In the normal-pH group, left-side loins were aged as bone-in cuts (dry-aged) for 7 days at 3 $_{o}$C, while right-side loins were deboned at 24 h post-mortem and vacuum-aged (wet-aged) for 7 days at 3 $_{o}$C. The same procedure was applied to the high-pH carcasses. After ageing, the muscles were sliced and packaged using three systems: oxygen-permeable film (FILM), vacuum-skin (SKIN), and modified atmosphere packaging (MAP; 80% O2 and 20% CO2). Samples were displayed in a refrigerated cabinet (3 $_{o}$C ± 1 $_{o}$C) under 12 h of daily illumination for 2, 5, 8 and 12 days, with the day of sampling considered as day 0 of display, and then vacuum-packaged and stored at -18 $_{o}$C. After thawing, 1-cm2 parallelepipeds were analyzed by compression using an INSTRON-4301. Meat cooked in a water bath until reaching 70 $_{o}$C internal temperature was used to obtain shear force with a Warner-Bratzler device on the same instrument. Water losses (WL) were calculated as the difference in weight before and after cooking. Data were analyzed using a GLM (SPSS 29.0) with treatment as a fixed effect and Tukey's test for mean differences. WL were lower in high-pH meat (20.6% vs 23.9%; P<0.001), regardless of ageing, display time or packaging (except SKIN), reflecting greater water-holding capacity, as these conditions allow muscle proteins to retain more water. Wet-aged samples in MAP showed lower WL (20.4%) than dry-aged (24.2%; P<0.005). FILM also reduced WL (P<0.001) at both pH levels by acting as a physical barrier retaining moisture and preventing dehydration. Although dry-ageing is known to improve sensory properties, no differences were observed between dry- and wet-aged meat in shear force or compression at 20% and 80% strain. In contrast, high-pH meat showed significantly lower shear force, regardless of other treatments, suggesting greater tenderness, consistent with our previous findings that such meat has a higher water-holding capacity. Display time reduced meat hardness by over 20% between days 2 and 12 (5.05 vs. 4.0; P<0.05). MAP-packaged meat had higher shear force than FILM (P<0.05), likely due to oxygen-induced protein oxidation increasing cross-linking. Compression at 20% showed more pronounced differences than at 80%, particularly in normal-pH meat, MAP and day 0 of display, as 20% compression reflects muscle fibers resistance and initial elasticity, sensitive to early biochemical changes induced by MAP and pH. In contrast, 80% compression reflects connective tissue resistance and overall structural integrity, which remain largely unaffected, masking subtle differences. Meat pH was the main factor affecting these parameters. Further studies are underway to confirm and extend these findings and guide the meat industry in optimizing processing while enhancing consumer satisfaction.

Incorporating dry-aged beef crust into burger patties: evolution of quality traits over a 7-day retail display

Y. Singh[1], M. Tóth[2], S. Sabbadin[1], D. Martini[1], M. Pozza[1], R. De Lazzari[1], M. De Marchi[1]
[1] University of Padov, Department of Agronomy, Food, Natural Resources, Animals and Environment, Viale dell'Università 16, Stecca 1, 35020 Legnaro, Italy, [2] Hungarian University of Agriculture and Life Sciences, Department of Feed Safety, Páter Károly u. 1., H-2100 Gödöllő, Hungary

Dry-aged (DA) beef crust is typically removed, yet its incorporation into patties could valorise trimming losses while modifying product quality during retail display. The present study investigated the effect of incorporating DA crust into 35-day DA beef patties by evaluating physicochemical quality and proximate composition over 7-day retail display storage. Two 35-day DA rib roasts (Austria, male; Poland, female) were trimmed, deboned, ground, and formed into patties weighing 50 g each (n=60; 10 patties/treatment/time point). The 2 treatments were DAN (DA meat without crust) and DAC (60% DA meat with 40% crust). For the 7-day simulated retail display, patties were wrapped in food-grade plastic film and stored at 4.0±1°C and 47±1% relative humidity, under cold LED illumination (natural white 4000 K, 490 lm, CRI>80), for assessment at days 0, 3, and 7. Measurements included pH, colour, drip loss, cooking loss, and proximate composition. Data were analysed by 2-way ANOVA with Treatment, Day, and their interaction (Treatment×Day) as fixed effects. Across retail display, pH increased over time (PD<0.001) and remained higher in DAC than DAN (PT<0.001; day 0: 5.90 vs 5.76; day 7: 6.23 vs 5.91), with a significant Treatment×Day interaction indicating a stronger increase in DAC by day 7 (PTxD<0.001). Lightness (L*) displayed a Treatment×Day (PTxD<0.05): DAN slightly darkened across display (PD<0.05), whereas DAC became lighter by day 7 (42.2 vs 39.8; PT<0.01). Redness (a*) and yellowness (b*) declined from day 0 to days 3-7 (PD<0.05); at day 0, DAC showed lower a* and b* than DAN (a*: 13.4 vs 15.1; b*: 12.9 vs 14.4, PD<0.05), suggesting that crust inclusion altered early colour development. Drip loss increased from days 0-3 to days 3-7 in both treatments (PD<0.001), while the treatment difference was small and only evident during days 0-3 (0.87 vs 0.94%; PT<0.05). Cooking loss declined progressively with display time (PD<0.001) but was consistently lower in DAC (PT<0.001; day 0: 20.7 vs 25.2%; day 7: 13.4 vs 19.9%), and the Treatment×Day interaction (PTxD<0.001) suggests crust inclusion increasingly improved cooking yield as display progressed. Crust inclusion shifted composition at each time point: water was lower in DAC than DAN (D0: 62.7 vs 66.1%; D3: 62.3 vs 66.0%; D7: 62.2 vs 64.6%; PT<0.001), while DAN showed a modest decline over the display period (PD<0.001), with a significant Treatment×Day (PTxD<0.001). Protein decreased over the display period in both treatments (PT<0.001) and was consistently higher in DAC (PT<0.001; D0: 22.6 vs 21.4%; D7: 21.4 vs 20.5%), without a significant Treatment×Day (PTxD>0.05). Fat was higher in DAC across storage (PT<0.001; D0: 7.81 vs 3.87%; D7: 7.62 vs 3.82%); a small change over time was detected only in DAN (PD<0.05), yielding a modest Treatment×Day (PTxD<0.05). Collectively, incorporating 40% DA crust increased fat content and improved cooking yield, but it also shifted colour dynamics during retail display (lower initial a* and b* and higher L* at day 7), indicating a potential trade-off between processability and appearance. To fully characterise shelf-life and consumer acceptability, future studies should evaluate microbiological safety, lipid oxidation, and sensory attributes in crust-incorporated DA patties.

Delivering consistent beef eating quality in Poland: consumer sensory testing supporting the QMP scheme

A. Neveu[1,2], G. Pogorzelski[1,3], R. Polkinghorne[1,2], H. Cuthbertson[1,2], E. Pogorzelska-Nowicka[4], J. Wierzbicki[1,5]
[1] IMR3GF, Smulikowskiego 4, 00389 Warszawa, Poland, [2] Birkenwood Europe, Lanon, 03240 Saint Sornin, France, [3] Institute of Genetics and Animal Biotechnology of the Polish Academy of Sciences, Jastrzębiec, 05552 Magdalenka, Poland, [4] Warsaw University of Life Sciences, Nowoursynowska 159c Street, 02776 Warszawa, Poland, [5] PZBM, Smulikowskiego 4, 00389 Warszawa, Poland

In Europe, beef is predominantly traded and valued based on carcass yield and conformation rather than predicted eating quality at the cut level. As a result, consumer eating experiences can be highly variable across muscles and products. Predicting beef eating quality from consumer perception is increasingly recognised as an effective approach to improve product consistency and consumer confidence in beef products and brands. The purpose of this study was to report recent consumer sensory trials conducted in Poland, contributing to the expansion of the national beef eating-quality database and supporting the development of the 3G system aimed at delivering consistent beef meals. The method used was based on internationally harmonised consumer testing protocols recognised by United Nations Economic Commission for Europe (UNECE) for beef eating-quality evaluation. Standardised sample preparation, cooking procedures and questionnaires for untrained consumers ensured comparability with datasets generated within the global 3G consumer-based grading framework. A new series of sensory sessions was conducted over the past two years, during which Polish consumers evaluated beef samples from 15 different muscles across the carcass, covering a range of carcass characteristics and ageing periods typical of commercial production. Consumers assessed tenderness, juiciness, flavour liking and overall liking using 100 mm continuous scales. These attributes were combined to generate a composite eating-quality score expressed as the MQ4 meat quality score. The trials expanded the Polish consumer dataset to more than 13,000 consumers evaluating thousands of beef samples, now the largest consumer sensory database for beef eating quality in the European Union. The dataset provides a strong foundation for analysing variation in eating quality between muscles and for strengthening the 3G predictive model, which estimates expected beef eating quality from carcass and processing measurements. By linking carcass characteristics, muscle type and processing conditions with consumer sensory outcomes, the 3G model enables more reliable prediction of beef eating quality and improved product segmentation across the carcass. The expanded Polish dataset therefore plays a key role in refining prediction accuracy and adapting the system to European production conditions. This work also provides a scientific foundation for the Quality Meat Program (QMP), a national beef quality assurance scheme supported by producers, processors and research institutions. QMP establishes standards across the beef supply chain, including livestock production, feed supply, transport and processing, ensuring traceability and consistent quality. Verified production standards strengthen trust among supply-chain actors and help respond to evolving market expectations. Within this framework, a 3G beef eating-quality prediction system based on consumer research is intended to support both the QMP scheme and the broader transition of the sector toward sustainable production. Together, these elements will underpin the development of the nationwide “Polish Beef” brand, based exclusively on beef originating from certified sustainable production systems meeting requirements for animal welfare, greenhouse gas reduction and full traceability. The official launch of the “Polish Beef” brand is planned for 2027.

Sensory quality and fatty acid composition of beef from Holstein–Friesian bulls finished with different protein sources

Z. Nogalski[1], M. Momot[1]
[1] University of Warmia and Mazury in Olsztyn, Department of Animal Nutrition, Feed Science and Cattle Breeding, Oczapowskiego 5, 10-719 Olsztyn, Poland

Sensory quality and fatty acid composition of beef from dairy bulls can be modified through dietary strategies applied during the finishing period, particularly by altering protein sources that affect ruminal lipid metabolism. In production systems based on dairy breeds, identifying alternative protein sources that improve meat quality without increasing fat deposition is of particular interest. We hypothesised that replacing rapeseed meal with legume seeds differing in condensed tannin content would modify sensory quality and fatty acid composition of beef without increasing intramuscular fat deposition. The objective of this study was to determine the effects of replacing rapeseed meal (RM) with faba bean grain containing condensed tannins (Vicia faba L.; VF) or with tannin-free white lupin seeds (Lupinus albus L.; LP) in finishing diets for Holstein–Friesian bulls on sensory quality, chemical composition and fatty acid profile of intramuscular fat. Thirty Holstein–Friesian bulls (initial body weight approximately 500 kg; age 17 months) were allocated to three experimental groups (n = 10 each) and fed isoenergetic and isonitrogenous total mixed rations differing only in the protein source of the concentrate for five months. Bulls were slaughtered under commercial conditions, and samples of the longissimus lumborum muscle were collected 96 h post-mortem. After 14 days of wet-ageing, chemical composition, sensory attributes (colour, aroma, juiciness, tenderness and flavour) and the fatty acid profile of intramuscular fat were determined. Data were analysed using one-way ANOVA with dietary treatment as the fixed effect. Replacing rapeseed meal with legume seeds did not affect intramuscular fat content (2.94–3.31%) or collagen content (2.06–2.22 g/100 g; $P > 0.05$). Dietary protein source significantly influenced sensory traits: beef from bulls fed VF diets was rated as more juicy ($P < 0.01$) and more flavourful ($P < 0.05$) than beef from RM-fed bulls, whereas meat from the LP group was characterised by higher tenderness scores than that from the VF group ($P < 0.05$). Dietary protein source also affected the fatty acid composition of intramuscular fat. Inclusion of faba bean grain reduced the proportion of trans-vaccenic acid compared with rapeseed meal ($P < 0.05$), whereas lupin-based diets induced moderate but distinct changes in fatty acid profile. In conclusion, replacing rapeseed meal with legume seeds in finishing diets for Holstein–Friesian bulls modifies beef quality primarily through qualitative changes in lipid metabolism and sensory attributes rather than through increased intramuscular fat deposition. Condensed tannins present in faba bean may play a role in shaping ruminal biohydrogenation and subsequent eating quality of beef.

Predicting beef eating quality: Evaluation by INRAE of an innovative approach to align with consumer and stakeholder expectations

J. F. Hocquette[1,3], I. Legrand[2], A. Neveu[3], M. P. Ellies-Oury[1,4], S. Chriki[1,5], D. Troy[3], V. Molinéro-Demilly[6], F. Gaymard[6], R. Polkinghorne[3]

[1] INRAE, UCA, VetAgro Sup, UMRH, Theix, 63122 Saint-Genès Champanelle, France, [2] Institut de l'Elevage, Boulevard des Arcades, 87060 Cedex 2 Limoges, France, [3] IMR3GF, ul. Smulikowskiego 4/217, 00-389 Warsaw, Poland, [4] Bordeaux Sciences Agro, CS 40201, 33175 Gradignan Cedex, France, [5] ISARA, 23 rue Jean Baldassini, 69364 Lyon, France, [6] INRAE, Direction de l'Evaluation, 147 rue de l'Université, 75007 Paris, France

INRAE has developed a standardised method for evaluating the societal and economic impacts of its research. This method, known as ASIRPA, provides greater insight into how research results are translated into innovation. The objective of this study was to use the ASIRPA method to assess the 3G grading scheme (standing for Global Guaranteed Grading), a system designed to evaluate and predict beef eating quality. First, some historical points were reviewed. The decline in beef consumption is driven by societal concerns, but also by its high price and by the high and inconsistent variability of its eating quality, as shown in consumer surveys. Eating quality depends on many pre-slaughter factors (e.g. sex and age of the animal). It is also influenced by slaughter conditions, carcass characteristics (pH, marbling, etc.), meat cutting and processing as well as meat ageing and cooking. Grading systems take little account of these factors, except the Meat Standards Australia (MSA) system developed in Australia. The system has created added value across the supply chain and ensured a better alignment between price and eating quality from the consumer's perspective. According to the 2024–2025 report, the MSA system generated 409 million Australian dollars (€245 million) in additional value for the more than 13,000 Australian farmers. Then, the ASIRPA method described how the principles of the MSA system have been investigated in Europe, taking into account the diversity of livestock systems and consumer expectations in several European countries (Poland, Ireland, France and the United Kingdom), where companies are exploring its use to enhance product quality. This research was carried out as part of over five research projects coordinated by INRAE or its partners, including the national EcoRegMeat3G project and the European INTAQT project, both led by INRAE. The work of five PhD students, all supervised by researchers from INRAE also contributed to this work. This research led to the development of the 3G system managed by the International Meat Research 3G Foundation established in Poland in 2017 and operating with the support of INRAE. It also contributed to the launch of a new premium beef brand (OR ROUGE) by the Beauvallet beef company in the French Limousin region. Beauvallet is engaging with the 3G system in the context of developing its new brand for high-quality Limousin beef, with improved farmer remuneration. In addition, the 3G system has been successfully evaluated in South Africa, South Korea, Japan, the United States and New Zealand. Worldwide, economic analyses indicate that the Meat 3G system generates added value of between €0.10 and €0.55 per kilogram of boneless beef for farmers. By enabling more accurate grading of meat, the system reduces economic losses while strengthening the competitiveness of the sector. The development and wider deployment of the system are currently overseen by the International Meat Research 3G Foundation in collaboration with the French company Birkenwood Europe, founded in 2021. Building on this work, the United Nations Economic Commission for Europe (UNECE) has issued new recommendations on beef eating quality that draw on the principles underpinning the 3G approach.

Participatory and iterative approach to design collective strategies of crop-livestock integration

F. Stark[1], M. Moraine[2], M. Grillot[3], J. Ryschavy[4]
[1] SELMET, Univ Montpellier, INRAE, CIRAD, Institut Agro,, Campus de la Gaillarde, 34060 Montpellier, France, [2] INNOVATION, Univ Montpellier, INRAE, CIRAD, Institut Agro,, Campus de la Gaillarde, 34060 Montpellier, France, [3] AGIR, Univ Toulouse, INRAE, INP-Toulouse, EI Purpan,, Chemin de Borde rouge, 31326 Castanet-Tolosan, France, [4] SAS, INRAE, Institut Agro, Campus de Rennes, 35042 Rennes, France

Climate change, ecological pressures, economic uncertainties and social expectations are increasing the vulnerability of livestock farming systems. Crop-livestock complementarities are seen as a solution to these challenges, but their consolidation and territorial scaling remain challenging. This paper describes and discusses an iterative participatory design framework developed to support such collective strategies and implemented in South-Western France. The study area is characterized by specialized viticulture and long-term pastoral disuse, leading to shrub encroachment, reduced biodiversity and weak local food provisioning. In response, several local initiatives have emerged to reintroduce livestock into vineyard landscapes and to rebuild crop-livestock complementarities. The participatory process combined a territorial agroecology perspective with an innovation ecosystem approach, aiming to connect research, advisory services, local authorities and practitioners around shared problems and concrete opportunities. First, field diagnosis and qualitative inquiry were used to document existing crop-livestock initiatives, identify success and failure conditions, and understand the diversity of actor perceptions and organizational arrangements. Second, biophysical assessments were conducted to estimate forage potential, grazing capacity and seasonal resource availability across agricultural, semi-natural and abandoned land uses. Third, design and exploration tools were mobilized, including serious game, consultation meetings and scenario-building workshops, to support collective reflection on technical, organizational and territorial options. Finally, simulation and evaluation were used to assess scaling-up potential, nutrient cycling, economic performance and the capacity of the landscape to sustain livestock reintroduction over time. Results show that crop-livestock integration in Mediterranean vineyard regions cannot rely on a single technical dimension. Instead, long-term viability depends on combining multiple levers: diversified forage resources, mobility of herds, access arrangements, stakeholder intermediation, public support, and local coordination. It also showed that practical solutions must be tailored to different scales, from vineyard estates to municipalities and larger territorial units. This study explore how an adaptive, participatory and multi-level design framework can support co-innovation in complex crop-livestock systems, while producing both context-specific solutions and transferable lessons. By combining qualitative and quantitative approaches, and by involving a complete innovation ecosystem, the project created conditions for dialogue, learning and collective action. This approach helps bridge transition studies, agronomy and territorial design, and offers pathways to strengthen resilient, multifunctional and low-input agricultural systems. Nevertheless, a reflective analysis of the co-design process implemented appears necessary in order to adapt it as effectively as possible to other situations. Extending this approach to other livestock farming contexts also seems relevant for examining the contribution of livestock farming to sustainable regional development, particularly in light of the challenges posed by planetary boundaries.

Livestock system transformation as a societal task: governance lessons from a stalled multi-stakeholder strategy in Germany

B. Grabkowsky[1], N. Zubek[2], T. Blaha[3]
[1] University of Vechta, trafo:agrar, Driverstrasse 22, 49377 Vechta, Germany, [2] Hochschule Osnabrück, Albrechtstraße 30, 49076 Osnabrück, Germany, [3] Tierärztliche Hochschule Hannover, Bünteweg 2, 30559 Hannover, Germany

Current livestock production systems are increasingly scrutinised due to their environmental and climate impacts and concerns about animal welfare. While there is broad consensus that livestock systems need to become more sustainable and animal-friendly, there is far less agreement on how feasible transformation pathways can be implemented in practice. This paper analyses why a broadly supported transformation strategy for the German livestock sector failed to translate into political implementation and derives governance-related lessons for future transition processes. The analysis is based on the experience of the German Commission on the Future of Agriculture (Zukunftskommission Landwirtschaft, ZKL), a multi-stakeholder initiative established by the federal government that brought together representatives from agriculture, the food industry, environmental and animal welfare organisations, science, and civil society. The commission developed a consensual strategy for transforming livestock production towards higher sustainability and animal welfare standards. A key outcome was the recognition that achieving these goals would require long-term financial support to compensate farmers for investments and increased production costs exceeding world market prices. Despite broad acceptance of the commission's recommendations among stakeholder groups, including the farming community, implementation has largely stalled. The analysis identifies several structural reasons: limited political ownership beyond a single ministry, absence of binding long-term financing mechanisms, misalignment between political decision cycles and agricultural investment horizons, insufficient cross-party consensus on how to distribute transformation costs between taxpayers and consumers, and institutional fragmentation across policy domains. The lack of political follow-up after the commission process created a governance vacuum that contributed to considerable investment uncertainty in the livestock sector, resulting in postponed investments, declining livestock numbers, and reduced production capacity. The German case illustrates that livestock transformation is not only a technical or sectoral challenge but primarily a systemic governance problem characterised by conflicting societal goals, including food affordability, economic viability of farms, environmental protection, and animal welfare. Transformation processes therefore require negotiated societal compromises rather than purely technical solutions. Even well-designed multi-stakeholder processes with broad consensus may fail without strong political commitment, institutional continuity, and societal agreement on financing public goods associated with sustainable food production. These findings underline that livestock transitions cannot be achieved by farmers alone but require coordinated action across the entire agri-food system, supported by coherent policy frameworks, long-term financing strategies, and broad societal responsibility. The lessons derived from the German experience may inform transformation processes in other livestock-producing regions facing similar governance challenges.

A Biocultural Diversity Index for Assessing Animal Husbandry Sustainability

B. A. Altmann[1], C. Heindorf[2], L. Jung[3], N. Kemper[1], E. Varela[4]
[1] University for Veterinary Medicine Hannover, Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] University of Kassel, Social-Ecological Interactions, Steinstrasse 19, 37213 Witzenhausen, Germany, [3] University for Veterinary Medicine Hannover, Science for Innovative and Sustainable Poultry Farming (WING), Bischofsholer Damm 15, 30173 Hannover, Germany, [4] Spanish Research Council (CSIC), Institute for Public Goods and Policies (IPP), C/Albasanz, 26-28., 28037 Madrid, Spain

Once defined as biological, cultural, and linguistic diversity which are interrelated within a complex social-ecological adaptive system, biocultural diversity (BCD) describes the co-dependence of cultural and biological diversity within social-ecological systems. The BCD Framework structures social-ecological systems to be made up of materialized, lived, and stewardship components contributing to biocultural diversity. Globalization and simplification of animal husbandry systems are contributing to biocultural homogenization, which refers to the loss of BCD through the homogenization of anthropogenic habits and knowledge and the creation of globally homogenous natural environments. Today, highly integrated and industrialized are increasingly replacing traditional animal husbandry systems in local, national, and global markets. Shifting systems has large implications for biocultural homogenization. For example, meat consumption has changed drastically within the past decades. Global meat production has surged through technological advancements where indigenous and local products are being replaced by global imports or Western production systems, leading to a shift in consumer preferences and further supporting global simplification. Overall, biocultural homogenization degrades sector as well as societal resilience, inclusivity, and the potential for sustainable transformation. In our previous work, we illustrate specific animal husbandry systems in Europe as biocultural diversity storehouses that contribute to biodiversity conservation, climate resilience and cultural values. The work is highly theoretical, yet provides a strong framework for elaborating BCD to understand transformation potential and holistically assess livestock systems' sustainability. Next steps, involve collecting and creating (semi-)quantifiable indicators for a BCD index for monitoring and comparing materialized, lived, and stewardship components of BCD across husbandry systems, regions, and time. A preliminary sustainability index is elaborated with stakeholders to reflect and assess poultry production through the BCD lens. A triangulation perspective of stakeholders covering production (e.g. organic and conventional producers), processing and retail (e.g. representatives from slaughterhouse and retail), and stewardship bodies (e.g. municipal governments, nature conservation groups, breeding associations) as well as researchers from the disciplines of social-ecological systems and poultry science are brought together to collect, rank, and weight indicators across the three components of BCD. First, stakeholders are introduced to the concept of BCD and the BCD Framework as part of a brief guided-question focus group discussion on poultry production sustainability. Next, a world café format commences brainstorming and a discussion on indicators' feasibility. Finally, indicators are then ranked and weighted based on consensus-based decision-making. The resulting index is summarized by the research team as an inter- and transdisciplinary approach for comprehensively understanding animal husbandry system sustainability. Acknowledgements: the Lower Saxony Ministry of Science and Culture and the Volkswagen Foundation funded this research as part of the zukunft.niedersachsen program.

Multicriteria evaluation of mixed sheep-beef production systems

P. Madrange[1], L. Thuault[1], M. Velghe[1], S. Passerieux[1], M. Miquel[1]
[1] Institut de l'Elevage, 149 rue de Bercy, 75012 Paris, France

Multicriteria evaluation is a mean to assess the durability of farming systems. Several methods and evaluation trees have been proposed for a variety of projects and objectives. So far most methods have focussed on specialised systems. Yet improving the synergy between beef and sheep enterprises within and between farms seems to have several assets such as a better economic resilience, a better valorisation of the fodder resources and an improve management of parasitism in sheep. In the project ACCOMPLIR, to assess the overall impact of sheep – beef mixed systems on farm durability, we proposed and tested a multicriteria evaluation tree and methodology. To consider the specificities of mixed systems, the methodology proposed some new indicators such as the Shannon Index and the proportion of the main enterprise in the gross product of the farm to quality the diversification of the farming system. In addition, since product units commonly used in sheep and beef production are not directly comparable (resp. / kg. of Carcass equivalent and /kg of live weight), we choose to evaluate the environmental indicators in relation to surface areas. Finally, with references only on specialised systems, each farm had 2 scores for each indicator. To combine those to scores in a single score, we prorated the results to the e were able to compare the mixed farms results to specialised sheep and beef farms, and to have a single score for each indicator, we prorated the result to the number of livestock unit between the two enterprises. Two ponderations between indicators and criteria have been tested, an Equi ponderation and a ponderation with a panel of 21 experts, and technicians. There was a significative difference only for the viability criteria between the 2 ponderation methods. We choose to keep the ponderation proposed by experts and stakeholders to favour a better understanding of the evaluation method. For aggregation between indicators, we compared two options: calculating the average of indicator and criterion scores on the one hand and limiting compensation between indicators using CONTRA software on the other. The actors involved in the project favour the limitation of compensation. This methodology was tested on 15 sheep-beef French mixed farms and highlighted that those farms were on average more resilient to risks and had a better economic viability yet were less transmissible than specialised systems on the economic pilar and were comparable to suckler farms without fattening systems on the environmental pilar. The comparison with specialised systems was not available on the social pilar due to the creation of a questionnaire for the needs of the project. In the future, the evaluation tree needs some adaptation for the social pilar to better consider animal welfare. In addition, there is a need to expand the method to include more farm data to establish references for mixed farms so that these systems can be compared with each other and the comparison with specialized systems can be strengthened.

Network Focus Animal Welfare – how to transfer practice-orientated knowledge into practice

K. Brase[1], C. Lambertz[2]
[1] Verband der Landwirtschaftskammern e.V, Netzwerk Fokus Tierwohl, Claire-Waldoff-Str. 7, 10117 Berlin, Germany, [2] FiBL Deutschland e.V., Kasseler Str. 1a, 60486 Frankfurt a.M., Germany

Germany lacked a structure that bundled and processed knowledge about animal welfare and made it accessible to livestock farmers. The solution was funded by the Federal Ministry of Food and Agriculture since 2020. The nationwide "Fokus Tierwohl" network aims to improve the transfer of knowledge on animal welfare into the agricultural practice, taking sustainability and environmental protection into account. For the first time, all federal states participated in this network, so that the knowledge could be coordinated nationwide. A focus was on promoting networking between experts and farmers. Specialist knowledge is bundled and made freely available, an exchange of experience between practitioners, scientists, consultants and other groups is organized, thus enabling and promoting networking within the industry. The target groups are employees on farms, in the upstream and downstream sectors, advisors, veterinarians and the interested public. Members of the network have access to a nationwide common calendar and a document sharing system. Coordinated monthly meetings, standard operation procedures and corporate identities ensure a joint appearance. A nationwide expert advisory board has been established in 2020, they selected around 900 animal welfare topics, including sustainability and environmental protection. Working groups – consisting of scientists, farmers, consultants and representatives of the authorities – started selecting, bundling and summarizing the newest information to make it available for the target groups. Animal welfare multipliers organize various events to disseminate the knowledge in each federal state. These vary from (farm) workshops to school visits, from seminars and fairs to farmers markets. Due to the different target groups, different ways of knowledge transfer have been established. Beside scientific articles, checklists, guidelines, training documents, virtual farmwalks, videos and podcasts are available. Given that farm staff originate from different nationalities, translations in English, Polish, Romanian and Ukrainian are available. About 120 demonstration farms complete the network. They are pioneers in the profession with innovative and sustainable animal welfare concepts and present their concepts at trade fairs and events. Practice-orientated knowledge is getting into practice, while the farmers network with each other, visit farms in Germany and abroad. In general, the three following ways of dissemination are used: 1) events of the network partners (so far 3.000 events with more than 130.000 participants); 2) website: www.fokus-tierwohl.de and 3) network of demonstration farms. The website provides links to research results, from funded research and development projects or the model and demonstration projects on animal welfare as well as other stakeholders. A very well-organized database is available and can continue to be used across borders. For the first time in Germany, a nationwide functioning network for knowledge exchange has been established. It can be used as a platform to disseminate results from all projects relating to animal welfare, sustainability and environmental protection and there are no technical obstacles to expanding it to other topics. This network can be used as a 'blueprint' for knowledge hubs in other areas.

How do livestock farming system issues come into play in the design of breeding programs for agroecology? Key points from researchers'narratives of their experiences in a transdisciplinary project

P. Coeugnet[1,2], N. Bedere[3], J. Labatut[1,2], F. Phocas[2], G. Restoux[2], M. Tixier Boichard[2], A. Lauvie[4]
[1] LISIS, INRAE, CNRS, Univ G.Eiffel, 3 allée Renoir, 93160 Noisy le Grand, France, [2] Univ.Paris Saclay, INRAE, AgroParisTech, GABI, rue de la Manufacture, 78352 Jouy en Josas, France, [3] PEGASE, INRAE, Institut Agro-Rennes-Angers, domaine de la prise, 35590 Saint Gilles, France, [4] SELMET, Univ Montpellier, CIRAD, INRAE, Institut Agro-Montpellier, 2 place Viala, 34060 Montpellier cedex 01, France

Several syntheses about genetic selection of livestock for agroecological transition have underlined key challenges for breeding activity and researches in genetics, like relevant breeding goals or role of diversity. Beyond these issues, agroecology involves to be context-sensitive, to do with the ecosystem processes rather than to control the environment, to take into account biological interactions etc. Consequently, as mentioned in the literature, this involves to reconsider genetic selection in a systemic perspective. However, little is known about how those principles are translated into actions in the fields, when co-designing breeding programs in an agroecological perspective. Particularly, how do livestock farming system issues come into play in the design of breeding programs for agroecology? To contribute to answer this question, we rely upon the analysis of narratives of research experiences produced by an interdisciplinary group of researchers gathered, in the frame of a project named 'Cobreeding', in a task to design and test various combinations of genetic resources in farming systems coupling plants and poultry. The narratives were produced through semi structured interviews, transcribed and used as material for a thematic analysis. It was followed by a workshop to explore the convergences and specificities identified in the experiences reported by researchers of this task. We highlighted several modalities through which genetic dimensions are invoked in livestock farming system design, and, reciprocally, how livestock farming system dimensions are invoked in genetic research. We emphasized several livestock farming systems dimensions, in line with agroecological principles, which are at play at the farm scale (e.g. which genetic resources to promote an autonomous feeding system) or challenges at higher levels of organization. We finally showed that the temporality of the co-definition of research questions and relevant experiments is not to neglect, to build convergence between (i) the challenges identified by scientists, relying on generic knowledge as well as their past researches' experiences, and (ii) challenges expressed by farmers in the specific context of the case study. For instance, if farmers were interested in the role of poultry to predate insects in orchard, they did not express wishes to work on the associated selection criterion. On the other hand, interest for selection criterion to face predation of poultry by birds of prey seemed more pronounced. We then discuss the interests and difficulties associated with such interdisciplinary and transdisciplinary set ups, and how they potentially put at play new research questions and practices (systems diversity, scales and levels of organization, targets and conceptions underlying the breeding goals, identification of relevant breeding criteria etc.). Finally, we emphasize the interest to extend this work to other tasks of the Cobreeding project, like the one on the re-conception of cattle breeding programs to meet the challenges of climate change.

Co-designing climate adaptation strategies in PDO/PGI livestock territories: a typology of participatory and multi-level approaches from the ADAoPT project

D. Neumeister[1], F. Bedoin[1], R. Lasbleiz[2], S. Dernat[3]
[1] Institut de l'Elevage, 149 rue de Bercy, 75595 Paris cedex 12, France, [2] CNAOL, 42 rue de Châteaudun, 75009 Paris, France, [3] INRAE, UMR Territoires, 9 avenue Blaise Pascal, CS 20085, 63178 Aubière, France

The ADAoPT project supports Geographical Indications (GIs) livestock value chains in the design of climate adaptation strategies. Thanks to 6 case studies, the project sought to explore how participatory and multi-level dynamics can structure strategic reflection in GI livestock systems. The 6 territories differ in production systems, organisational structures, exposure to climatic risks and prior experience on climate issues. To initiate the process, each GI first established a common reference framework (delineation of the perimeter, governance arrangements, time horizon, available resources, existing knowledge and strategic objectives). Consequently, the themes addressed and the composition of working groups varied. Rather than applying a standardised methodology, each GI developed a pathway reflecting its resources, constraints and ambitions. Cross-analysis of the six experiences led to a two-dimensional framework for characterising adaptation methodologies. The first dimension, Spatial–Functional, concerns the scale and composition of mobilised groups. A spatial approach engages a broad diversity of actors representative of the territory (farmers, processors, technical advisors, local authorities). A functional approach relies on a smaller, task-oriented group focusing on a specific mission or expertise. The second dimension, Thematic–Systemic, relates to the breadth of issues addressed. Thematic approaches focus on a single issue (e.g. water, forage, energy), whereas systemic approaches integrate interconnected challenges such as natural resources, biodiversity and labour. Combining these axes results in four configurations:(1) Thematic–Functional: a restricted group explores a targeted issue to produce operational tools and build focused expertise.(2) Systemic–Functional: a small governance-linked group develops a comprehensive strategic vision for the GI.(3) Systemic–Spatial: territory-wide mobilisation supports shared diagnosis, scenario-building and cross-actor dialogue.(4) Thematic–Spatial: a specific issue is addressed through broad participation, fostering experimentation and connections between value chain segments. In practice, territories rarely remained within a single configuration. They navigated between them according to emerging needs, available capacities and decision timelines. Alternation between systemic and thematic phases proved particularly important: global reflection helps prioritise and align ambitions, while thematic focus translates vision into actionable plans. This iterative movement supports collective learning and progressive alignment. A central challenge lies in articulating diverse initiatives into a coherent roadmap. Actions often address specific facets of climate change, yet their cumulative contribution depends on explicit coordination and strategic integration. Governance appears as the keystone of this articulation across scales and groups. Combining broad participation with specialised working groups enriches deliberation but may generate tensions regarding representation and decision-making. Clarifying roles, consultation procedures and arbitration mechanisms is therefore critical to ensure legitimacy. The ADAoPT experience shows that effective adaptation in GI livestock systems does not rely on a single participatory model. It emerges from context-sensitive combinations of spatial and functional groups, and from deliberate alternation between systemic and thematic approaches, embedded in transparent governance arrangements.

Lessons learned from living labs on Swiss and Italian beef production in the Project "INnovative Tools for Assessment and Authentication of chicken meat, beef and dairy products' QualiTies"

R. Eppenstein[1], E. Sturaro[2]
[1] Research Institute of Organic Agriculture, FiBL, Ackerstrasse 113, 5070 Frick, Switzerland, [2] Università degli studi di Padova, DAFNAE, viale dell'università 16, 35020 Legnaro, Italy

The INTAQT project (EU Horizon 2020) studies the relationship between animal husbandry systems and the quality of animal products. Within the project two farmer field-groups (living labs) were established, one in Switzerland and one in northern Italy involving 5 farms each, on the topic of sustainable beef production. In Switzerland, crossbred calves from the dairy sector are moved to fattening farms, where they are extensively fattened until the age of 24 month, using at least 75% of grass in the diet. In Italy, conventional beef farms are based on intensive fattening of young bulls, fed with a total mixed ration based on corn silage and concentrates. The aim of the living labs was to implement on-farm changes in the production processes (e.g. feeding regimes, outdoor access, herd management) expected to improve intrinsic quality traits of the products and/or sustainability traits of the farms. From 2023 to 2025 farmers within each living lab met 2-3 times on each other's farms, allowing discussions about their experiences, successes and drawbacks; the present contribution summarized lessons learned from these two living labs. In Switzerland, during the first year of the living lab, participants identified as main obstacle to the current production system the large genetic variety of the animals, which limits their ability to achieve a homogenous carcase quality. As a result, participating farms requested a broader research project on this topic, which lead to increased cooperation and data-sharing between the leading researchers, fatteners and the value chain. The second meeting, highlighted challenges regarding feed supply in dry summers and limited growth rates during the alpine estivation of animals. Jointly, farmers developed strategies to overcome drought and feeding challenges, such as the pre-emptive production of maize silage, the switch to breeds, such as Angus, which are better adapted to extensive feeding and increased farm collaborations. The third living lab meeting identified the supply of cross-bred organic calves as important barrier to the growth of the sector. This eventually led to an active involvement in the restructuring of the fattening sector as well as the establishment of a second research project including not only the beef production value chain but also stakeholders from the dairy industry. In Italy, the aim of the living lab was to co-develop protocols and guidelines for the implementation of a certification of "Sustainable beef"; meetings and on farm visits were organised, and the outputs of the process were the definition of specific advisory services and the establishment of a demo farm to favour the implementation of good practices (such us low impact diets, use of beef on dairy, reduction of antibiotic). The experience of both living labs highlights the importance of allowing a farmer lead research approach by establishing trust, ensuring active involvement of researchers and allowing flexibility in the definition of the living lab's framework. This resulted in a fertile research ecosystem in which farmers perceive to be actors rather than subjects of the process.

SPICER² : a multi-partners network to promote the improvment of Cultures-Livestock Interactions in the French agriculture

P. Mischler[2], G. Martel[1], M. Moraine[1], V. Thenard[1], S. Ramonteu[3], S. Pissonier[6], C. Gava[4], S. Bruley[5], E. Merot[1]
[1] INRAE, Centre I.N.R.A.E. Occitanie-Toulouse Castanet Tolosan Cedex, BP 52627 - F 31326 Tolosa, France, [2] Idele, INRAE, site d'Estrées-Mons 2, chaussée Brunehaut, 80200 Estrées-Mons, France, [3] ACTA, 149 rue de Bercy, 75595 Paris, Cedex 12, France, [4] Le Groupement d'Intérêt Économique (GIE) Élevage Occitanie, 2 Avenue Daniel Brisebois BP 82256 Auzeville, 31322 Castanet-Tolosan Cedex, France, [5] Lycée Agricole de Fontaines, 10 la platière, 71150 Fontaines, France, [6] AgroParisTech, Campus Agro Paris-Saclay 22 place de l'Agronomie, CS 20040 91 123 Paris, France

The SPACER² Network follows on from the SPyCE and SPICEE Networks. It aims to strengthen understanding and promote Crops – Livestock Interactions (CLI). French agriculture is increasingly subject to climatic and geopolitical uncertainties, which call into question the functioning of systems that rely heavily on the consumption of non-renewable or low-renewable resources (minerals, soil) and fossil fuels. An agroecological transition towards more sober, robust and resilient systems can be facilitated by increasing interactions between crops and livestock, increasing the circularity both at the farm level and among collectives across territories.The overall objective is to promote agricultural systems that are more autonomous and resilient to climatic and economic uncertainties by involving a wider range of actors, including those involved in agricultural research, training and development, as well as new actors, whether agricultural or not, who are involved in agriculture in the regions. The programme is structured around four areas: one steering area and three thematic areas. The latter focus on (1) capitalising on and disseminating knowledge, (2) documenting, monitoring and designing new forms of crop-livestock organisations, and (3) evaluating their contributions to the performance of farms, sectors and regions in a fluctuating economic and climatic environment.

Enhancing interoperability through transparent multidirectional data architecture for individual animal data valorization in the pig value chain

S. Retz[1], D. Moerlein[2], Y. Chen[2], Z. Bodor[2], F. Heinrich[2], A. Schmitt[2], H. Grevemeyer[3], V. Beck[4], S. Fischer[5], R. Hoelscher[6]

[1] University of Vechta, trafo:agrar, Driverstraße 22, 49377 Vechta, Germany, [2] University of Göttingen, Department of Animal Sciences, Kellnerweg 6, 37075 Göttingen, Germany, [3] SLA Software Logistik Artland GmbH, Friedrichstr. 30, 49610 49610 Quakenbrück, Germany, [4] Brand Qualitätsfleisch GmbH & Co. KG, Brandstr. 21, 49393 Lohne, Germany, [5] Fraunhofer IZFP, Campus E3 1, 66123 Saarbrücken, Germany, [6] Hölscher + Leuschner GmbH & Co KG, Siemensstraße 15, 48488 Emsbüren, Germany

Digital transformation holds great promise for sustainable, resilient pig production systems. Yet, fragmented data use hampers progress. Current systems suffer from isolated solutions, unclear data ownership, inconsistent recording, missing interfaces and limited individual animal-level linkage, preventing effective value creation. The German pig sector faces intense competition from international imports while needing to meet rising demands for animal welfare, meat quality, transparency and resource efficiency. This project addresses the interoperability along the pig production value chain by developing a transparent, multidirectional data architecture connecting all value chain stages via individual animal identification. The three-year project will run until the end of 2027. Core is a large-scale UHF-RFID implementation across the chain, enabling automated data capture from genetics through slaughter. In two different farms, existing infrastructure (animal feeders, handling areas) is supplemented by UHF-RFID readers and 3D-cameras for individual performance and weight estimation. Piglets receive individual tagging (UHF-RFID) for system comparison across 4-6 fattening cycles. Automated antennas at loading/unloading points ensure seamless tracking through transport to slaughterhouse intake. Within the slaughterhouse multiple antennas and sensors for a gapless recording of the individual animal are also installed. Additional qualitative and quantitative information about the carcasses is also recorded in the slaughter house along the processing chain. Individual animal identification is the connecting link that makes all other information along the chain compatible with each other. In addition, the possibility of integrating new automated quality measurements is being examined. These measurements allow for more detailed evaluations thanks to traceability back to individual animals. This can be used to determine new information and create added value e.g. in the context of breeding and feeding. A central digital platform serves as an interoperability hub, harmonizing farm management, logistics and slaughter data while preserving data sovereignty through role-based access. Individual data is not stored on a central platform but rather accessed, retrieved, and distributed in a targeted manner as in a transshipment station. Therefore animal-level data (genetics, growth curves, treatments, transport quality, meat quality traits like intramuscular fat content as eating quality proxy) becomes linkable for holistic analyses. Expected outcomes are for example enhanced planning for the farmer and the slaughter house, resource efficiency (logistics matching), animal health/welfare monitoring and quality-based payment. Interoperable data flows via digital delivery notes enable data monetization, supporting “less but better meat”, breeding for sensory quality, and differentiation from commodity products. This strengthens economic resilience and transparent value chains. The GlasSchwein project is funded by the German Federal Office for Agriculture and Food (Project ID 28DI107B23).

Supporting Farmers in Developing Systems with Higher Human-Edible Protein Output: Balancing Animal and Crop Production at Farm Level

B. Genin[1], M. Fazzari[2], P. Aeby[3], E. Ollion[4], P. Rufer[5], P. Veysset[6], B. Reidy[2]
[1] IDELE, Soudanières 45, 01250 Ceyzeriat, France, [2] BFH, Länggasse 85, 3052 Zollikofen, Switzerland, [3] Grangeneuve, Grangeneuve 31, 1725 Posieux, Switzerland, [4] ADICE, Lorzier 34, 38430 Moirans, France, [5] Proconseil, Jordils 3, 1001 Lausanne, Switzerland, [6] INRAE, Theix, 63122 St-Genès-Champanelle, France

Ruminants are often criticized as inefficient protein producers, despite their ability to utilize grassland unsuitable for crop production. The objectives of the Interreg Proscor project are: (1) to select indicators to measure protein production efficiency and land use on cattle farms; (2) to involve farmers in redesigning systems that maximize protein production for human consumption; and (3) to disseminate a simple tool and method for estimating farm efficiency and identifying improvement opportunities. Five indicators were selected: edible protein feed conversion efficiency (epFCE), land use ratio (LUR), protein autonomy (PA), global protein yield (GPY) and net protein yield of the production system (nPYPS). Two groups of dairy cattle farmers (9 French and 8 Swiss farms) and two groups of beef cattle farmers (5 French and 7 Swiss farms) were formed. Technical and economic data from 2023 were used to calculate the indicators. Farmers were brought together repeatedly in 2025 and 2026 to contribute to indicator analysis and refinement, and to develop scenarios for redesigning their systems. Sharing reference values for human-edible protein from various crops and animal products allowed farmers to consider new crop rotations adapted to their pedoclimatic context. These rotations incorporate crops with a high potential for human-edible protein (grain legumes, cereals, potatoes), along with catch crops and pastures used to feed animals and produce animal protein. Farmers could thus explore a new crop–herd balance, identifying arable land suitable for crops and areas to remain under pasture. Initial findings indicate that in three-quarters of the scenarios, herd size or milk and meat production was reduced. For the least efficient systems for producing human-edible protein (notably suckler systems), redesigning the system to produce both plant and animal protein simultaneously increases human-edible protein production and consequently reduces feed–food competition. The economic aspects of these changes are being considered to assess system viability. Farmers identified key barriers to implementing these scenarios, including limited time to manage new production activities, investment needs for livestock buildings, availability of equipment for new crops, lack of marketing channels, and climate-related uncertainties affecting legume crops from year to year. These results suggest that the levers for improving protein efficiency on farms will need to be deployed at the regional level.

Understanding drivers and barriers for implementing grassland and feeding measures to reduce ammonia and methane emissions in Dutch dairy farming

A. Van Den Pol-Van Dasselaar[1], W. Van De Geest[1]
[1] Aeres University of Applied Sciences, De Drieslag 4, 8251 JZ Dronten, Netherlands

Reducing ammonia (NH_3) and methane (CH_4) emissions from dairy systems requires the implementation of technical mitigation measures at farm level. However, adoption depends not only on technical feasibility but also on farmers' perceptions, motivations and structural constraints. This study aimed to identify opportunities, drivers and barriers influencing the implementation of grassland and feeding strategies to mitigate NH_3 and CH_4 emissions in Dutch dairy farming. The study is part of a nationally funded project (https://www.sia-projecten.nl/project/integrale-aanpak-ammoniak-en-methaan) and consisted of a literature review combined with a baseline assessment (2023). Data were collected through online surveys (106 dairy farmers, 98 animal husbandry students and 51 sector stakeholders) and in-depth interviews with farmers and sector representatives. Survey respondents evaluated their attitude towards various mitigation measures using a five-point Likert scale and reflected on perceived feasibility, risks and incentives. Attitudes towards potentially promising measures differed substantially. Feeding-related measures such as increasing concentrate proportion (mean score 2.35) and the use of nitrate (2.78) or 3-NOP-based additives (2.92) were viewed more critically. In contrast, management-based measures such as optimised mowing strategies (3.49), increased grazing (3.58) and multispecies grasslands (3.60) were perceived more positively. Interviews revealed that many farmers already apply certain mitigation practices unconsciously, indicating hidden opportunities for emission reduction. At the same time, knowledge on emission-reduction mechanisms was often fragmented, and uncertainty about policy goals and effective strategies limited targeted action. The survey revealed key drivers and barriers influencing the implementation of emission-reducing measures in grassland management and livestock feeding. Key drivers included less costs/higher revenues, animal welfare/animal health, the image of the livestock sector, own norms and values, and less labour/better working conditions. Important barriers were perceived animal welfare/animal health risks, financial constraints, regulatory uncertainty, lack of knowledge/education, and time/available labour. Multiple "lock-ins" were identified in the in-depth interviews, where existing infrastructure, investments or established habits restrict the ability to change practices. Across groups, farmers tended to perceive more threats than opportunities in current emission-reduction debates. The findings demonstrate that successful emission mitigation requires alignment with farmers' intrinsic motivations and farm systems rather than focusing solely on technical optimisation. Addressing and unlocking systemic lock-ins and clarifying long-term policy objectives appear crucial to enhance effective implementation of NH_3 and CH_4 mitigation measures in dairy systems.

Integrated assessment of sustainability indicators in pasture-based and intensive dairy sheep systems in Central Italy

A. Iannetta[1], M. Dos Santos Lima[1], L. Torricella[1], L. Baldacchini[1], C. Cimini[1], L. Iannetti[1], G. Vignola[2], A. Collin[3], M. Podaliri Vulpiani[1]

Dairy sheep farming in Mediterranean areas ranges from pasture-based to fully intensive indoor systems. In Central Italy, pasture-based farms are typically semi-extensive, with grazing during favourable seasons and indoor housing from late October to March. Although pasture access is often associated with improved animal welfare, farm sustainability is influenced by management practices, housing conditions and seasonal variability. Therefore, integrated assessments are needed to support sustainable dairy sheep farming. This study aimed to compare pasture-based and intensive dairy sheep systems in terms of animal welfare and environmental, economic and social sustainability. The study was conducted within the EUPAHW (European Partnership on Animal Health and Welfare) framework and focused on case studies analysing trade-offs between sustainability dimensions and animal welfare. The study was carried out in the Abruzzo region (Central Italy) over one year, covering all seasons. At the current stage, five commercial farms were evaluated during winter: two pasture-based (semi-extensive) and three intensive system, all rearing Lacaune sheep. Pasture-based farms included about 120 lactating ewes each, while the intensive farm housed about 150. During winter, animals in pasture-based systems were also kept indoors. Animal welfare assessment was based on health and behavioural indicators. Health indicators included body condition score, lameness prevalence assessed through visual scoring and mobility evaluation, mastitis incidence and somatic cell count, parasitic burden, and heat stress evaluated using the Temperature–Humidity Index (THI). Behavioural indicators focused on activity patterns, social interactions and stress-related behaviours. Environmental sustainability was assessed using life cycle assessment–related parameters, focusing on feed management, manure handling, water consumption and land use. Economic sustainability was evaluated through indicators of production efficiency and resource use, while social sustainability was assessed through structured questionnaires addressing labour organization, workload, occupational health and safety, perceived work-related stress, farmer-animal interaction and job satisfaction. Preliminary winter results showed that welfare and management criticalities were more evident in pasture-based systems during the housing period, with greater variability in housing structures and health management practices compared with intensive systems. These findings highlight the importance of considering seasonal housing conditions and management strategies when assessing the sustainability of pasture-based dairy sheep systems. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW. Views and opinions expressed are those of the author(s) only and do not necessarily reflect those of the European Union or the European Research Executive Agency.

Evaluation of animal-level strategies for reducing nitrogen and phosphorus losses and their effectiveness in mitigating the environmental burden of pig production

F. Garcia-Launay[1], L. Cappelaere[2], F. De Quelen[1], P. Lin[3,4], P. Schlegel[3], R. Aklikokou[2], M. P. Létourneau Montminy[2]
[1] INRAE - Institut Agro, PEGASE, 16, Le Clos, 35590 Saint-Gilles, France, [2] Laval University, Department of animal Science, G1V, 0A6 Quebec, Canada, [3] Agroscope, Swine Research Group, Tioleyre, 1725 Posieux, Switzerland, [4] Milan University, Via dell'Università, 26900 Lodi, Italy

Dietary nitrogen (N) and Phosphorus (P) are essential nutrients to animals, and the produced fecal and urinary N and P are essential fertilizers for plants. When the agronomic nutrient cycle becomes unbalance in regions with high livestock densities, losses of N and P lead to a range of environmental impacts, like water eutrophication of coastal, freshwater and groundwater ecosystems as well as soil acidification. Efforts have been made by the pig sector to mitigate these impacts but it is necessary to go further. For instance, the pig science community has (1) developed strategies aimed at improving nitrogen (N) and phosphorus (P) use efficiency in pigs to reduce nutrient excretion without compromising animal performance, and (2) evaluated the environmental performance of these strategies through Life Cycle Assessment (LCA) to quantify their effectiveness. This review focuses on fattening pigs, which contribute the most to N and P losses. Reduction of crude protein (CP) content of diets (-1 to -1.5 pt relative to current practice) with balanced supply of digestible amino acids (AA) has proven to be effective in reducing N excretion while maintaining animal performance. Further reducing CP content has recently produced more contrasted results on animal performance and N emissions. For P, the use of phytases is widely recognized to improve P digestibility, what makes possible to reduce P excretion. The strategy of depletion – repletion can further improve P utilization efficiency and lower P excretion without affecting growth. In addition, precision feeding, by providing to each animal each day tailored supplies in digestible amino acids and digestible P, has also proven to be effective in reducing N and P excretion. To establish the effectiveness of these strategies, LCA inventories the resources and emissions along the life cycle of the product, from the inputs for feed ingredients production to the live pig at farm gate, including feed manufacturing, emissions from animals and manure, and all the transports steps. In this field of research, the perimeter usually also includes emissions at field application of manure and the economy of mineral fertilizer permitted by manure. With LCA, the potential of these strategies depends on 1) the set of the environmental impacts considered 2) the relative impacts of the feed ingredients substituted and the ingredients incorporated in the mitigation strategy, 3) the origin and environmental impacts of feed-grade amino acids, 4) the levels of digestible amino acids, digestible P, CP and total P contents in the reference strategy and 5) the practices for field application of manure. To overcome the limits of these strategies, there is further interest in associating them with multi-objective feed formulation and good environmental practices for manure management (e.g. frequent manure removal from buildings). In addition, the amount of manure applied on field is largely determined by the N to P ratio of manure relative to crop requirements. If the ratio is unbalanced, more mineral fertilizer will be applied, and the benefits obtained from mitigation strategies implemented in pig production could thus be negated. Therefore, the effective application of strategies targeting N and/or P losses should be also analyzed in the next future with a broader view at farm and territory levels.

Variation in N and P excretion from sows, weaners and grower-finisher pigs

A. L. F. Hellwing[1], P. Tybirk[2], S. S. Grove[2], P. Kai[1], C. F. Børsting[1]
[1] Aarhus University, Blichers alle 20, 8830 Tjele, Denmark, [2] SEGES Innovation, Agro Food Park 15, 8200 Århus N, Denmark

Surplus of nitrogen (N) and phosphorus (P) from production of livestock and associated application of manure can cause eutrophication. Estimated amounts of N and P in manure from pigs are used by Danish farmers in a manure accounting system to document surplus or deficit of N or P for the land owned by the farm. If there is a surplus the farm must export manure, while if there is a deficit, the farm is allowed to buy fertilizer or receive manure from another livestock farm. The calculated excretion of N and P per sow per year or per produced pig is based on average values. However, there is variation in efficiency between farms. The aim of the study was to investigate the variation between farms based on farm data for feed intake and expected difference in crude protein (CP) and P content in the feed as well as emission of N from the barn. The ex-storage excretions of N and P used in the Danish manure accounting system are based on mass balances. Input of feed, number of piglets born, weaning weight and weight gain for weaners (6.4 kg to 31 kg) and grower-finisher pigs (31-117 kg) are reported by the farmers. The expected N and P content in feed is based on a survey involving the major feed companies in Denmark. The N and P contents per kg of weight gain are based on literature values. Emissions of N in the barn and storage system are subtracted and inputs of N and P in bedding are added. Data was obtained from 716 sow farms, 422 weaner farms and 1111 grower-finisher farms covering approximately 63%, 39% and 73% of the sow, weaner and grower-finisher farms in Denmark. The farms were divided into five percentile groups of equal size based on feed intake, and within each percentile group average feed intake was calculated. The same productivity was used in each percentile group. Three different CP and P content in feed (low, medium and high) were applied for each feed intake percentile group, based on theoretical recommendations for sows and growing-finisher pigs, while six different levels of CP and P were used for weaners. Three different housing emission values for ammonia were applied. All other parameters were kept constant. That gave in total 45 different combinations of feed intake, feed composition and barn emission for sows and grower-finisher pigs and 90 for weaners. The mean, standard deviation and coefficient of variation (CV) were calculated for ex-animal, ex-storage and intake of N and P. The ex-storage values for sows were on average 19.3 kg N/sow/year and 4.76 kg P/sow/year and the CV was 12.5% and 14.9%, respectively. The ex-storage values per produced weaner were on average 0.37 kg N and 0.091 kg P and the CV was 17.9 and 17.0%, respectively. The ex-storage values per produced grower-finisher pig were on average 2.32 kg N and 0.43 kg P and the CV was 6.7% and 9.3%, respectively. The CV for the ex-animal and ex-storage within N and P were nearly identical. This indicates the main source of variation in manure N and P ex-storage is variation in feed efficiency and CP and P content of the feed. The N-intake was on average 29.6 kg N/sow/year, 1.1 kg N/weaner and 5.3 kg N/grower-finisher pig with a CV on 5.9%, 6.4% and 3.6%, respectively. The P intake was on average 6.6 kg P/sow/year, 0.21 kg P/weaner and 0.91 kg P/grower-finisher pig with a CV of 10.7%, 7.4% and 4.4%, respectively. The variation ex-storage was only partly explained by CV in intake of N and P. The gains of N and P in products were kept constant within group causing higher variation in ex-storage values than input values. In conclusion, the variations between farms in ex-storage excretion of N and P are mainly caused by differences in feed efficiency, CP and P content of the feed.

Continuous monitoring of ammonia emissions in a fully slatted, mechanically ventilated commercial finishing pig facility, Ireland

Department of Technology and Cybernetics, University of South Bohemia, 1668, 37005, Ceske Budejovice Ceske Budejovice, Czech Republic

This study aimed to determine the ammonia emission characteristics of a fully slatted and mechanically ventilated finishing pig facility. Continuous real-time measurements were carried out in a fully slatted and mechanically ventilated finishing pig facility during two monitoring periods – summer (40 days) and winter (51 days) using a Gasera photoacoustic gas analyser. Three separate and identical fully slatted finishing pig rooms with similar environmental conditions were utilised. Each room measured 12 m × 9 m and had manure tanks with a depth of 1.4 m operating under a negative-pressure ventilation system. Airflow rate in the system was measured using an anemometer. Gaseous monitoring followed the VERA test protocol and emission calculations accounted for outliers, mortality, pig numbers and incomplete monitoring days. Diets were similar during the summer period, while animals were fed different diets during winter. Model assumptions and homogeneity of variance were verified prior to applying appropriate parametric or non-parametric tests. Differences, relationships, and associations between rooms, ammonia emissions, and environmental and animal factors were assessed using the Kruskal–Wallis test, Spearman's rho and General Additive Model (GAM). On average, results showed a higher ventilation rate of 144.6 ± 17.9 m^3 pig^{-1} h^{-1} in summer compared with 58.2 ± 19.6 m^3 pig^{-1} h^{-1} in winter (mean ± SD). Differences were observed among the three rooms in winter ($p < 0.05$), whereas no differences ($p > 0.05$) were observed among the rooms during the summer period. Across the rooms, the average ammonia emission factor was 1.40± 1.3 g pig^{-1} day^{-1} in winter and 1.6 ± 1.2 g pig^{-1} day^{-1} in summer, ranging from 0.043 to 4.91 g pig^{-1} day^{-1} in summer and from 0.040 to 7.21 g pig^{-1} day^{-1} in winter. Higher emission rates were also observed during daytime across both seasons, with different peak times. A strong relationship ($p < 0.05$) was observed between ammonia emission factors and environmental parameters. In winter, all parameters were positively correlated ($p < 0.05$) except for the body weight of the pigs ($p > 0.05$), whereas in summer all parameters were positively correlated ($p < 0.05$) except for relative humidity ($p > 0.05$), despite showing a positive relationship. Ammonia concentration appears to strongly influence ammonia emissions in both seasons. Results from the GAM showed that a non-linear relationship exists between ammonia emission and environmental parameters such as temperature, relative humidity, ammonia concentration and airflow rate. In contrast, body weight showed a linear but significant relationship with ammonia emissions. A good agreement was also found between the predicted and measured ammonia emission across the three rooms and seasons, with room A having the best model fit, followed by rooms C and B. Results from this study enhanced the understanding of environmental drivers of ammonia emissions and the emission characteristics of mechanically ventilated, fully slatted finishing pig facilities, supporting the application of targeted mitigation strategies and improvement of emission inventories for the Irish pig production sector.

Integrated nutritional and housing strategies to improve nitrogen utilization efficiency and mitigate ammonia emissions in pig production

E. Nnando[1], C. Anozie[1], E. Aidelomon[1]
[1] University of South Bohemia, Technology and Cybernetics, Studentská 1668, 370 05 Ceske Budejovice, Czech Republic

Ammonia (NH3) emissions from pig production pose a major environmental threat, contributing to eutrophication of ecosystems, soil acidification, and the formation of secondary particulate matter (PM2.5), with ecological and health consequences. Inefficient nitrogen utilization results in substantial urinary nitrogen excretion, which is the major precursor of NH3 volatilization, making the pig sector one of the largest agricultural sources of reactive nitrogen loss. It was hypothesized that combining low crude-protein diets supplemented with synthetic amino acids with modified housing systems would improve nitrogen utilization efficiency and significantly reduce ammonia emissions in grow-finish pigs without compromising growth performance. The objective of the study was to evaluate the combined effects of reduced crude-protein (CP) diets supplemented with synthetic amino acids and optimal housing systems on nitrogen utilization efficiency (NUE) and NH3 emissions in grow-finish pigs. A total of 144 grow-finish pigs were allocated to four treatment groups in a randomized complete block design based on initial body weight, with six replicate pens per treatment and six pigs per pen. Dietary interventions were implemented in 10 g/kg increments of crude protein reduction, with essential amino acids adequately supplemented with lysine, methionine, threonine, and tryptophan to maintain animal performance. Modifications to housing included a urine-feces separation system with V-shaped slurry scrapers and increased slurry removal frequency to limit substrate availability for NH3 formation. Photoacoustic infrared spectroscopy was used to measure ammonia concentration and estimate emission flux, while nitrogen mass balance, slurry pH, and total ammoniacal nitrogen (TAN) were monitored during the trial. Data were analyzed in R using a linear mixed-effects model with treatment as a fixed effect, block and pen as random effects, and significance was declared at $P < 0.05$. Findings showed that a 10 g/kg decrease in CP resulted in a 10% decrease in NH3 emissions, and dietary fiber intake lowered slurry pH by 0.4 to 0.6 units, thereby inhibiting volatilization by 38% ($P < 0.05$). The combined housing and nutritional approach produced a cumulative NH3 reduction of 50-54% compared with conventional systems, and growth performance was not significantly affected ($P > 0.05$). Such savings are reflected in quantifiable reductions in reactive nitrogen deposition in local ecosystems and help meet farm-level national and EU emission limits, indicating that precision nutrition and housing innovation can be a scalable, cost-effective route towards sustainable pig production.

Low-protein diets with graded essential amino acid supplementation as a strategy to improve nitrogen utilisation and reduce ammonia production in growing-finishing pigs reared under contrasting hygienic conditions

A. Antonacci[1], P. Silacci[2], G. Bee[1]
[1] Agroscope, Pig Research Unit, Rte de la Tioleyre 4, 1725 Posieux, Switzerland, [2] Agroscope, Animal Biology Group, Rte de la Tioleyre 4, 1725 Posieux, Switzerland

Nitrogen (N) losses from pig production are a major environmental concern, contributing to approximately 15% of global livestock ammonia (NH3) emissions. Reducing dietary crude protein (CP), and thus N intake, is an established strategy to improve N efficiency and decrease N losses. Adequate essential amino acid (EAA) supplementation may further optimize N utilisation without compromising growth. This study evaluated the effects of low-protein diets with graded EAA supplementation on N utilisation and in vitro NH3 production in slurries of growing-finishing pigs reared under contrasting hygienic conditions. Forty-eight Swiss Large White pigs (females and castrated males; initial BW 20 ± 2.2 kg) were assigned to three isoenergetic low-protein diets, all formulated with CP reduced by 20% relative to the Swiss feeding recommendations for pigs (grower: 124 g/kg CP; finisher: 100 g/kg CP), but differing in the level of supplemental digestible EAA (Lys, Met, Thr, Trp, Val): at 80% (LP), 100% (LP+), or 120% (LP++) of requirements. To assess hygiene effects, LP pigs (n = 24) were equally divided between good hygiene (daily manure removal) and poor hygiene (weekly manure removal) conditions, while LP+ and LP++ pigs (n = 12 per group) were housed exclusively under poor hygiene. This resulted in four experimental groups: LP good hygiene, LP poor hygiene, LP+ poor hygiene, and LP++ poor hygiene. Weekly BW, feed intake (FI), and carcass composition were assessed for each pig. Faecal and urinary spot samples were collected during the grower and finisher periods. In vitro NH3 production was measured on reconstituted slurry obtained from the faecal and urinary spot samples using a dynamic chamber system. Data were analysed using linear models (R, v4.4.1), with hygiene effects assessed within LP pigs (LP good hygiene vs. LP poor hygiene) and dietary effects assessed among pigs under poor hygiene (LP poor hygiene vs. LP+ poor hygiene vs. LP++ poor hygiene). Hygiene did not affect any of the traits considered. Over the entire grower-finisher period, average daily gain did not statistically differ among dietary treatments. However, EAA supplementation significantly reduced total FI, with LP+ and LP++ pigs spending on average 3.5 fewer days on feed and consuming 4.2% less feed than LP pigs ($P \leq 0.018$), resulting in a 4.1% higher feed efficiency ($P = 0.010$). Despite a 2.9% lower CP intake, LP+ and LP++ pigs maintained similar carcass protein content compared with LP pigs, leading to a 6.5% higher N deposition efficiency ($P \leq 0.015$). Faecal N concentration did not differ among treatments, whereas urinary N concentration tended to decrease in LP+ and LP++ pigs, resulting in a significantly lower urinary N:creatinine ratio ($P = 0.015$). Total in vitro NH3 production was reduced by EAA supplementation and was on average 38.2% lower in slurry from LP+ and LP++ pigs compared with LP pigs, with NH3 peak values also 38.0% lower and peak occurrence delayed by 43.3 h ($P \leq 0.034$). Importantly, no differences were detected between LP+ and LP++ pigs for any of the traits evaluated, indicating that EAA supplementation above requirement levels did not confer additional benefits. Overall, reducing dietary CP combined with adequate EAA supplementation improved N utilisation and markedly reduced in vitro NH3 production without impairing growth. These findings highlight that meeting minimum EAA requirements in low-protein diets is sufficient to enhance production efficiency and mitigate nitrogen losses, even under poor hygienic conditions.

A controlled medium scale open circuit chamber approach to quantify the effect of crude protein and lysine supply on nitrogen efficiency and ammonia emissions in pigs

S. Goethals[1], T. Van De Gucht[1], N. Peiren[1], P. Bikker[2], A. J. Jansman[2], S. Millet[1]
[1] ILVO, Burg. Van Gansberghelaan 119, 9090 Merelbeke-Melle, Belgium, [2] Wageningen University & Research, PO BOX 338, 6700 AH Wageningen, Netherlands

Improving efficiency of nitrogen (N) utilization is essential to reduce N excretion and ammonia (NH_3) emission in pig production. Many nutritional mitigation strategies are first tested under laboratory conditions, but validation at barn scale remains challenging due to large environmental variation. To bridge this gap, this study used medium-scale open circuit chambers that allow controlled, replicated measurements on small groups of pigs, providing a unique experimental scale between lab-based assays and full commercial housing. We tested a key nutritional strategy: reducing crude protein (CP) while maintaining ideal amino acid balance. We investigated the effects of CP reduction and standardized ileal digestible lysine (SID Lys) supply in growing–finishing pigs on growth performance, N balance and NH_3 emission. Two crossover trials were conducted in six open circuit chambers, each housing five barrows. In Trial 1, pigs (initial BW 68 kg) received low (12 %) or high (16 %) CP diets, both with 8.5 g/kg SID Lys. In Trial 2, pigs (initial BW 42 kg) received diets with an adequate (8.3 g/kg) and deficient (7.0 g/kg) SID Lys level at constant CP (15 %). Each experimental period consisted of one week of adaptation to diets followed by three weeks in the chambers. Diets were switched for each group in the second period with the same group of pigs housed in the same chamber during both periods. Slurry was continuously collected, BW and feed intake were recorded when entering and leaving the chambers, and NH_3 concentration was monitored sequentially for 15 min in outlet air of each chamber during the final week. Nitrogen efficiency was calculated as the proportion of dietary N retained in the body based on start and end body weight. Faecal N excretion was estimated by the dietary N intake and an estimated value for CP digestibility (75 %), whereas urinary N excretion was estimated from N intake, faecal N excretion and estimated N-retention in the body. Chamber was considered as experimental unit, and data were analysed using ANOVA with dietary treatment, period and their interaction (if P value for interaction <0.20) as fixed factors and chamber as random factor for repeated measurements. Preliminary results show that in Trial 1, reducing CP by 4 % points did not affect daily gain or feed intake. However, a period-dependent effect on feed conversion ratio (FCR) was observed, with a significant lower FCR (2.43 versus 2.72 g/g) in the pigs receiving the high CP diet compared to the low CP diet in the first period, but no significant effect of dietary treatments was observed in the second period. Across both periods, lowering CP markedly improved N utilization, resulting in a 35 % reduction in total N excretion, a 24 % increase in N efficiency, and a 45 % reduction in NH_3 in the air compared to the high CP diet. In Trial 2, no diet × period interactions were observed. Adequate SID Lys supply improved animal performance, increasing daily gain by 10 %, while reducing FCR by 8 % compared with the Lys-deficient diet. Lys deficiency impaired N utilization, leading to 6 % higher total N excretion, 9 % lower N efficiency, and a 33 % increase in NH_3 concentrations. These trials demonstrate that reducing CP, while maintaining an adequate amino acid balance, is an effective strategy to mitigate NH_3 emission in growing–finishing pigs. The open circuit chamber set-up proves particularly valuable to quantify differences in excretion and emission of N at a scale that bridges the gap between experimental controlled and practical housing conditions.

Effects of dietary lysine supply on nitrogen utilisation in organic growing–finishing pigs

L. Stødkilde[1], T. F. Pedersen[1], E. T. Jørgensen[1], M. Eskildsen[1]
[1] Aarhus University, Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark

The lack of nutrient guidelines tailored to organic pigs forces pig producers to rely on conventional requirements, often resulting in excessive crude protein (CP) intake and increased nitrogen (N) excretion when meeting essential amino acid standards. This study aimed to evaluate the physiologically optimal supply of standardised ileal digestible (SID) lysine for organic growing–finishing pigs by quantifying N utilisation across compound feed differing in SID lysine content. We hypothesised that N utilisation would be low at insufficient SID lysine levels, increase toward an optimal supply, and decline again at excessive lysine levels due to oversupply. Thirty female DLY pigs (average weight 30.9 ±1.6 kg) were assigned to one of five compound feeds with increasing SID lysine concentrations (g/kg; Lys 6.1, Lys 6.5, Lys 6.9, Lys 7.3, and Lys 7.7). Lysine levels were increased by raising overall CP content while maintaining a constant SID lysine: CP ratio. To comply with organic production principles, pigs had ad libitum access to grass–clover silage (GCS). Two three-day balance trials were conducted: trial 1 at an average pig weight of 57.2 kg, and trial 2 at 99.6 kg. During each trial, urine was collected via catheter, faeces was collected quantitatively, and individual intake of compound feed and GCS was recorded. Blood samples were taken from the jugular vein at the end of each trial and analysed for urea and creatinine. Nitrogen in urine and faeces could not be attributed separately to compound feed or GCS, so in the calculations, N from both sources was treated as a single pool for intake as well as for urinary and faecal excretions. Data were analysed using PROC GLIMMIX in SAS. Three-day GCS intake ranged from 863-1479 g in trial 1 and 1330-2252 g in trial 2 and was unaffected by compound lysine level, indicating no compensatory roughage intake. In trial 1, increasing SID lysine elevated N intake ($P = 0.027$) and urinary N output ($P = 0.018$), resulting in an overall diet effect on N balance ($P = 0.022$). However, N digestibility (78.9–81.5 %) and N retention (68.5–73.3 % of digested N) were unaffected. Plasma urea/creatinine ratio differed among diets ($P = 0.044$), but post-hoc comparisons detected no significant pairwise differences. In trial 2, three-day N intake increased from 222 g in the Lys 6.5 group to 268 g in the Lys 7.7 group ($P < 0.001$). Faecal N excretion was unaffected, but the three-day urinary N output rose from 58.9 g in the 6.1 Lys group to 92.1 g in the Lys 7.7 group ($P < 0.01$). Although overall N retention did not differ among diets, a linear decline was observed with increasing lysine ($P < 0.01$), from 68.4 % in the Lys 6.1 group to 56.9 % in the Lys 7.7 group. Plasma urea/creatinine showed a numerical increase at higher lysine levels, but only a trend towards significance ($P = 0.06$). The study demonstrates that increasing SID lysine levels in organic compound feeds elevates total N intake and urinary N excretion in growing–finishing pigs, without improving N retention. Pigs did not adjust their intake of GCS in response to dietary lysine supply, indicating limited capacity for compensatory roughage intake under organic conditions. Contrary to the hypothesised intermediate optimum, no improvement in N utilisation was observed. Within the tested range, SID lysine levels above the lowest level primarily increased N excretion rather than supporting additional protein deposition. The findings highlight the need for tailored amino acid guidelines to improve nutrient efficiency and environmental sustainability in organic pig production.

Evaluating the Role of Dietary Silicate (SiO_3) and Zinc Oxide on Growth Performance, Nutrient Utilization, Gas Emission, Blood parameter and Environmental Impact in Weaning Pigs

K. Das[1,2], S. Y. Jang[1,2], L. Pu[1,2], D. K. Kang[1,2], I. H. Kim[1,2]
[1] Dankook University, Department of Animal Biotechnology, 119, Dandae-ro, 31116 Cheonan, South Korea, [2] Smart Animal Bio Institute, Dankook University, 119, Dandae-ro, 31116 Cheonan, South Korea

Dietary zinc oxide (ZnO) is commonly used in the swine industry to reduce post-weaning diarrhea and improve growth performance in weaned pigs. However, its poor absorption in the gastrointestinal tract results in excessive zinc excretion, leading to serious environmental pollution. Consequently, alternative or complementary feed additives are being explored to sustain growth and gut health while minimizing environmental impact. Dietary silicate (SiO_3) has attracted attention for its adsorptive and buffering properties and its potential to enhance intestinal integrity and nutrient utilization. Silicate-based minerals may bind toxins, stabilize gut microflora, and reduce harmful gas emissions from manure. Therefore, this study aims to evaluate the effect of different levels of ZnO with and without SiO_3 on growth performance, nutrient digestibility, blood parameters, gas emissions, and fecal consistency in 200 [Duroc × (Yorkshire × Landrace); 28 days old; 6.41 ± 0.24 kg] weaning piglets. For a period of 6 weeks, all pigs were assigned to four dietary treatments in a 2 × 2 factorial arrangement. The dietary treatments were as follows: High and Low ZnO (HZnO, 2000ppm and LZnO, 50ppm), with (+) and without (-) 0.1% SiO_3. Each treatment has 10 replicates with 5 pigs/pen. Data was analyzed using two-way analysis of variance with GLM procedure of SAS to evaluate the effects of different ZnO levels (high vs. low), SiO_3 supplementation (with vs. without), and their interaction. Pigs fed a HZnO diet showed significantly greater body weight at the end of week 6, and higher ADG during weeks 1–6 and the overall period compared with pigs fed a LZnO diet ($P < 0.05$), with a tendency for increased ADG during week 1 and improved FCR during weeks 3–6 ($P < 0.10$). Supplementation of 0.1% SiO_3 with HZnO further increased ($P < 0.05$) ADG during weeks 3–6 and overall compared with LZnO + SiO_3. At week 6, HZnO significantly($P < 0.05$) improved nitrogen digestibility, WBC counts, lymphocyte percentage, and reduced NH_3 emissions ($P < 0.05$). Fecal consistency was improved by ZnO and silicate supplementation ($P < 0.05$). There were no interaction effects observed during the experimental period. In summary, combining dietary silicate with a high ZnO diet proved to be effective in enhancing growth performance, nutrient utilization, immune function, and mitigating gas emissions in weaning pigs. Keywords: growth performance, nutrient digestibility, weaning pigs, silicate, zinc oxide.

Reducing environmental nitrogen losses through improved nitrogen retention in weaned piglets fed humic acids

S. Rongen[1], I. Van Den Belt[1], A. Van Enckevort[1], I. Van As[1]
[1] Denkavit, Tolnegenweg 65, 3781PV Voorthuizen, Netherlands

Reducing nitrogen (N) emissions in pig husbandry systems is essential because excessive N excretion contributes to environmental challenges, such as ammonia emissions and soil- and water pollution. A common way to reduce N excretion is via reducing the protein content of the diet. However, it was hypothesized that humic acids by binding pathogenic substances[1], like endotoxins, can support intestinal health, saving N and energy for growth. Furthermore, humic acids could reduce N excretion emission through acidifying the manure and urine, thereby increasing the ratio NH_4^+:NH_3, keeping more N as NH_4^+ and thereby reducing the NH_3 gas emission. In addition, a lower pH may reduce the urease activity, resulting in less conversion of urea in the urine into NH_3 and CO_2. In this context, a digestibility trial was conducted to assess the potential of humic acids on performance, nutrient digestibility and N excretion. 48 piglets (TN70 x PIC 408 Piétrain) were weaned at 22 days of age and were housed in pairs. Piglets were evenly allocated into one of two dietary treatments based on individual weaning weight. From day 1 to 4 post-weaning all piglets received semi ad-libitum creep feed and thereafter from day 5 to 12 semi ad-libitum performance-oriented weaner diet. On day 13 the experimental period started and piglets received either a rearing diet (3.6 mm pellet) without (A) or with 0.15% humic acids (B, Humigut) until the end of the trial (day 26). Piglets were weighed individually on day 12, 19 and 26 of the trial. The first week piglets received the diets semi ad-libitum to adapt and no measurements were taken. From day 20 to 26 piglets were fed restrictedly based on registered weights on day 19. Feed intake was measured per pen, faecal samples were collected twice per day and urine samples once per day between day 22 to 26. On day 22 and 23 the faeces and urine were analysed separately to determine nutrient digestibility. On day 24 to 26 the faeces and urine were collected separately but were mixed into a slurry and stored uncovered to mimic the manure pit to measure N excretion[2]. On day 26 a pooled sample was taken for analysis. All data were statistically analyzed using R Studio with an ANCOVA model, using weight on day 12 as a covariate. The inclusion of humic acids resulted in improved growth (4.0 vs. 4.5 kg/piglet; P=0.003) between day 13-26 and therefore a significantly higher weight on day 26 (11.2 vs. 11.7 kg/piglet; P=0.004). Nitrogen absorption was similar between treatment groups, but N retention was significantly higher for group B (70.9 vs. 74.7%; P=0.02). Increased N utilization by the pig implies that a smaller proportion of N is excreted via the manure. The manure pH was significantly lower in group B (6.6 vs. 6.2; P=0.01). It is known that the acidification of pig manure (pH 5-6) could reduce urease activity[3], which decreases NH_4^+ formation. Although the NH_4^+ content in the slurry of both groups was similar, piglets in group B significantly produced less slurry (734 vs 575 g/pig/day; P=0.03). Therefore, the calculated NH_4^+ excretion per pig per day was significantly reduced in group B (1968 vs 1640 mg/pig/day; P=0.02). There was no difference between fat- and dry matter absorption between treatment groups. The results of this trial showed that the addition of humic acids results in a significantly higher N retention, which proves that more N is used for growth rather than being excreted as waste. In addition, less N would be available for conversion to ammonium, which reduces environmental emissions. On that account, humic acids could contribute to more sustainable pig husbandry.

Relationship between nitrogen and phosphorus intake during pig fattening and the CO_2 footprint per kilogram of live weight.

S. Rosengart[1], C. Timme[2], S. Büngener-Schröder[2], K. Sehlen[1], J. Gickel[3], C. Visscher[1]
[1] University of Veterinary Medicine Hannover, Institute for Animal Nutrition, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] FutterAllianz Nordwest GmbH & Co. KG, Raiffeisenstraße 4, 49685 Schneiderkrug, Germany, [3] University of Veterinary Medicine Hannover, Science and Innovation for Sustainable Poultry Production, Bünteweg 13, 30559 Hannover, Germany

Germany aims to reach climate neutrality by 2045. In conventional pig production systems, feed is typically the dominant emission source, contributing roughly half to more than 60% of total greenhouse gas output. Consequently, nutrient use during fattening plays an important role. This study therefore aimed to describe the relationship between nitrogen (N) and phosphorus (P) intake during pig fattening and the CO_2 footprint per kilogram of live weight. The analysis was based on data from a representative sample of 21 fattening groups (grower to finisher) from a total of 13 conventional pig finishing farms located in northwestern Germany. All farms were connected to the same piglet production system and operated under similar management practices. The recorded data included the raw components used in the compound feeds, their average consumption per animal, and the contents of N (crude protein/6.25) and P. In addition, performance data such as live weight at entry and exit were documented. The life cycle assessment was carried out using the software SimaPro Craft, version 10.2.0.2, with the GFLI database. The exact input of N and P was calculated by multiplying the content of the feed by the amount of feed consumed. Emissions from the barn and from outdoor manure storage with a natural crust cover were calculated according to the literature. The calculated nutrient excretion of N, P, and potassium are contained in the slurry. As an organic fertilizer, slurry can reduce the need for synthetic fertilizers in crop production. The production of synthetic fertilizers is highly energy intensive. In the pig production model used in this study, the amount of synthetic fertilizer that can be replaced by applying the produced slurry to cropland was credited. Electricity consumption for the production of 1 kg of feed was set at 0.02 kWh. The assessment was carried out based on a cradle-to-farm model with a functional unit of 1 kg of liveweight pig. The statistical analysis was performed using SAS Enterprise Guide (version 7.1, SAS Institute Inc., Cary, NC, USA). Normal data distribution was assessed using the Kolmogorov–Smirnov test. Subsequently, the Spearman correlation coefficient was calculated. N and P intake were not normally distributed, whereas the CO_2 footprint data were. Higher total N intake per kg of weight gain during fattening correlated positively with the carbon footprint per kg of live weight (Spearman's $r = 0.61$, $p = 0.003$). No clear correlation was found for P intake ($r = 0.25$, $p = 0.27$). The raw materials with the highest P contents were wheat bran (13 g/kg DM) and rapeseed meal (12 g/kg DM), while soybean meal (7 g/kg DM) and cereals (4 g/kg DM) contained less. The soybean meal included was not certified as deforestationfree, which increased the calculated carbon footprint. Today, soybean meal used in Germany is typically from production without deforestation. If the land use change from this study would be excluded, the correlations would become more pronounced (N: $r = 0.74$, $p < 0.001$; P: $r = 0.56$, $p = 0.008$). In conclusion, N intake during the fattening phase appears to be a relevant driver of the carbon footprint per kg of live weight, whereas P intake showed not such a clear association. These findings confirm the importance of optimizing N efficiency in livestock production to mitigate environmental impacts.

Feeding the balance: how diet optimisation goals affect nitrogen and phosphorus inputs and outputs in Swiss grower-finisher pigs

M. Girard[1], M. Lautrou[1], P. Schlegel[1]
[1] Agroscope, Swine Research Group, Tioleyre 4, 1725 Posieux, Switzerland

The Swiss agricultural system uses two annual nutrient balances to assess nitrogen (N) and phosphorus (P) flows. The first balance (Balance 1) compares national agricultural inputs and outputs. It currently shows a surplus that must be reduced by 15% for N and 20% for P by 2030. The swine sector can contribute by reducing imports of N- and P-rich feedstuffs such as soybean meal and mineral P, which account for 47% of imported N and 56% of imported P in animal feed. Greater use of domestic resources should therefore be promoted. The second balance (Balance 2) is calculated at farm level and compares crop fertilisation requirements with fertiliser use. To avoid surpluses, i.e. excessive N and/or P excretion, one strategy is to minimise dietary crude protein (CP) and/or P content. The Swiss Confederation already enforces a maximum ratio of CP to digestible energy (DE) in pig feed which must not exceed 10.5 g CP/MJ DE throughout the fattening period. This study evaluated seven scenarios for optimising least-cost two-phase diets for growing–finishing pigs in order to assess: (1) how reducing imported N and P sources (Balance 1) affects N and P excretions (Balance 2), and (2) how maximising reductions in N and P excretions (Balance 2) influences the use of imported N and P sources (Balance 1). Seven least-cost optimisation scenarios (SCEN) were tested for grower (40 kg BW) and finisher (80 kg BW) diets containing 13.7 MJ DE/kg and a fixed calcium to digestible P ratio of 2.8. All diets met the Swiss requirements for the nine essential amino acids and digestible P. SCEN 0 represents a compromise optimisation limiting both input and excretion. SCEN 1–3 prioritise reducing N and P inputs (SCEN 1), or N input alone (SCEN 2) or P input alone (SCEN 3). SCEN 4–6 prioritise reducing excretions by imposing minimum CP and P levels (SCEN 4), or minimum CP (SCEN 5) or minimum P (SCEN 6), without restrictions on ingredient origin. The N and P intake per animal was calculated based on dietary CP and P levels, assuming feed intake of 90 kg in the growing and 125 kg in the finishing period. The share of N and P derived from imported feedstuffs was also determined. N and P excretions were estimated for 80 kg weight gain, assuming fixed retentions of 2.08 kg N and 432 g P. Results were expressed relative to SCEN 0. Compared with SCEN 0, input-oriented SCEN (1–3) reduced N from non-Swiss feedstuffs by 23–55% and mineral P use by 10–27%. However, they increased P excretion by 13–16% and had little effect on N excretion due to the reached CP/DE limit. Feed costs rose by 3% in SCEN 2 due to higher inclusion of synthetic amino acids. Excretion-oriented SCEN (4–6) reduced N excretion by 3–17% and P excretion by 25–30%, but markedly increased reliance on non-Swiss feedstuffs (+33–77% N from soybean meal and potato protein; +65–100% P from mineral P). When the objective was to reduce both N and P excretion (SCEN 4), or N alone (SCEN 5), feed costs increased by 5–9% as lower CP levels required greater use of synthetic amino acids and potato protein. The study highlights the high sensitivity of N and P balances to optimisation constraints. Prioritising either input reduction or excretion reduction generates substantial trade-offs between nutrient flows, costs and ingredient origin. Reducing N and P inputs (Balance 1) is possible but negatively affects Balance 2, particularly P excretion, as the ingredients used (rapeseed or sunflower meal and milling by-products) are rich in P. Similarly, formulations targeting lower N and P excretions (Balance 2) worsen Balance 1 by promoting the use of feedstuffs rich in N and P (soybean meal, potato protein and mineral P).

Impact of swine influenza on greenhouse gas (GHG) emissions on Japanese commercial farms

S. Yoshikawa[1], A. Ogino[2], J. Mine[3], K. Miyazawa[3], Y. Uchida[3], Y. Mizoguchi[1], Y. Sasaki[1]
[1] Meiji University, Graduate School of Agriculture, 1-1-1 higasimita tamaku, 214-8571 Kawasaki city, Japan, [2] Institute of Livestock and Grassland Science, National Agriculture and Food Research Organization, 2 ikenodai, 305-0901 Tukuba city, Japan, [3] National Institute of Animal Health, National Agriculture and Food Research Organization, 3-1-5 kanondai, 305-0856 Tukuba city, Japan

Reducing GHG emissions is a critical social goal in achieving a sustainable society. Pig production contributes to GHG emissions through various processes, primarily from manure management, animal housing, and feed production and transportation. GHG emissions of pig production are notably influenced by farm productivity. Swine influenza is a respiratory disease caused by influenza A viruses of swine (IAV-S), which is one of the major respiratory pathogens affecting pigs in large parts of the world. Infection results in clinical signs of fever and coughing, which leads to decreasing productivity and substantial financial losses. However, no study has yet been conducted in Japan to investigate the extent to which IAV-S affects GHG emissions. Therefore, this study aims to investigate the impact of the presence or absence of swine influenza on GHG emissions from pig farms. This study collected data from 9 farrow-to-finish commercial farms in Japan. Active surveillance was performed in July 2024, October 2024, and January 2025 to collect nasal swab samples that were randomly collected from 30 weaned pigs by veterinarians on each farm. The samples were examined for the presence of IAV-S by real-time RT-PCR. Farms with at least one IAV-S positive sample in all three surveillance rounds (n = 4) were defined as ”high IAV-S farms,” while the remaining farms testing positive in fewer than three rounds (n = 5) were defined as ”low IAV-S farms.” Using the calculated GHG emissions as outputs, we compared the emissions between high and low IAV-S farms for finishing section. To assess the GHG emissions in each process, productivity indicators were obtained directly from the surveyed farms. For manure management, GHG emissions was calculated by four processes: CH_4 and N□O generated from excreta, indirect N□O emissions from NH□ during feeding, and CO_2 from fuel and electricity associated with manure management. For animal housing, GHG emissions were calculated by fuel and electricity-derived CO_2 associated with animal housing in the barn and enteric CH_4. The functional unit in finishing section was 1 kg of carcass weight of fattening pig. In the finishing section, high IAV-S farms showed numerically higher emissions across all processes: feed production and transport (2092.17 ± 162.07 vs. 1951.77 ± 119.44 g CO_2e), animal housing (690.04 ± 60.91 vs. 647.28 ± 30.46 g CO_2e), and manure management (1375.01 ± 121.38 vs. 1289.79 ± 60.70 g CO_2e), with a total of 4157.2 ± 208.9 vs. 3888.8 ± 202.8 g CO_2e/kg carcass weight. This study assessed the impact of swine influenza on GHG emissions across nine Japanese farms. Despite the small sample size, GHG emissions were consistently higher on high IAV-S farms than low IAV-S farms in finishing section. These findings demonstrate that swine influenza prevalence negatively impacts environmental sustainability by increasing GHG emissions per unit of production.

Evaluation on low crude protein diet with protease supplementation on growth performance, fecal score, backfat thickness and lean meat percentage, nutrient digestibility, meat quality, and carcass grade in finishing pigs

K. J. Lee[1,2], C. C. Henry[1,2], K. Das[1,2], D. K. Kang[1,2], I. H. Kim[1,2]
[1] Dankook University, Department of Animal Biotechnology, 119, Dandae-ro, Cheonan,, 31116 Cheonan, South Korea, [2] Smart Animal Bio institute, Dankook University, 119, Dandae-ro, Cheonan,, 31116 Cheonan, South Korea

The purpose of this study was to evaluate the effects of protease supplementation in a low crude protein (CP) diet on growth performance, fecal score, backfat thickness, lean meat percentage (LMP), nutrient digestibility, meat quality, and carcass grade in finishing pigs. A total of 96 crossbred pigs [Landrace x Yorkshire) x Duroc] with an initial body weight (BW) of 59.75 kg were used in a 9-week trial. Pigs were randomly assigned to one of three dietary treatments, with eight replicates per treatment and four pigs per pen in a randomized complete block design. The dietary treatments were positive control (PC as a typical finishing diet based on corn and soybean meal); negative control (NC) (low crude protein diet); and NCP (low CP + 0.025% protease). Data was analyzed as a randomized complete design using one-way ANOVA in the GLM procedure of SAS (SAS Institute, Cary, NC, USA). $P < 0.05$ was set as significant. Protease supplementation had no significant effects ($p > 0.05$) on BW, average daily gain (ADG), average daily feed intake (ADFI), and feed conversion ratio (FCR) at week 5. However, FCR tended to increase ($p = 0.056$) at week 9, while BW, ADG, and ADFI remained unchanged throughout the entire trial. Fecal score and lean meat percentage (LMP) were not significantly affected by protease supplementation. However, nitrogen (N) digestibility was increased significantly ($p = 0.0215$) in pigs fed the NCP diet. Meat quality traits, including pH, water holding capacity (WHC), longissimus muscle area, meat color, cooking loss, drip loss, and sensory evaluation, were not affected ($p > 0.05$) by protease supplementation. Nonetheless, there was a tendency for differences in day 1 drip loss ($p = 0.060$) and marbling score ($p = 0.091$) in the protease-supplemented pigs. Furthermore, carcass grade and backfat thickness were not significantly affected by protease inclusion. In summary, protease supplementation in a low crude protein diet enhanced nitrogen digestibility and showed a tendency to improve feed efficiency in finishing pigs without adversely affecting growth performance, fecal score, carcass characteristics, or meat quality. These findings indicate that dietary protease can support efficient protein utilization and allow for a reduction in dietary crude protein and soybean meal inclusion in finishing pig diets, contributing to more sustainable and cost-effective swine production systems. Keywords: Protease, low crude protein, growth performance, nutrient digestibility, meat quality.

Effects of dietary silicate supplementation with varying levels of proteins on growth performance, nutrient digestibility, gas emission, blood profile and fecal score in weaning pigs

S. Y. Jang[1,2], K. Das[1,2], J. H. Kim[1,2], K. Han[2], I. H. Kim[1,2]
[1] Dankook University, Department of Animal Biotechnology, 119, Dandae-ro, 31116 Cheonan, South Korea, [2] Smart Animal Bio Institute, Dankook University, 119, Dandae-ro, 31116 Cheonan, South Korea

Weaning is a critical and stressful phase in pig production, often resulting in reduced growth performance, impaired nutrient utilization, and compromised gut health. Although adequate dietary protein is essential for growth, excessive protein intake can increase nitrogen excretion and harmful gas emissions. Silicate (SiO_3) has emerged as a functional feed additive with potential benefits for nutrient digestibility, intestinal health, and ammonia reduction; however, its combined effects with varying dietary protein levels in weaning pigs remain limited. Therefore, the objective of this study was to evaluate the effects of dietary silicate supplementation under different protein levels on growth performance, nutrient digestibility, gas emissions, blood profiles, and fecal characteristics in weaning pigs. A total of 200 crossbred weaning pigs ([Yorkshire × Landrace] × Duroc, 21 d old with an initial body weight (BW) of 6.47 kg) were randomly allotted to 1 of 4 dietary treatments based on the BW and sex and in a 2 × 2 factorial arrangement. Each treatment has ten replicates with (5 pigs per pen [2 barrows and 3 gilts]. Data was analyzed using two-way analysis of variance with GLM procedure of SAS to evaluate the effects of different crude protein levels (high vs. low), SiO_3 supplementation (with vs. without), and their interaction. The dietary treatments were as follows: High Crude Protein (HCP) and Low Crude Protein (LCP), with (+) and without (-) 1% SiO_3. Pigs fed an HCP + SiO_3 diet showed significantly greater average daily gain (ADG) during weeks 1–6 and over the entire experimental period ($P < 0.05$). Also, it resulted in increased nitrogen digestibility and reduced fecal ammonia (NH_3) emissions ($P < 0.05$). Compared with pigs fed LCP diets with or without SiO_3, those receiving the HCP + SiO_3 diet exhibited higher white blood cell counts ($P < 0.05$) and a tendency toward increased lymphocyte percentages ($P < 0.10$). No interaction effects between dietary protein level and silicate supplementation were observed for any measured parameters. In conclusion, dietary supplementation with 0.1% silicate improved growth performance, nitrogen utilization, immune response, and intestinal health and reduced fecal ammonia emissions in weaning pigs, independent of dietary protein level. Keywords: growth performance, nutrient digestibility, weaning pigs, silicate, protein

Individual and Combined Supplementation of Microbial Phytase and β-Mannanase in Growing Pigs: Impacts on Growth Performance, Nutrient Digestibility, and Fecal Scores

S. Y. Jang[1,2], W. Zhao[1,2], L. Pu[1,2], D. K. Kang[1,2], I. H. Kim[1,2]
[1] Dankook University, Department of Animal Biotechnology, 119, Dandae-ro, 31116 Cheonan, South Korea, [2] Smart Animal Bio institute, Dankook University, 119, Dandae-ro, 31116 Cheonan, South Korea

In modern pig production, enhancing growth efficiency and nutrient utilization while minimizing costs and environmental impact is a key priority. Nevertheless, digestive inefficiency and nutrient loss continue to challenge sustainable production. Therefore, the objective of this study was to assess the effects of single and combined effect of microbial phytase and β-mannanase on growth performance, nutrient digestibility, and fecal score in growing pigs. For a period of 35 days, a total of 128 crossbred pigs [(Landrace × Yorkshire) × Duroc] with an initial body weight of approximately 29.61 ± 1.57 kg were randomly assigned to one of four dietary treatments: (1) CON, a basal diet without enzyme supplementation; (2) TRT1, the basal diet supplemented with 500 U/kg microbial phytase; (3) TRT2, the basal diet supplemented with 1600 U/kg β-mannanase (4) TRT3, the basal diet supplemented with 1600 U/kg β-mannanase + 500 U/kg microbial phytase. Each treatment included 8 replicates with 2 barrows and 2 gilts per pen. Data was analyzed as a randomized complete design using one-way ANOVA in the GLM procedure of SAS (SAS Institute, Cary, NC, USA). $P < 0.05$ was set as significant. The inclusion of microbial phytase and β-mannanase in pigs diet had significantly improved ($P< 0.05$) average daily gain (ADG) and feed conversion ratio (FCR) during days 0–5. From days 5–35 and throughout the entire experimental period, all enzyme-supplemented groups exhibited significantly ($P < 0.05$) higher ADG and lower FCR compared with the CON group. Similarly, nutrient digestibility of dry matter, nitrogen, and energy were significantly ($P< 0.05$) increased in pigs fed microbial phytase and β-mannanase supplementation. No significant differences were observed in fecal scores among the treatment groups ($P > 0.05$). Collectively, these results suggest that the combined use of microbial phytase and β-mannanase is an effective strategy to enhance growth performance in growing pigs. Keywords: microbial phytase; β-mannanase; growing pigs; growth performance; nutrient digestibility; fecal score

Feasibility and repeatability of standard protocol to assess animal welfare

Animal welfare is assessed throughout the animal's life, including on-farm, during transport and at slaughter. Welfare protocols have therefore been developed in several research projects, such as Welfare Quality®, AWIN, ClassyFarm, and EBENE. To obtain a clear overview of the animal welfare's progress in Europe, the internal project (SOA9) of the European Partnership on Animal Health and Welfare (EUPAHW) is developing a knowledge platform compiling all these elements. Within SOA9, the different welfare protocols used at the European scale have been reviewed to harmonize and standardize animal welfare protocols focusing on 60 indicators across 9 livestock species and production categories, i.e., dairy cattle, pig, sheep, goat, broiler chicken, laying hens, turkey, rabbit and fish. In addition, a specific study is currently being set in poultry to assess feasibility and repeatability of the standardized protocols, where there is a gap of knowledge. For laying hens, the following indicators have been assessed on-farm using the transect method: feather damage, beak condition, foot damage, toe damage, and wounds. On the other hand, plumage cleanliness, breast blisters, and footpad dermatitis have been assessed in broiler chickens at the slaughterhouse. Feasibility of protocols has been assessed in at least three different rearing systems (e.g. cage, floor, aviary for laying hens) using an assessment methodology that considers the following aspects: specific equipment required, automatization of assessment, time required, animal handling, training time, and doable of the slaughter line (if the assessment is carried out at the slaughterhouse). To assess repeatability, the protocols used to evaluate the above-mentioned indicators have been carried out by three observers (inter-observer repeatability) and in three rounds (intra-observer repeatability). The results will feed the EUPAHW knowledge platform by displaying repeatability, feasibility, and the level of effort required for implementation for each indicator and its protocol.

Animal Welfare Index – A new on-farm welfare assessment method

D. Debiasi[1], S. Götz[2], U. Höne[1], J. Krieter[1], J. Probst[2], N. Kemper[2], S. Küster[1], I. Reker[3], G. Otto[4], I. Traulsen[1]
[1] Christian-Albrechts-University, Institute of Animal Breeding and Husbandry, Hermann-Rodewald-Str. 6, 24116 Kiel, Germany, [2] University of Veterinary Medicine Hannover, Institute for Animal Hygiene, Bischofsholer Damm 15, 30559 Hannover, Germany, [3] Lower Saxony Chamber of Agriculture, Experimental Station for Pig Farming, Hermann-Ehlers-Str. 15, 26160 Bad Zwischenahn-Wehnen, Germany, [4] Böseler Goldschmaus GmbH & Co. KG, Industriestraße 10-12, 49681 Garrel, Germany

On European level, one of the biggest organizations responsible for the control of food production chains is QS® – Quality Scheme for food (QS Qualität und Sicherheit GmbH, 53177 Bonn, Germany). Within this scheme, health and welfare of livestock are mainly rated based on observations made at the slaughterhouse. These observations are determined by a protocol named Animal Welfare Index. The index is classified into four primary categories: 1) respiratory health, 2) organ health, 3) limb health, and 4) integrity. The primary categories are furthermore divided into subclasses identifying the affected organs or the pathologies: 1) lung, pleura, pericardium, 2) liver, intestines, 3) joint inflammation, bursitis, 4) skin, ear, tail, and chasing marks. Subsequently, the rating is converted into values using a scale ranging from 0 to 100, with 0 representing the lowest score and 100 the highest attainable score. The aim of this study is to propose an additional index that is based on scores documented at farm level and focused on living animals. A thorough examination of the production process has led to the identification of three candidates time points where the rating could be implemented: weaning; the end of the rearing process; and day 80 of the fattening period. For the development of the farm index, the primary categories were left unaltered, while the subclasses underwent modifications to ensure their adaptability on farm level. The subclasses include new parameters to be measured on living animals like: 1) nasal discharge, chough, sneezing, cardiovascular problems, 2) diarrhea, 3) lameness, arthritis, hoof changes, 4) old/fresh ear injury, loss of tail length, tail tip necrosis, and old/fresh tail wound. For testing, the assessments were conducted on four farms, which were found to comply the production standards 1 to 4 of the German "Haltungsform (HF)". These housing standards range progressively from conventional pig farming (HF1) to an enhanced system that provides 100% more space per animal and continuous access to outdoor areas (HF4). Preliminary results demonstrated congruence with marginal differences between the ratings of the standard slaughterhouse index and the novel on farm index for respiratory health (91 vs. 98), organ health (95 vs. 99), and limb health (95 vs. 92). Nevertheless, discrepancies between the indices were found for the primary category of integrity (97 vs. 48). The on-farm index includes a higher percentage of damages compared to the slaughterhouse index. One of the advantages of the on-farm index is the ability to facilitate management decisions within the farm and at the slaughterhouse. However, for monitoring of integrity, particularly tail lesions in the context of tail biting, the on-farm index reveals a more detailed picture to improve husbandry and management conditions regarding animal welfare. The project is supported by funds of the Federal Ministry of Agriculture, Food and Regional Identify (BMLEH) based on a decision of the Parliament of the Federal Republic of Germany. The Federal Office for Agriculture and Food (BLE) provides coordinating support for future farms and future regions as funding organization, grant number 2823ZR016.

New welfare assessment protocol for dairy cattle herds

L. Frondelius[1], M. Mughal[1], L. Tuomisto[1], K. Sarjokari[1], T. Koistinen[1]
[1] Natural Resources Institute Finland, Welfare of farmed animals, Production systems, Halolantie 31A, 71750 Maaninka, Finland

The present study developed a new set of measurements for assessing animal welfare in dairy herds. The protocol created reflects five dimensions of welfare: nutrition, health, environment, behaviour, and emotional state. It covers all animal groups on a dairy farm: calves, youngstock, and dairy cows. Our goal was to create a welfare assessment protocol scientifically valid yet practical and time-efficient. We aimed for a procedure that can be implemented widely and is compatible with the existing quality assurance systems in Finland. Therefore, it will be useful in promoting welfare improvements in high proportion of dairy farms in the future. The development process consisted of a literature review to identify potential measurements, followed by testing feasibility and reliability and estimating required sample sizes. The protocol was tested on dairy farms in three phases. Measurements showing low inter-observer reliability or limited practicality were refined or removed. Sample sizes for animal-based measurements were defined using field data and published values in scientific literature. During development, an understanding of welfare as the animal's own subjective experience was emphasized; therefore, animal-based measurements were prioritized. However, to realistically achieve scalability, on-farm assessment of a typical size of a Finnish dairy herd (40 to 200 cows) should not take more than half of a working day. Consequently, some of the most time-consuming animal-based measurements were replaced with reliable alternatives of resource- or management-based measurements, when satisfactory options were available. Also, the protocol was designed to interfere with farm routines as little as possible. In addition to measurements conducted on-farm, we incorporated into the protocol several database-derived indicators (for example mortality, incidence of mastitis, structural restrictions, adequacy of claw trimming). This was possible, because in Finland, veterinarians, advisors, and farmers routinely collect structured data relevant to welfare. Data are sourced from the Naseva herd health and welfare register, the national cattle register, and Dairy Herd Improvement records. Moreover, a complementary questionnaire for farmers was included. It covers measurements that cannot be obtained from databases or farm-level measurements (for example calf feeding practices, outdoor access, and using pain relief). The final welfare assessment protocol includes 44 measurements: 17 measurements conducted on farm, 9 database-derived variables, and 18 questions for farmers. Unlike many earlier protocols, this one covers pre-weaned calves and youngstock. We developed some new measurements specifically for them, also, measurements that have earlier been developed for adult animals but were suitable for calves and youngstock are used. The number of measurements vary between animal groups. Pre-weaned calves and dairy cows are assessed individually (e.g. body condition score, skin lesions, symptoms of disease), whereas youngstock are assessed at group level from outside pens, because of safety and reliability. The welfare assessment protocol system is designed to be dynamic, allowing updates as welfare research and technology continuously advance. Future developments may include additional measurements, particularly those addressing positive welfare. Work to create an aggregation method for generating welfare indices is ongoing.

Potential of barn climate parameters as iceberg indicators in welfare assessment and their relationships with productivity in fattening pigs

N. Puttkammer[1], J. Witt[2], K. Büttner[3], J. Krieter[4], P. Sandøe[1,5], I. Czycholl[1]
[1] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 8, 1870 Frederiksberg, Denmark, [2] ISF GmbH, An der Mühlenau 4, 25421 Pinneberg, Germany, [3] Justus Liebig University Giessen, Faculty of Veterinary Medicine, Frankfurter Straße 95 95, 35392 Giessen, Germany, [4] Christian-Albrechts-University Kiel, Institute of Animal Breeding and Husbandry, Olshausenstraße 40, 24118 Kiel, Germany, [5] University of Copenhagen, Department of Food and Resource Economics, Rolighedsvej 23, 1870 Frederiksberg, Denmark

Welfare assessment on-farm by animal-based measures remains time-consuming and therewith lacks feasibility. The use of post-mortem indicators at the slaughterhouse is also problematic, as these data are retrospective in nature. The question thus arises whether currently applied animal-based indicators could be partially substituted by barn climate data. These can be continuously recorded by widely available and affordable digital devices. This study investigates the potential of barn CO_2 concentration (CO2), relative humidity (HUM) and the temperature-humidity index (THI) as potential iceberg indicators for welfare assessment in fattening pigs. Climate sensor data and weekly assessed on-farm indicators were collected on 2 conventional German pig farms with forced ventilation. Post-mortem indicators, including performance data, were recorded at slaughter. Data were available for 387 pigs in all. To capture short- and medium-term barn climate effects (potentially reflected in on-farm animal-based indicators), CO_2, HUM and THI were summarized by their mean values on the respective assessment morning and by weekly mean, minimum, maximum and cumulative values (loads) for the preceding week. To capture long-term effects (potentially reflected in post-mortem indicators), this was carried out for three periods: 4 and 8 weeks before slaughter and the entire fattening period. Logistic regression models were calculated with the dependent variable being the respective animal welfare indicator (on-farm (e.g. sneezing, tail lesions) or post-mortem (e.g. pneumonia, pleuritis) and the independent variables the respective climate indicator and the pen. For the performance data analysis, the dependent variable was the respective performance parameter obtained from the slaughterhouse via AutoFOM (e.g. carcass weight, lean meat percentage) and the independent variables were the respective climate indicator and the age at slaughter. The analysis for the welfare indicators revealed most significant effects for HUM, particularly impacting the prevalence of ear lesions, tail lesions, fever, coughing and pneumonia. Single THI parameters affected the prevalence of ear lesions, tail lesions, sneezing and pneumonia. The CO2 parameters only impacted the prevalence of ear lesions, tail lesions and pneumonia. As for the performance indicators, multiple THI parameters significantly affected lean meat percentage, average daily weight gain and carcass weight, whereas HUM only affected lean meat percentage and carcass weight. Significant effects of CO_2 were only observed for lean meat percentage. In both farms, climate parameters only occasionally exceeded recommended thresholds. Stronger effects might have been observed under greater variability in barn climatic conditions. It is noteworthy that harmful effects of elevated CO2 were detected, although the threshold was set comparatively low at 1,500 ppm. Furthermore, our results indicate a significant impact of HUM on pig welfare and performance, suggesting that future research should place greater emphasis on this parameter. Overall, our findings confirm the potential of various barn climate parameters as iceberg indicators in pig welfare assessment.

Effect of dehorning on salivary cortisol responses in South African Bonsmara beef calves

R. Erasmus[1], M. Combrink[1,2], C. Uys[3], S. Lashmar[1], E. Van Marle-Köster[2]
[1] Agricultural Research Council, Animal Production, Irene, 0062 Pretoria, South Africa, [2] University of Pretoria, Department of Animal Science, Hatfield, 0002 Pretoria, South Africa, [3] Dagbreek farm, Warrenton, 8532 Warrenton, South Africa

In South Africa, dehorning is a routine management practice performed on most beef cattle farms, either to prevent injuries to other cattle or handlers, to adhere to breed standards, or for entry into the feedlot. Dehorning is a painful and stressful procedure for calves, especially since very few farmers administer any form of medication for pain relief. Various studies observed an immediate rise in plasma cortisol levels, an indicator of stress, which can last up to six hours after dehorning. Saliva collection is a non-invasive alternative to blood sampling that incurs additional stress, especially for calves in extensive production systems. Saliva is regarded to be a good estimate of plasma cortisol following activation of the HPA axis in response to acute stress in cattle. This study aimed to measure the stress associated with dehorning in Bonsmara beef calves in a commercial setting using salivary cortisol as a biomarker. Ethical approval was obtained from the AEC of the University of Pretoria (NAS308/2025). Sixty nine Bonsmara pre-weaner calves, three to four months of age, and representing first and second parity plus cows were divided into two treatment groups: polled control group (n=35) and a dehorned group (n=34). The 34 calves were dehorned as part of routine management practices on a Bonsmara stud farm using a hot disbudding iron and treated with an aerosol ectoparasitide afterwards. Saliva samples were taken using synthetic swabs (Salivette Cortisol, Sarstedt, Germany) before dehorning, immediately after dehorning, approximately 2 hours after dehorning and the following day. Within three hours after sampling, the samples were centrifuged at 12 000 rpm for 20 minutes. Salivary cortisol concentrations were determined with a competitive cortisol enzyme immunoassay (EIA). Statistical analyses were performed in R fitting a linear mixed-effects model. Salivary cortisol concentrations differed significantly between treatments, with dehorned calves showing substantially higher cortisol levels than polled calves. Mean peak cortisol concentrations were approximately 10.8 ± 4.1 ng/ml in dehorned calves compared with 5.65 ± 2.92 ng/ml in polled calves, representing a large treatment effect (Cohen's $d \approx 1.47$). These results were similar to previous studies in cattle using plasma cortisol as a biomarker to evaluate stress. Significant effects were observed for treatment ($P < 0.001$) and sampling time ($P < 0.001$) on cortisol concentrations, with a significant treatment × time interaction ($P < 0.001$). This indicates that dehorned calves exhibited a pronounced cortisol spike following dehorning, while cortisol levels in polled calves remained relatively stable over time. Dehorning causes acute stress in beef calves, that can be mitigated by incorporating polled genetics in breeding programs.

Circulating MiRNAs as Potential Biomarkers Of Pain And Stress in Piglets Undergoing Castration

E. Nadlučnik[1], M. Arigoni[2], R. Calogero[2], M. Štukelj[1], C. Lecchi[3]
[1] University of Ljubljana, Veterinary Faculty, Clinic for Reproduction and Large Animals, Clinic for Ruminants and Pigs, Gerbiceva 60, 1000 Ljubljana, Slovenia, [2] University of Torino, Department of Molecular Biotechnology and Health Sciences, Bioinformatics and Genomics core-lab, Via Nizza 52, 10126 Torino, Italy, [3] University of Milano, Veterinary Faculty, Department of Veterinary Medicine and Animal Sciences, Via Dell'Università 6, 26900 Lodi, Italy

Castration of piglets is a breeding practice performed globally, and it is usually performed without pain relief. Such a procedure raises important ethical and scientific questions regarding the welfare of piglets and the level of pain experienced by piglets. The pain assessment in animals is particularly challenging, as animals do not express pain in a way that is easily recognized or measured. Moreover, the stress caused by handling, restraint, or the mere presence of humans is often so intense that it can mask or overshadow behavioural and physiological indicators of pain. Micro ribonucleic acids (miRNAs) regulate genes involved in pain and stress pathways, are stable in biofluids, and can provide more specific information on the biological processes. Our goal was to investigate the use of circulating miRNAs as potential biomarkers of pain and stress experienced by piglets during castration and to evaluate how their expression is modulated by the administration of meloxicam in combination with isoflurane for pain relief during the castration. The study included 24 four-day-old piglets assigned to four experimental groups. The first group served as a handling control and was handled without castration. The second group underwent castration without anaesthesia or analgesia. The third group was handled following the administration of anaesthesia and analgesia but was not castrated. The fourth group underwent castration following the administration of anaesthesia and analgesia. Piglets' plasma was collected before handling or castration and 2 h, 24 h, and 48 h after handling or castration. MiRNAs were isolated from piglets' plasma using a commercially validated miRNA extraction kit. To characterize the whole profile of circulating miRNAs, a pilot next-generation sequencing (NGS) analysis was performed, and differentially expressed miRNAs (DE-miRNAs) were identified by comparing the groups at different time points. Gene ontology was subsequently conducted to predict the target genes of DE-miRNAs and to assess their involvement in stress- and pain-related pathways. The results of NGS showed DE-miRNAs between the treatments and across time points. Gene ontology demonstrated that these miRNAs are involved in stress- and pain- related pathways. Therefore, miRNAs have the potential to act as biomarkers of pain and stress in piglets during castration. These findings provide a molecular basis for objective pain assessment and support the development of evidence-based welfare strategies in pig production.

Effect of plumage condition on the welfare of end-of-lay broiler breeders exposed to a transport model

J. Verlaat[1], E. M. Leishman[1], C. J. A. Williams[1,2], M. S. Herskin[1], A. B. Riber[1]
[1] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Alle 20, DK-8830 Tjele, Denmark, [2] Aarhus University, Aarhus Institute of Advanced Studies, Høegh-Guldbergs Gade 6B, DK-8000 Aarhus C, Denmark

End-of-lay broiler breeders are exported for slaughter from Denmark to other EU member states year-round, at approximately 60 weeks of age. The hens often have poor plumage condition due to repeated mounting of the hens by roosters, feather pecking, wear and tear from the environment, and nutritional factors. Poor plumage condition (i.e., reduced feather cover and more exposed skin) could pose an increased risk for injuries and thermal stress during transports occurring during colder seasons. Herein, we present an experimental model study of poultry transport to gain knowledge on whether transport at lower temperatures affects the welfare of broiler breeder hens and if these effects depend on plumage condition. The transport model we designed contained two replicates (nTotal = 144, 62-week-old broiler breeder hens, Ross 308) in a constrained Latin square design with each replicate acting as its own control while rotating through simulated transports at three different temperatures (5, 12 and 20 □C) representing a realistic temperature range of Danish outdoor conditions. Hens were scored for plumage condition using the methods of Bilcik and Keeling (1999) and designated as having Better (score ≥19), Moderate (16 – 18), or Worse (0 – 15) plumage condition. Hens were assigned to groups of 6 in commercial transport crates (N=12 crates per replicate, 50 x 85 x 30 cm, i.e., 708 cm^2 per bird) with two birds from each level of plumage condition in each crate to reflect possible mixing of birds during transport. The birds were exposed to the model conditions in a temperature-controlled room equipped with cooling capabilities and real time monitoring of temperature and humidity. In addition to monitoring room temperature, each crate was equipped internally with a temperature and humidity sensor. Furthermore, in the experimental room multiple thermal sensors were used to determine the room temperature. During each replicate, a random sample of three crates were removed successively after 3, 6, 9 and 12 h, respectively, of exposure to the conditions. Twelve hours was chosen as the maximum duration, corresponding to the maximum time that birds can be transported without provision of feed (Council Regulation (EC) No1/2005). The welfare of the birds was assessed before and after exposure to the simulated transport conditions using a variety of physiological and behavioural indicators. To monitor thermal stress, half of the birds (n = 72) were orally administered a temperature datalogger to approximate core body temperature which will be compared to cloacal temperature. Additionally, birds were weighed and an injury assessment (including the number and severity of scratches and wounds) was performed. Venous blood samples were taken from a subset of birds (n = 24 per simulated transport) to quantify glucose, lactate, electrolytes, haematocrit and venous blood gases. After each replicate, hens were placed into behavioural test pens to assess feed and water intake, thermoregulatory and comfort behaviour, and activity level. This newly established model of poultry transport will ultimately provide knowledge on the effect of plumage condition of end-of-lay broiler breeder hens transported for slaughter during colder seasons. The included animal-based measurements will provide information about possible welfare concerns that can be further studied.

Indicators for assessment of animal welfare on euthanized or deceased animals

C. Over[1], B. Prottengeier[1], R. Magner[2], S. Schlierenkamp[2], U. Schultheiß[2]
[1] Johann Heinrich von Thünen Institut, Bundesallee 50, 38116 Braunschweig, Germany, [2] Kuratorium für Technik und Bauwesen in der Landwirtschaft e.V. (KTBL), Bartningstraße 49, 64289 Darmstadt, Germany

There are very few studies that assess animal welfare by examining carcasses at animal by-product rendering facilities. The existing studies consistently show that numerous animal welfare–relevant findings were identified in fallen stock and that these findings occur frequently. Based on this evidence, fallen stock were included in the NaTiMon project (National Animal Welfare Monitoring) as one important data source. The aim of the NaTiMon project was to design a national animal welfare monitoring system for Germany in order to generate knowledge about the current status of animal welfare in livestock husbandry. To achieve this goal, welfare indicators from the literature were selected, and a set of indicators for different livestock species was tested for their practical on-site applicability. Indicators for assessment on cattle and pig carcasses were selected that can be evaluated without dissection, relying solely on visual inspection and, where necessary, palpation. This approach allows a large number of carcasses to be examined within a short period of time without significantly disrupting the workflow of the plant. All indicators should be reliably measurable, provide a valid assessment of animal welfare, and it should be possible to train auditors without veterinary education to carry out the assessment. After a preliminary identification of indicators from the literature, the selection of indicators for testing was carried out through an expert panel. The resulting set of indicators was tested at ten facilities in eight federal states in Germany, with assessments conducted on one to two days per facility. On each day, between 20 and 100 animal carcasses were evaluated, resulting in a total of approximately 800 animal carcasses being examined. Data collection during ongoing operations was feasible in all facilities visited; however, carcasses had to be set aside for examination, which resulted in additional workload for the staff. Finally, a selection of six indicators was established, four of which apply to both cattle and pigs, and two specifically to pigs. In addition to the correct performance of emergency killing (indicator 1), the focus is on signs of prolonged illness prior to death, such as severe emaciation (indicator 2) and the presence of decubital lesions (indicator 3), as well as severe swellings (indicator 4) and, additionally in pigs, severe hernias (indicator 5) and the loss of tails and ears (indicator 6). At the end of the project, the indicator set, along with guidelines for data collection and instructions for conducting on site visits and ensuring biosecurity, was published. The results of the assessments were not statistically analyzed within the NaTiMon project, as the primary objective was to define a set of indicators and to test the feasibility of collecting these indicators. The project has shown that collecting data on fallen animals is possible and useful for maintaining the status quo of animal welfare in Germany. Regular monitoring of indicators can help identify acute animal welfare issues and inform the development of preventive measures for the future. This work was funded by the Federal Ministry of Food and Agriculture (BMEL) based on a decision of the Parliament of the Federal Republic of Germany, granted by the Federal Office for Agriculture and Food (BLE).

Field Feasibility and Repeatability of Standardised Protocols for Turkey Welfare Assessment

V. Monistero[1], S. Podda[1], O. Girardie[2], V. Michel[3], A. Velarde[4], N. Abdelli[4], J. Zemzmi[4], S. Celozzi[5], V. Ferrante[5], L. J. Vinco[1]

[1] Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia Romagna (IZSLER), Italian National Reference Centre for Animal Welfare, Via A. Bianchi, 9, 25124 Brescia, Italy, [2] French Agency for Food, Environmental and Occupational Health & Safety (ANSES), Pathology and Welfare of Ruminants Unit, 60 rue de Pied de Fond, 79024 Niort, France, [3] French Agency for Food, Environmental and Occupational Health & Safety (ANSES), Direction de la Stratégie et des Programmes, 14 rue Pierre et Marie Curie, 94701 Maisons-Alfort, France, [4] Institute of Agrifood Research and Technology (IRTA), Animal Welfare Program, Veïnat de Sies s/n, 17121 Monells, Girona, Spain, [5] University of Milan (UNIMI), Department of Agricultural and Environmental Sciences, Via Celoria, 2, 20133 Milan, Italy

Despite regulatory and private efforts to improve animal conditions from farm to slaughter, the practical application of welfare assessment protocols remains challenging, as existing systems still face limitations in comparability and reproducibility across European countries. As part of the EUP AH&W SOA9 activity, this study aims to harmonise turkey welfare assessment across Member States by reviewing existing protocols and developing standardised procedures for selected animal-based measurements (ABMs), evaluated on-farm and at slaughter. The validation of the proposed standard protocols focuses on field feasibility, inter-observer and intra-observer repeatability. In turkeys, breast blister (BB) and footpad dermatitis (FPD) were identified as key indicators. The comprehensive bibliographic review revealed substantial differences in scoring methods and evaluation conditions, highlighting the need for methodological harmonisation. Therefore, the following standardisation approach was proposed to fill the gap of knowledge. For feasibility, the selected ABMs have been visually assessed in multiple slaughterhouses in three different countries (France, Italy, and Spain) to ensure representativeness, and account for variability in animal and operational conditions. For repeatability, the field evaluations have been carried out by multiple observers per country who completed a harmonized training phase prior to data collection. During this phase, photographs and videos were jointly reviewed to align scoring criteria and to ensure consistent ABM interpretation. Field assessments started only after a predefined level of inter-observer agreement had been achieved. BB, defined as a form of contact dermatitis characterized by a pathological response of the skin in contact with hard surfaces, have been evaluated on the slaughter line after plucking using a binary scoring system (0 = absent; 1 = present), with a lesion threshold of ≥ 0.5 cm². FPD, described as a contact dermatitis of the plantar surface of birds' feet affecting both the skin and subjacent tissues, have been classified into the three scoring categories, based on lesion extent on the metatarsal footpad. For intra-observer repeatability, each left foot has been assessed after removal from the slaughter line, and independently evaluated three times by each observer. Preliminary results indicate that the standardised protocols are applicable under diverse field conditions, with inter- and intra-observer repeatability currently ongoing. The resulting dataset will be integrated into a European knowledge platform summarising feasibility, repeatability and implementation effort, thereby strengthening harmonised and comparable turkey welfare monitoring across Member States.

Animal welfare in pork production: Farmer and Veterinarian perspectives

M. E. Lagoda[1], K. A. Moak[1], K. Arisman[1], M. Kaczur[2], T. L. Sandri[3], N. Wuyts[3], L. Van De Weyer[4], Y. M. Seddon[1]
[1] University of Saskatchewan, Western College of Veterinary Medicine, 52 Campus Dr, SK S7N 5B4 Saskatoon, Canada, [2] University of Saskatchewan, Canadian Hub for Applied and Social Research, 3 Campus Dr, SK S7N 5A4 Saskatoon, Canada, [3] Zoetis, Global Medical Affairs, 10 Sylvan Way, 07054 Parsippany, United States, [4] Zoetis Canada, 40 Trans-Canada, 60477 Kirkland, Canada

Good animal welfare is known to enhance productivity, contribute to improved economic margins, and long-term sustainability. However, clearer stakeholder understanding of these relationships is needed to support industry decision making for broader adoption of welfare strategies. The objective of this study was to examine how pork industry stakeholders perceive animal welfare and its role in business decisions by assessing: (1) how producers and swine veterinarians define animal welfare, including the metrics they use to monitor it on-farm; and (2) stakeholder understanding of how management procedures influence welfare, whether decisions are driven by welfare or productivity concerns, and whether barriers to implementation exist. Concept elicitation interviews with open-ended questions were conducted to capture stakeholder experiences with on-farm welfare management. Ten participants were interviewed; four experienced swine managers and six veterinarians, including eight from Canada and two from the United States. Interviews elicited detailed descriptions of participants' definitions of animal welfare, the management practices they implemented and the motivations behind management decisions, welfare and productivity indicators used, perceived impacts of management practices on staff well-being, and views on the interconnections between welfare and production performance. Generally, producers did not provide a clear definition of animal welfare, but referenced welfare indicators they use to assess welfare; these included primarily visible, physical measures related to economically relevant performance metrics (i.e., skin injuries, disease), rather than indicators reflective of affective states (i.e., behavioural indicators). Respondents acknowledged the value of good welfare for profitability and staff well-being, but welfare considerations were secondary to economic priorities, and practices involving upfront costs were rarely adopted unless mandated. This study indicates that, while animal welfare is broadly acknowledged as a key component of pork production, it is not yet fully understood or integrated into the workplace culture or business models of pork production. This may reflect a limited appreciation of the broader long-term benefits of welfare for economic viability. Future research that integrates welfare improvement strategies and practical assessment tools with economic analyses could strengthen understanding of its contribution to long-term business viability.

Harmonization and Standardization of Indicators for Assessing Sheep Welfare

M. Milazzo[1], C. Cimini[1], L. Baldacchini[1], D. Hazard[2], N. Abdelli[3], D. R. Arney[4], F. Johansen[5], J. Zemzmi[3], O. Girardie[6], G. E. Martin Valls[6], V. Michel[6], M. Podaliri Vulpiani[1], A. Velarde[3], L. Iannetti[1], S. Mullan[7]
[1] Istituto Zooprofilattico Sperimentale dell'Abruzzo e del Molise, Via Campo Boario, 64100 Teramo, Italy, [2] National Research Institute for Agriculture, Food and Environment, Chemin de Borde Rouge - Auzeville, 31326 Toulouse, France, [3] Institute for Agrifood Research and Technology, Finca Camps i Armet, 17121 Girona, Spain, [4] Estonian University of Life Science, Kreutzwaldi tn 1a, 51006 Tartu, Estonia, [5] Teagasc Food Research Centre, Moorepark, Moorepark West, Fermoy, P61 C996 Cork, Ireland, [6] Agency for Food Environmental and Occupational Health & Safety, rue Pierre et Marie Curie, 94701 Maisons-Alfort Cedex, France, [7] University College Dublin, Belfield, D04 V1W8 Dublin, Ireland

Within the European Partnership for Animal Health and Welfare (EUPAHW), a group of experts from Research Performing Organisations in five EU countries (France, Spain, Estonia, Ireland and Italy) carried out a literature review for the harmonisation of selected animal-based welfare indicators for sheep. The activity was conducted under Task 2, coordinated by ANSES and UAB and contributes to Set of Activities 9 (SoA9), aimed at developing a European Knowledge Platform on animal welfare. A pre-existing digital database (More Welfare project OC/EFSA/ED/2022/02), including peer-reviewed studies previously screened for relevant welfare indicators, was used as the main starting reference. The objective was to harmonise and standardise existing assessment indicators through literature review and systematic data extraction. A comparative analysis of peer-reviewed studies and documented methodologies from the database identified methodological similarities and differences and supported evidence-based harmonised approaches based on validated protocols.The indicators assessed were: panting, nasal discharge, fleece cleanliness, tail length, social withdrawal, qualitative behaviour assessment (QBA), human approach test, and lameness and leg injuries. Data were extracted into a structured Excel dataset including sample size, production stage, farming system, assessment location (farm or slaughterhouse), study design, protocol characteristics, body regions assessed, scoring methods, welfare criteria and thresholds. This enabled comparison of methodological heterogeneity and identification of strengths and limitations. Following comparative analysis, methodologies for indicator harmonisation were proposed. These proposals were reviewed by sheep welfare experts to assess scientific robustness, feasibility and applicability across production systems.For most indicators, widely used protocols were confirmed as valid and requiring no substantial modifications. The only exception was panting, for which a harmonised simplification was proposed: the original 7-point scale (Lees et al., 2019) was reduced to a 5-point scale to improve clarity, inter-observer agreement and on-farm feasibility without compromising sensitivity. Next steps include a bibliographic review to evaluate feasibility and repeatability of each method. Inter- and intra-observer agreement tests will quantify reliability. Field validation of the harmonised panting protocol will be conducted on at least three farms per country representing different systems, with assessments performed by at least two observers and repeated three times to ensure robustness.This coordinated effort enhances consistency, comparability and implementation of sheep welfare assessment across countries, supporting harmonised methodologies within SoA9 and strengthening the scientific basis for future monitoring frameworks. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW.

Sensor-based monitoring of behavioural adaptation of dairy calves during regrouping from individual or social housing to group housing

J. M. Chapa Gonzalez[1], J. Sonntag[2], S. Wiedemann[1]
[1] Rhine-Waal University of Applied Sciences, Faculty of Life Sciences, Sustainable Food Systems Research Centre, Marie-Curie-Str. 1, 47533 Kleve, Germany, [2] Rhine-Waal University of Applied Sciences, Faculty of Communication and Environment, IoT Lab, Friedrich-Heinrich-Allee 25, 47475 Kamp-Lintfort, Germany

Regrouping of dairy calves from individual or pair housing to larger group pens represents a major management transition and may induce behavioural and physiological stress responses. Automated monitoring approaches can support objective and continuous welfare assessment under practical conditions. The aim of this study was therefore to investigate behavioural adaptation of dairy calves during regrouping using accelerometer-based monitoring. The study was conducted on a commercial research farm and included 61 Holstein calves housed either individually (n = 31) or in pair/small group housing (n = 29) during the first two weeks of life. At an average age of approximately 14 days calves were regrouped into larger group pens equipped with an automatic milk feeding system. Behaviour was continuously recorded using tri-axial accelerometers (HOBO Pendant G) attached to the hind leg of each calf. Sensors recorded acceleration and position data at 10-second intervals for approximately 2.5 days before and 2.5 days after regrouping. A previously developed and video-validated classification algorithm was used to assign behavioural states (lying, standing, activity) from the raw sensor data (overall accuracy ≈ 88 %, Cohen's $\kappa \approx 0.75$). Behavioural time budgets and bout characteristics were calculated for each calf and analysed using linear mixed models including period (before vs. after regrouping), initial housing (individual vs. social), and their interaction. Across the observation period calves spent most of their time lying, followed by standing and activity. Regrouping was associated with clear behavioural changes in both housing groups. Standing time increased after regrouping, suggesting increased exploration and social interaction in the new environment. Calves previously housed individually showed increases in both standing and activity after regrouping, whereas calves with prior social housing mainly showed increased standing time but tended to reduce lying and activity durations. In addition to changes in time budgets, behavioural bout structure also changed. In individually housed calves, lying and standing bouts became longer after regrouping, indicating reduced fragmentation of these behaviours. Circadian patterns of behaviour remained largely stable across the observation period. The results demonstrate that regrouping represents a relevant adaptation phase for dairy calves and that prior social experience influences behavioural responses to this management change. The study further highlights the potential of accelerometer-based monitoring systems to provide objective and continuous welfare indicators in calf rearing systems

On-farm self-assessment – tools to improve cattle welfare

J. Brinkmann[1], K. Cimer[1], S. March[1], S. Ivemeyer[1], A. Pelzer[2], U. Schultheiß[3], R. Zapf[3], C. Winckler[4]
[1] Thünen Institute of Organic Farming, Trenthorst 32, 23847 Westerau, Germany, [2] Chamber of Agriculture North Rhine-Westphalia, Haus Düsse 2, 59505 Bad Sassendorf, Germany, [3] Kuratorium für Technik und Bauwesen in der Landwirtschaft, Bartningstraße 49, 64289 Darmstadt, Germany, [4] University of Natural Resources and Life Sciences, Gregor-Mendel-Straße 33, 1180 Vienna, Austria

Since February 2014, in addition to daily routine inspections, livestock farmers in Germany are obliged to check the welfare status of their animals within the framework of on-farm self-assessment (Animal Welfare Act § 11(8)). For this purpose, they have to use animal-based indicators (termed "Animal Welfare Indicators"). This should ensure that the requirements of § 2 Animal Welfare Act are met. The aim of the project "Eigenkontrolle Tiergerechtheit (EiKoTiGer)" was to test the feasibility of the guideline for on-farm self-assessment (dairy cows, calves and beef cattle), published in 2016, and to develop an online training course, tools for data recording as well as reference values, which help to appraise the results. The guideline was developed by a group of cattle experts. In a first step, indicators suitable to detect relevant animal welfare issues, appropriate for on-farm self-assessment, were identified and described. The descriptions cover background information and definitions including result formulas and illustrations. Within the "EiKoTiGer" project, the feasibility and reliability of these indicators were investigated on 44 cattle farms. Based on the results and farmers' feedback the guidelines were revised and data recording tools were further developed. In addition, an online training course was set up to support reliable assessment of the indicators. Reference values for evaluating the farms' own results were elaborated in a multi-stage process by means of a Delphi survey, literature review and expert panels involving different stakeholder groups. The guideline for dairy cows, calves and beef cattle (updated edition published in 2020) supports cattle farmers to carry out self-responsible and systematic inspections on the welfare status of their herds (https://www.ktbl.de/themen/tierwohlbewertung#c2729). The 44 farmers involved in the pilot study rated the guideline as largely self-explanatory. The online training course (https://tierschutzindikatoren-schulung.ktbl.de) enables participants to apply the indicators reliably and in a standardised way under farming conditions. The course includes exercises with a feedback function and an online test. Obtaining a certificate is possible with a positive test result. To support digital data recording, an Excel® based tool was developed (https://www.ktbl.de/webanwendungen/tierschutzindikatoren-erhebung/). The tool includes automated data processing and provides a summary of the results at farm level. In addition, printable sheets are available for a paper-based data recording in the stable. Furthermore, farmers can compare their results with reference values and thereby determine, whether action to improve animal welfare on their farm is needed (https://www.ktbl.de/themen/tierwohlbewertung#c4100). The German Animal Welfare Act requires livestock farmers to assess and evaluate animal-based indicators in order to monitor whether housing conditions meet their animals' need. The guideline and the tools presented are intended to support cattle farmers to carry out systematic assessments of animal welfare in their herds and are freely available at: http://www.ktbl.de/themen/tierwohlbewertung. They help to identify weaknesses and to improve cattle welfare and support herd management based on the systematic assessment of reliable objective animal welfare indicators.

Promoting Cattle Welfare Planning

U. Peschel[1], J. Brinkmann[1], S. March[1]
[1] Thünen Institute of Organic Farming, Trenthorst 32, 23847 Westerau, Germany

Animal welfare in cattle farming is of high ethical relevance and closely linked to resilient livestock systems, resource efficiency and GHG emissions. Despite the duty to on-farm self-assessment since February 2014 (Animal Welfare Act § 11(8)), there is still considerable room for improvement in animal welfare in cattle farming. The predominant welfare challenges involve multifactorial production diseases such as lameness, udder health disorders and metabolic imbalances. These conditions can be effectively addressed only through preventive, risk-based management approaches. The concept of animal health and welfare planning follows a cyclical and continuous process encompassing systematic monitoring, definition of target values, risk analysis, implementation of measures and regular evaluation. This structured management concept has been extensively investigated and successfully implemented in various on-farm projects, yet its adoption in German cattle farming remains limited. Against this background, the project 'InnoRind' aimed to facilitate the practical implementation of animal welfare planning by developing a practice-oriented guideline and an accompanying online platform. These tools are designed to support preventive herd management and to contribute to improved animal welfare and sustainability in cattle farming. In the project 'InnoRind', the concept of animal welfare planning was further developed based on existing scientific knowledge and adapted to the needs of the target group. The approach was implemented through a practical guide and the digital platform https://www.tierwohlplanung.de/, where existing tools, supplementary information and materials on animal welfare assessment were systematically structured and made accessible. Successful implementation of animal welfare planning requires active responsibility and engagement by animal caretakers. Accordingly, the primary target group for communicating the concept comprised German speaking cattle farmers in practice as well as in education and training contexts, followed by advisors and trainers. For this purpose, a clearly structured and easily understandable animal welfare planning scheme was developed, illustrating the cyclical and continuous process of implementation: (1) monitoring and evaluation of animal welfare ('See'), (2) risk analysis ('Understand'), and (3) planning and implementation of measures ('Improve'). Complementing the guide, the website https://www.tierwohlplanung.de/ presents the concept concisely, provides practical implementation tips, and offers access to existing tools for welfare planning in dairy cows, calves, and beef cattle. Each tool is described with its potential applications and includes direct links to the respective providers. Since the introduction of mandatory self-monitoring of animal welfare (§11(8) Animal Welfare Act, 2014), a variety of scientifically validated tools for monitoring cattle welfare have been developed in Germany. Embedding these tools within a structured, preventive management framework enables systematic use of monitoring data for herd-level decision-making. Guideline (https://www.tierwohlplanung.de/ratgeber), digital platform (https://www.tierwohlplanung.de/), and tools (ibidem) were developed to enable practical implementation of the animal welfare planning concept by communicating its method and benefits and providing easy access to relevant tools. This approach can increase farmer engagement, support preventive herd health management, and help to reduce disease-related losses and medication use. Consequently, it fosters sustainable improvements in animal welfare and can enhance resilient livestock systems and resource efficiency in cattle farming.

From Knowledge to Practice: Ensuring Long-Term Impact in the European Equine Sector through EUnetHorse and TANet

N. Aldai[1], E. Martínez-Monasterio[1], S. Vilumbrales[1], S. Kuhnke[2], A. Julien[3], M. Addes[4], E. C. Eunethorse Consortium[4]

[1] University of the Basque Country (EHU), Pharmacy & Food Sciences, Paseo de la Universidad 7, 01006 Vitoria-Gasteiz, Spain, [2] Landwirtschaftskammer Nordrhein-Westfalen, Nevinghoff 40, 48147 Münster, Germany, [3] French Horse and Riding Institute (IFCE), Route de Troche - BP3, 19230 Arnac Pompadour Cedex, France, [4] French Horse and Riding Institute (IFCE), Development, Innovation and Research,, Les Ecuries du Bois, 61 310 Le-Pin-Au-Haras, France

The European equine sector remains structurally fragmented and insufficiently integrated into national Agricultural Knowledge and Innovation Systems (AKIS), limiting its capacity to respond to environmental, socio-economic and political challenges. Strengthening resilience requires coordinated knowledge exchange and long-term dissemination strategies tailored to the sector's needs. EUnetHorse addresses this gap by establishing an active multi-actor network across nine European countries (France, Portugal, Spain, Belgium, Germany, Romania, Poland, Finland and Switzerland). The project enhances the resilience and performance of equine farms through three dimensions: (1) socio-economic performance and crisis preparedness, (2) animal welfare and health, and (3) environmental sustainability. A central innovation is the structuring of National Horse AKIS networks, ensuring balanced knowledge flows while accounting for regional diversity. Grassroots solutions are identified, technically assessed and translated into accessible practice-oriented formats. Breeders, advisors, trainers, researchers, policy makers and sector representatives engage in workshops, demonstration events, cross-visits and targeted training, fostering peer learning, co-creation and improved adoption of solutions. The Communication and Dissemination (C&D) strategy is conceived as a sustainability instrument rather than a purely promotional tool. Project outputs are integrated into the EUFarmBook platform, the EUnetHorse website—maintained for at least two years beyond project completion—and the Zenodo repository, ensuring open access and long-term availability of results. A key pillar for durable uptake is the Trainers and Advisors Network (TANet), launched in April 2024 and currently comprising 70 members from nine countries. TANet members identify advisory needs and co-develop training materials, embedding project results into national advisory systems. The network is expanding beyond partner countries and is structured to operate autonomously beyond the project lifetime. Target indicators include 20 members in the international TANet, 80 trainers and advisors within national TANets, and outreach to 300 trainers and 120 advisors across participating countries. National Facilitators act as knowledge brokers, aligning activities with existing training and advisory structures. By the end of the project, a digital training kit compiling methodologies, technical sheets, posters, videos and other practice-oriented materials will be developed. To reinforce impact, a strategic C&D plan ensures coherent EU-level branding while allowing national adaptation. Dissemination combines mass communication and targeted channels, including 80 EIP-AGRI practice abstracts, biannual newsletters and two policy briefs. Materials are translated into eight partner languages to maximise accessibility. Since project initiation, social media engagement has increased by more than 300%, reflecting growing sector involvement. By integrating structured AKIS networks, participatory co-creation and a sustainability-oriented communication model, EUnetHorse proposes a replicable framework for durable knowledge transfer in the equine sector, strengthening farm resilience beyond the lifespan of EU-funded projects.

Improving resilience of equine farms: EUnetHorse's methodology for assessment of solutions and best practices in the areas of animal welfare, socio-economics and environmental sustainability

U. König Von Borstel[1], S. Lojewski[1], L. Rantamäki-Lahtinen[2], E. U. Eunethorse Consortium[1,2,3], M. Addes[3]
[1] University of Giessen, Section Husbandry, Behaviour and Welfare, Leihgesterner Weg 52, 35392 Giessen, Germany, [2] University of Helsinki, PL 28 (Koetilantie 5), 00014 Helsingin Yliopisto, Finland, [3] Institut français du cheval et de l'équitation, Les écuries du bois, 61310 Le-Pin-Au-Haras, France

EUnetHorse is a collaborative EU project aiming to collect, process and disseminate evidence-based knowledge and best practice examples among equine farmers in the thematic areas animal welfare, socio-economics, and environmental sustainability. The ultimate aim of the project is to increase resilience of equine farms. Here, we provide information on the methodology used for the selection and evaluation of solutions. The process includes three steps: (1) data collection, (2) assessment, and (3) feedback from end-users. The objective of this process is to select solutions that have the most pronounced effects on farm resilience. (1) To collect information on farmers' needs and existing solutions, 365 farmers across the 9 participating countries were surveyed. Additionally, operational groups, focus-groups and national projects were consulted, and literature searches were conducted. This resulted in 72 prioritized needs and more than1000 identified solutions. Based on criteria such as readiness level for implementation, scientific validity, availability, and format (digital or not), a minimum of 120 solutions are selected for assessment, with a target of 80 positively assessed, adapted, and ready-to-implement solutions. (2) Using a multi-actor approach involving various stakeholders and experts such as farmers, scientists, advisors, and trainers, an assessment grid was used during national workshops, to evaluate: a) performance, based on the solution's impact on 15 areas distributed across the three thematic areas (e.g., environmental performance: climate change, biodiversity, water and land management), and scored on a scale from -2 (negative) to +2 (positive); b) resilience, based on how the solution mitigates six predefined external challenges such as events of inflation or disease outbreak; and c) the cost-benefits-balance. Scores are calculated for each challenge and aggregated into an overall resilience score. (3) Using a cost-benefit analysis, a scenario with the adopted solution is compared to a scenario without such solution in place. Evaluators identify stakeholders who may be affected by the solution and catalogue the associated benefits and costs across the three thematic areas. Subsequently, solutions are presented at European workshops to discuss scores and cost-benefit analyses, filtering out those with negative scores. For successful solutions technical-sheets and posters are created. At this stage, to facilitate understanding of the solutions' overall impact within a given topic, total performance and resilience scores are also rescaled to the -2 to +2 scale. End-user acceptance is tested during demonstration days and through online surveys. Technical sheets and posters will be made freely available on the EUfarmbook website (eufarmbook.eu), providing a public resource for all stakeholders. The overall methodology itself is also reviewed with the project's trainers- and advisors network, and national stakeholders to ensure clarity and usability across partner countries. This participatory and scalable approach enables EUnetHorse to quantify the performance and resilience contributions of hundreds of solutions, ensuring that the final portfolio is robust, cost-effective, and widely acceptable to farmers, trainers, and advisors.

EUnetHorse : Recognising the equine sector : unlocking its contribution to Europe's climate, rural and competitiveness goals

M. Addes[1], A. Julien[1], M. Rinne[2], L. Tourneur[3], A. Santos[4], N. Aldai[5]
[1] French Horse and Riding Institute, Development, Innovation and Research, Les Ecuries du Bois, 61310 Le-Pin-Au-Haras, France, [2] Natural Resources Institue Finland (LUKE), Production systems, Tietotie, 4 31600 JOKIOINEN, Finland, [3] Association de coordination des Instituts techniques agricoles (ACTA), Europe and Regions, 149 rue de Bercy, 75595 PARIS, France, [4] Feedinnov, Research and Innovation, Estação Zootécnica Nacional, Rua Professor Doutor Vaz Portugal, 2005-424 Vale de Santarém, Portugal, [5] University of the Basque Country (UPV/EHU), Lactiker Research Group & Faculty of Social and Communication Sciences, Paseo de la Universidad 7, 01006 Vitoria- Gasteiz, Spain

EUNetHorse is the first European agricultural project dedicated to equine animals and is setting up a new dynamic across the European equine sector, by fostering connections among the different equine sectors, geographical levels and categories of actors. The overall objective of EUNetHorse is to establish an active multi-stakeholder network in order to increase the resilience and performance of equine farms. First, following a bottom-up approach, 365 farmer interviews and 9 national workshops were conducted across the nine countries in order to identify and prioritize farmers' needs and existing solutions. Then, at the EU level, 72 needs were prioritized and organised into 9 priority areas (profitability, working conditions, accommodation and equine welfare, biosecurity and emerging diseases, adaptation to climate change, biodiversity, grassland management, land access, training and knowledge transfer). More than 1,000 solutions and best practices were identified and characterised (readiness level (redefined scale), digital or not, farm or industrial level, availability in Europe). A total of 428 solutions met the minimum requirements. A matchmaking process between needs and solutions was performed at the EU level and some solutions were grouped allowing to identify and analyse gaps (i.e. no relevant solution for a given need). 17 gaps were identified at the industrial level and 5 at the farm level. A total of 41 needs were identified as requiring significant research and development support. As a conclusion of this report, a policy brief was produced and will be disseminated soon in order to obtain strategic EU-level support to unlock the full potential of the equine sector which is at a crossroads facing external challenges. The Policy brief is structured into 4 parts: 1) an introduction highlighting the importance of the equine sector from a socio-economic point of view; 2) a focus on the sector's key contributions to European objectives: an attractive agricultural sector for young people and particularly women, maintenance of permanent grasslands, high value chain, preservation of fragile ecosystems (Camargue, Konik Polski), a sector that uses few pesticides, non-relocatable and inclusive jobs that contribute to rural development (tourism, services, culture); 3) urgent policy actions (reaffirming the agricultural status of equines and reintroducing equines into agricultural statistics); 4)the need for R&D support (ensuring the eligibility of equine animals and activities in FP10 calls and focusing on more specific themes such as adapting existing digital tools at the European level). The next EU Framework Programme for Research and Innovation (FP10, 2028–2034) is currently under negotiation. Supporting the specific needs of the equine sector within this future programme represents a key opportunity to direct funding towards the knowledge gaps identified by EUnetHorse. It is therefore important that the scientific community is informed of these priorities in order to position itself, if necessary, to respond to EU calls for proposals.

Group discussion Part 1

M. Addes[1], C. Vial[1,2], G. Mathieu[3]
[1] French Institute for Horse and Riding (IFCE), Development, Innovation and Research, Les Ecuries du Bois, 61310 61310 Le-Pin-Au-Haras, France, [2] MoISA, Univ Montpellier, CIHEAM-IAMM, CIRAD, INRAE, Institut Agro, IRD, 2 place Pierre Viala, 34060 Montpellier, France, [3] Institut de l'élevage, 149 rue de Bercy, 75012 Paris, France

This project session is dedicated to the EUnetHorse project and its future perspectives. The three previous presentations introduced the project and its main results. EUnetHorse is the first European agricultural project dedicated to equine animals. Its overall objective is to establish an active multi-stakeholder network in order to increase the resilience and performance of equine farms. In this perspective, the project has created a new dynamic across the European equine sector by fostering connections among the different equine sectors, geographical levels, and categories of stakeholders. Its aim is to collect and disseminate research results in order to make them useful and accessible to the equine industry. Another important outcome of the project has been the identification of major research gaps within the equine sector.Building on these results, the second part of this session will be dedicated to discussion and collective reflection with the objective of creating consortia for future European projects dedicated to equines. This working session will therefore be divided into two parts: Part 1 of the group discussion:Before the coffee break, we will summarize the main research gaps identified through the EUnetHorse project and present relevant European calls for proposals that will have been previously identified. These gaps and calls will be discussed together in order to identify funding opportunities. Additionally, participants will be invited to express their interest in potential future projects.

Group discussion Part 2

M. Addes[1], C. Vial[1,2], G. Mathieu[3]
[1] French Institute for Horse and Riding (IFCE), Development, Innovation and Research, Les Ecuries du Bois, 61310 Le-Pin-Au-Haras, France, [2] MoISA, Univ Montpellier, CIHEAM-IAMM, CIRAD, INRAE, Institut Agro, IRD, 2 place Pierre Viala, 34060 Montpellier, France, [3] Institut de l'élevage, 149 rue de Bercy, 75012 Paris, France

Following the first part of the group discussion, here is the programme for the second part:After the coffee break, we will organize several parallel workshops dedicated to project development. Each workshop will be chaired by a facilitator. The 45-minute session will be dedicated to initiating reflections on the project content and on potential partnerships between participants and other researchers, institutions, and professionals who may be identified during the discussions. By the end of these workshops, we aim to have initiated collaborations and consortia and to have begun preparing future European project proposals, including possible timelines, deadlines, and project contents.Finally, the objective of this session is to stimulate the emergence of new research projects for the equine sector that address real and pre-identified needs, correspond to relevant European funding calls, and are supported by new research consortia willing to collaborate on these topics.

Thematic expert panel insights on state-of-the-art digital tools and technologies in the livestock sector

S. Vouraki[1], V. Anestis[2], A. Arsenos[3], G. Arsenos[4], T. Bartzanas[2]
[1] University of Ioannina, Kostakioi, 47100 Arta, Greece, [2] Agricultural University of Athens, Iera Odos, 11855 Athens, Greece, [3] National and Kapodistrian University of Athens, Euripus Campus, 34400 Euboea, Greece, [4] Aristotle University, University Campus, 54124 Thessaloniki, Greece

The aim of this study was two-fold: (i) to identify challenges and opportunities related to state-of-the-art digital tools and technologies in the livestock sector and (ii) to propose solutions that could help increase efficiency and adoption rates based on insights from expert stakeholders. A thematic expert panel (TEP; n=10) of software developers (n=2), technology providers (n=4), and stakeholders (farmers, consultants, breeding companies) that use digital solutions (n=4) was created within the framework of Digi4Live project (https://digi4live.eu/); their activities, geographical distribution, and diversity of species of interest were considered. Five TEP meetings were scheduled to discuss: (i) recent developments in digital tools and technologies, (ii) user requirements, (iii) level of automation and potential for customization, (iv) market penetration, and (v) associated costs. Insights from the first two TEP meetings indicated that artificial intelligence (AI), internet of things (IoT), global positioning systems (GPS) and satellite devices, robotics, and sensors for monitoring environmental conditions and animal performance are key recent advancements. Poultry, swine, and dairy cow sectors were identified as the main adopters because they tend to have higher profit margins and producers with higher levels of education. Most experts (63%) considered that available technologies are moderately user-friendly for farmers. Major user requirements included account creation (100%), internet access (86%), documentation (86%), and data input (63%). Limitations regarding real-time data monitoring, interpretation and integration, poor connectivity, complexity, financial barriers, and data ownership issues were reported as the most frequently cited user complaints that hinder adoption. Improving available products based on user feedback providing both online and hands-on training, and AI-assisted decision support tools were considered imperative to increase adoption and support farmers to use digital technologies effectively. Emerging trends expected to shape the future of user requirements included new legislations, data sharing, predictive animal health status, animal identification and herd level metrics, precision feeding and resource use efficiency. Future TEP meetings are expected to provide further valuable insights regarding challenges, opportunities, and solutions for adoption of digital technologies in the livestock sector. The work is part of the Digi4Live project (ID: 101134866), funded by the European Union.

UHF RFID technology in livestock applications: synthesis of French case studies in the ruminant sector over 10 years

S. Duroy[1], G. Tesnière[2], U. Jean-Louis[3], L. Depuille-Plais[2], P. G. Grisot[4], F. Gimbert[5], C. Medina[6], F. Dehmas[7], N. Deparis[7], D. Gautier[8], C. Allain[1]

[1] IDELE, French Livestock Institute, 8 route de Monvoisin, 35650 Le Rheu, France, [2] IDELE, French Livestock Institute, CS 52637, 31321 Castanet-Tolosan, France, [3] IDELE, French Livestock Institute, 149 rue de Bercy, 75012 Paris, France, [4] IDELE, French Livestock Institute, 570 Avenue de la Libération, 04100 Manosque, France, [5] PAGE UP, 13 Rue Marguerite Yourcenar, 21000 Dijon, France, [6] Get-ID, 1375 Rue des Monts du matin, 26320 Saint Marcel les Valence, France, [7] CEA-LETI, 17 avenue de Martyrs, 38054 Grenoble, France, [8] CIIRPO, Le Mourier, 87800 Saint-Priest-Ligoure, France

Widely adopted in dairy farming, wearable technologies have struggled to scale to small ruminants and extensive systems due to prohibitive costs at whole-herd level. Meanwhile, mandatory RFID (Radio-Frequency Identification) ear tags in parts of Europe remain underutilised because operational constraints limit their practical value. Could UHF (Ultra High Frequency) ear tags overcome these barriers and provide an affordable, frugal, and scalable solution across multiple applications? This presentation illustrates several use cases of UHF ear tags and discusses the remaining technological and systemic challenges to large-scale adoption. Compared with low-frequency RFID, UHF RFID offers longer reading ranges without restraining animals, the ability to process high-density tag populations efficiently, and low per-animal costs thanks to passive (battery-free) tags, key assets for scalable and frugal precision livestock farming innovation. Over the past 10 years, IDELE conducted a series of trials and projects (H2020 TechCare, Salto, Horizon Europe Open Agri, Pacapit, OviFlash, Aboire) to assess the practical potential of UHF RFID in ruminant farming. Use cases have covered: (i) traceability with batch readings using RFID gates; (ii) herd management through rapid counting and detection of missing individuals (inventories); and (iii) monitoring of "points of interest" (e.g., passages, feeders, water points) to explore long-term behaviours and derive potential health-related indicators. These investigations were performed in both indoor and outdoor conditions, including settings without grid electricity, using solar stations – highlighting pathways to reduce infrastructure constraints, energy needs, and operational complexity. This work also supported the co-development with industry and research into pragmatic and innovative solutions: a transportable UHF RFID reading device combining fully embedded hardware/software, a cloud database with a user interface, a mobile application offering the possibility of offline and low-energy use, innovative antenna enabling indoor location. This summary synthesizes the main technical lessons learned across this exploratory program (based on laboratory's measurements and real-farm deployments). This presentation highlights the co-evolution of tools and use-case needs, showing how technology has progressed from early batch management and individual sheep traceability to a range of on-farm precision livestock farming solutions for both cattle and small ruminants. Beyond performance, each trial provided actionable insights into the technology's advantages, limitations and the precautions required for reliable on-farm use with the objective of guiding robust, user-friendly, and cost-effective deployment of UHF RFID-based tools in livestock systems. UHF RFID widely adopted in logistics and retail, is now being standardized by ISO for animal identification and will soon provide an additional option for electronic livestock identification.

Machine Learning models for Auto-Annotation of Behavioral Data to Generate Digital Ethograms

D. Foy[1,2], T. Smith[1], J. Reynolds[1], T. Parsons[2,3]
[1] AgriGates, Philadelphia, 19146 PA, United States, [2] DAT-AI-LAB, Kenneth Square, 19348 PA, United States, [3] University of Pennsylvania School of Veterinary Medicine, Swine Teaching and Research Center, Kennett Square, 19348 PA, United States

The application of machine learning (ML) models to ethology promises to transform the study of animal behavior and provide new insight into animal health, production, and welfare. However, the development of these models is increasingly constrained by the time-intensive and subjective nature of manual coding or annotation of behavioral data. The use of wearable Inertial Measurement Units (IMUs) that provide continuous, animal-level behavioral data streams offers an opportunity for more objective behavior classification and validated behavioral metrics. The IMUs also generate high-frequency, long-duration datasets, and thus converting raw IMU signals into structured, high-quality behavioral labels remains a critical bottleneck for scalable ethologically based ML models. This work presents an ML framework first for annotating IMU data for key behavioral states and events (e.g., standing, lying, left- and right-side lying, feeding) in sows. Frame-by-frame analysis of video data can be used when needed as a high-resolution reference modality during annotation. This enables precise temporal alignment of IMU output with behavior and unparalleled delineation of ethological event transitions and their durations. This high-quality data set provides the foundation for the second aspect of our novel ML framework, the auto-annotation of time-series IMU data using ML models. A total of 184 hours of synchronized IMU outputs (6,593,272 data points) and video were recorded and annotated. The models are trained on 138 hours and validated on 46 hours of this data. Over 1,634,000 data points were subjected to the trained Random Forest Classifier model that predicted sow posture with greater than 90% accuracy, specificity, and sensitivity. The resulting auto-annotation ML pipeline substantially reduces manual coding time and produces standardized, reproducible behavioral labels from continuous IMU data. Adopting a digital ethogram and auto-annotation workflow accelerates the creation of foundational behavioral datasets, supporting downstream deep-learning applications, individual-animal modeling, and cross-study comparability. More broadly, this work demonstrates how time-resolved ML approaches can bridge the gap between primary IMU sensor outputs and biologically meaningful ethological representations in Precision Livestock Farming.

Individual fattening pig growth profile estimation

J. Slootmans[1,2], T. Norton[1], J. Maselyne[2]
[1] M3-BIORES, KU Leuven, Department of Biosystems, Kasteelpark Arenberg 30, 3001 Leuven, Belgium, [2] ILVO (Flanders Research Institute for Agriculture, Fisheries and Food), Technology and Food Science Unit, Burg. Van Gansberghelaan 115 bus 1, 9820 Merelbeke-Melle, Belgium

Monitoring fattening pigs is important to ensure adequate production and welfare during the rearing period. Pig growth is a rather stable variable which is directly linked with production but also indirectly with a range of health issues. Therefore, monitoring and modelling pig growth can provide important information, which can be used for precision feeding or digital twins. However, up until now, the body weight and growth of fattening pigs is often monitored on the group level, thereby concealing variation between individual pigs or issues on the individual pig level. This study explores using the existing mechanistic InraPorc model to estimate individual fattening pig growth profiles, integrating automated body weight and feed intake data. Data of two pig batches was used (1) 120 pigs, aged 68–167 days with a body weight between 25.2–106.8 kg and (2) 120 pigs, aged 67–179 days and 23.5–121.5 kg. The pigs were housed in 8 pens within a single compartment, where feed intake measurements were available in half of the pens via feeding stations. Daily body weight measurements of all individual pigs were available in all pens through weighing scales in front of the feeding stations or drinkers. The InraPorc software was used to calculate the average pig profile of batch 1, which consisted of the 4 main model parameters. This average pig profile and an initial individual pig body weight acted as a baseline estimation for this study. Different scenarios were explored to update the optimal values for the 4 main model parameters for individual pigs on a daily basis. The scenarios differed in (1) the amount of data used (last step update or rolling update), (2) the initial guess for the model parameters (average profile parameters or last known parameters), (3) the use of feed intake data (with or without feed intake data), and (4) the batch of pigs tested (batch 1 or batch 2). The mean absolute percentage error (MAPE) was calculated for each pig to evaluate the performance of the individual profile estimation. All scenarios except one resulted in a numerical decrease of the MAPE compared to the average profile, although the decrease of the MAPE was not always significant. Last step updates resulted in the most flexible estimation of the pig profile, quickly adapting to changes in the animal profile, while the rolling parameter update scenarios resulted in more stable animal profile estimations reacting slower to changes in the animal profile, resulting in MAPE of 2.2-5.2 and 5.4-7.8% respectively. Using the last known parameters as initial guess presented a high risk for the optimization step to fail due to the model's imposed maximum growth, which created regions where the optimization function plateaued. Because the model in pens without individual feed intake measurements used the average profile's feed intake parameters, calibrated on the overall performance of batch 1, the individual profile estimation in those pens did not differ substantially from the pens with feed intake, with MAPE of 1.4-5.9 and 2.2-7.8% respectively. Similarly, the performance of the individual profile estimation in batch 2 did not differ substantially from the batch 1 profile estimation, with MAPE of 1.4-7.8 and 1.6-6.3% for batch 1 and batch 2 respectively, which was expected given the similarities between the batches. In conclusion, the results indicate that it is possible to estimate the individual fattening growth profile, although the error on the estimation differs depending on the method used to estimate the profile, offering new possibilities in daily pig body weight monitoring.

Risk Factors for Piglet Preweaning Mortality in Spanish Breeding Farms. Preliminary Results from the Bdporc-Smartporc Project

S. Rani[1], A. Arrazola[1], M. Pascual[1], N. Alos[1], M. Visa[1], M. Piles[1], R. Quintanilla[1], J. Tarres[1], L. Tusell[1]
[1] Institut de Recerca i Tecnologia Agroalimentàries (IRTA), Animal breeding and Genetics, Torre Marimon, 08140 Caldes de montbui, Barcelona, Spain

BDporc (www.bdporc.irta.es/en) is a reference database of sow breeding performance in Spain and a strategic digital tool in smart livestock systems, providing standardized analytics that enable affiliated producers to identify strengths and weaknesses in their farm management. BDporc has recently launched the SMARTporc project to develop a data-driven digital decision-support tool aimed at optimizing sow longevity and piglet survival in breeding farms. The project focuses on 1) creating a Data Lake compatible with BDporc to integrate on-farm precision data with information about farm emissions, management, and pen characteristics, already collected in official databases, 2) identifying key factors affecting piglet survivability and sow longevity, and 3) developing a digital twin of pig a breeding farm to simulate management actions and evaluate their effects on piglet survival, sow longevity, and farm profitability. Preliminary results using BDporc data analyzed 10.5 M reproductive cycle records from 2.6 M sows in 630 commercial breeding farms (2020-2024). Pairwise correlation analyses identified that litter size and piglet losses traits are associated as the number of piglets born alive (PBA) was positively correlated with piglet mortality during lactation (r=0.28). Furthermore, Bayesian regression models fitted separately per cycle showed that higher piglet pre-weaning mortality was related with higher number of PBA, longer lactation lengths, and piglets weaned in the preceding cycle (i.e., highest posterior density interval at 95 % of 0.59-0.69, 0.42-0.52 and 0.24-0.34 in cycle 3, respectively). Moreover, percentage of piglet losses in the previous lactation impacted piglet mortality and this effect peaked at cycle four followed by a gradual decline thereafter. Season and year recorded during insemination were also associated with piglet mortality, with higher risks observed during spring and summer, as well as increased losses during the 2021–2023 period. Altogether, these initial results suggest that indicators of sow past performance can provide new insights to improve piglet pre-weaning survival.

Drone-based mapping of geese range use under heat across pasture systems: implications for silvopastoral agroforestry design

J. Menne[1], S. Eßer[2], P. Eßer[2], S. Wiedemann[1]
[1] Rhine-Waal University of Applied Sciences, Faculty of Life Sciences, Marie-Curie-Str. 1, 47533 Kleve, Germany, [2] Der Gänsepeter GmbH, Stiftshof, Kölner Straße 2, 41569 Ramrath, Germany

Outdoor access can improve animal welfare in commercially kept geese (fattening and laying flocks). However, during hot conditions these benefits depend on pasture systems providing effective shade and shelter. Orthomosaics derived from unmanned aerial vehicles (UAV), combined with Geographic Information Systems (GIS), offer a scalable approach to analyse clustering and behaviour across pasture systems and structural features. Such information can support climate-adaptation strategies such as (agro-)silvopastoral systems. We aimed to implement a UAV workflow to quantify welfare-relevant space-use metrics of free-range geese across varying weather conditions and pasture systems. Between 30 July and 16 October 2025, six flocks of commercially kept geese (fattening and laying), ranging from approximately 300 to 2,200 animals per flock, were surveyed across contrasting pasture systems. These included maize-based systems (maize-only; maize-grassland) and grass-based systems with limited tree cover (grassland-only; grassland with young orchard or walnut trees and/or shade near buildings) as well as grassland with older fruit trees. UAV grid flights (typically 80-90 m above ground level; adjusted to avoid disturbing the flock) were used to generate orthomosaics, followed by spatial analyses in a GIS environment. Across six field days, 43 flights were conducted at different times of day and under varying weather conditions. Goose positions and clusters were extracted from orthomosaics using manual annotation and currently tested computer-vision approaches. Detection performance was validated across ground covers; initial tests in maize were promising due to high contrast between white geese and vegetation, but occlusion and crop-row structure can affect detectability. Response variables include cluster size, distance to structural elements, and shade-use proportion, modelled as functions of pasture system and environmental covariates using mixed-effects models. Weather data were obtained from the nearest German Weather Service (DWD) station. Pilot observations during hot conditions (air temperature up to ~34 °C) indicated strong thermal constraints on range use across all six flocks. Geese largely avoided ranging far into paddocks during the hottest hours. Two laying-goose groups on grassland with only small-canopy orchard or walnut trees lacked effective shade and clustered in barn-adjacent shade throughout the day. Three fattening-goose groups with access to maize also remained mainly indoors or close to the barn, and use of the maize range was detected only later in the evening. In contrast, a fattening-goose group on grassland with older fruit trees intensively used the limited tree shade, suggesting that not all shade types are functionally equivalent. Overall, these pilot data indicate that heat can strongly suppress range use in commercial geese and that shade effectiveness depends on shade type. Drone-based orthomosaics provide a practical on-farm approach to quantify these welfare-relevant space-use patterns and to support the design and evaluation of silvopastoral pasture systems for heat mitigation.

An introduction to bioacoustics with a focus on chicken vocal responses to birds of prey

A. Langehennig-Peristenidou[1], L. Hofmann[1], N. Kemper[1], N. Volkmann[1]
[1] Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, University of Veterinary Medicine Hannover, Bischofsholer Damm 15, 30173 Hannover, Germany

Bioacoustics is the scientific field that investigates sound production and perception in animals. Animal vocalisations can be used to extract information about the sender, such as physical characteristics or emotional, reproductive and health state. Such information is obtained by analysing the different types of vocalisations within a species and their temporal, frequency and spectral characteristics. This allows researchers to address various questions about animal behaviour, including individual differences in calling behaviour, changes in call structure under stress or disease and which call types are produced in specific contexts. Due to its wide range of applications, bioacoustics are increasingly applied in livestock farming, for example to detect potential health risks or stress in animals. Free-range farming of laying hens is becoming increasingly popular due to its benefits for animal welfare. However, outdoor access also exposes chickens to a higher risk of predation, creating a major challenge for farmers in preventing attacks by birds of prey. Therefore, this study aims to identify and describe the vocal responses of chickens in the presence of birds of prey, with the long-term goal of using these calls as the foundation for developing a potential deterrent system aimed at scaring off birds of prey. Audio and video recordings were conducted over three months on a flock of 990 hens and 20 roosters housed in a mobile housing system with daily access to a free-range area. Cameras and audio recorders operated daily from 9 am to 7 pm and captured the behaviour and vocalisations of the chickens within a maximum distance of 11.3 m from the mobile house. All recordings were screened for the presence of birds of prey, identified either visually or through their vocalisations. For each event, the corresponding video sequence was analysed to determine when chickens first perceived the birds of prey, defined as the moment a chicken (first animal) raised its head, elongated its posture and showed a behavioural change. Anti-predator behaviour was considered to end when the first animal and 75% of visible animals resumed normal movement. Audio segments between perception and the end of anti-predator behaviour were visually inspected and acoustically characterised to identify the call types produced. Our results show that chickens produce a variety of call types in response to the presence of birds of prey. Calls produced by roosters differed from those produced by hens. Chickens often emitted call types not specific to alarm situations during the presence of birds of prey. However, roosters frequently produced aerial alarm calls, suggesting that they may be suitable candidates for developing a vocalisation-activated deterrent system. However, as group composition may influence calling behaviour, further recordings in flocks with different social structures are planned to evaluate whether aerial alarm calls are consistently produced across the group compositions commonly found in chicken husbandry. This research is funded by the Lower Saxony Ministry of Science and Culture and the Volkswagen Foundation as part of the zukunft.niedersachsen program within the ZERN project.

Eyes & Ears – the auditory perspective: evaluating the potential of sound-based monitoring for livestock health, behaviour and welfare

M. Coutant[1], S. Ntalampiras[2], W. Wang[3], P. Llonch[4], E. Mainau[4], M. Van Der Sluis[5], L. Büttgen[5], C. Gaillard[6], L. Canario[7], T. B. Rodenburg[8]

Bioacoustic approaches have gained increasing interest for monitoring health, behaviour and welfare in farm animals remotely, continuously and non-invasively. Compared with other sensor technologies, acoustic systems require relatively low computational power and data storage, facilitating practical on-farm deployment. However, important challenges remain before bioacoustics can be reliably implemented under commercial settings. Technical limitations related to complex and noisy farm environments continue to hinder the translation of experimental methods into robust tools, while the sound outputs of livestock species remain incompletely understood, making it unclear which health or welfare conditions can be consistently detected using sound. The newly initiated Eyes & Ears project, part of the European Partnership on Animal Health and Welfare and co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW, aims to facilitate the identification, development and validation of on-farm surveillance tools based on both visual and auditory monitoring. Within this framework, the task dedicated to auditory monitoring brings together 12 partners from seven European countries to evaluate the potential of bioacoustics across multiple species, including pigs, poultry, cattle and small ruminants, and across different production stages and husbandry systems. The task will generate case studies, performed in experimental facilities and commercial farms, exploring the use of sound to monitor, for example, respiratory disease, resource use, maladaptive behaviours, and signs of both negative and positive affective states, while examining technical feasibility and methodological considerations for on-farm application. A key objective is to identify which health and welfare indicators show potential for feasible monitoring using audio alone, and which may require multimodal approaches combining sound with other sensing technologies. In parallel, the project aims to promote collaboration across research groups by encouraging standardized methodologies, cross-partner studies, and the development of best-practice guidelines. Running over three years (2026-2028), this work will contribute to establishing a stronger scientific and methodological foundation for livestock bioacoustics and support the transition of sound-based monitoring from experimental research towards practical on-farm applications to assist farmers and improve animal welfare management.

Development of a Practical Benchmark for Pig Vocalizations in Noisy Farm Environments

M. Wutke[1], H. Geffert[1], S. Geisler[1], S. Küster[1], C. Post[1], J. Wahmhoff[1], I. Reker[2], I. Traulsen[1]
[1] Christian-Albrechts-University Kiel, Institute of Animal Breeding and Husbandry, Hermann-Rodewald-Straße 6, 24118 Kiel, Germany, [2] Chamber of Agriculture Lower Saxony, Division Agriculture, Mars-la-Tour-Str. 6, 26121 Oldenburg, Germany

Acoustic monitoring is a promising, non-invasive approach for assessing welfare and management aspects in livestock systems. Previous studies in pigs have shown that acoustic information can support the detection of welfare-related problems and that vocalizations are linked to the emotional state, discomfort, and stress. Recent approaches use state of the art AI models to extract information on abnormal behavior and critical situations using vocal signals in both unimodal and multimodal settings. However, robust development and deployment in agricultural operations require suitable annotated ground truth datasets, which are currently only available to a limited extent. Pig vocalizations include several call types that differ in structure and context, ranging from low-frequency grunts to high-frequency calls such as squeals and screams. In commercial farms, call assessment is complicated through continuous transitions between call types, overlapping calls, and strong background noise. These factors reduce model performance and complicate the transfer from controlled environments into practice. Although some acoustic datasets are now publicly available and allow training of more advanced AI models, many recordings were collected under controlled conditions and often contain little to no background noise. This limits generalizability and makes it challenging to benchmark models under realistic conditions. Reliable benchmark datasets also depend on an objective sound rating and consistent annotation rules. Single-observer labeling can be subjective, especially when calls overlap or when boundaries between call types are unclear. Therefore, a multi-observer annotation approach can reduce this uncertainty, making inter-observer agreement and intra-observer reliability important indicators of annotation quality and allows the evaluation of systematic difficulties in sound assessment. To address these challenges, the aims of this study are twofold. First, a practical benchmark dataset of pig vocalizations recorded in realistic farm environments is developed, supporting future method development and standardized performance evaluation. Second, an inter-observer analysis is conducted, to improve understanding of call structure and bioacoustic features to identify common obstacles in pig sound assessment. Data were collected on a research farm in Lower Saxony (Germany). Audio and video were recorded in one compartment with six weaning pens and 24 pigs each. For annotation, 30-min sequences from different activity phases were split into 6-s, non-overlapping segments (n=1,500). Five trained observers applied one–zero sampling and assigned presence/absence labels for the classes grunt, squeak, scream, barn noise, machine sound and quiet. Segments were arranged in five overlapping subsets (900 each) so that every segment was rated blindly by three observers. Subsequently, a label was accepted when the observer agreement was ≥2, yielding 1,487 labeled segments (13 unresolved). Inter-observer agreement was evaluated using Fleiss Kappa and was substantial for quiet (0.75), grunt (0.74) and squeak (0.71), and moderate for machine sound (0.62), barn noise (0.55) and the rare scream class (0.58). Mean intra-observer reliability using Cohens kappa ranged from 0.70 (barn noise) to 0.85 (squeak). Overall, this study provides a realistic benchmark dataset recorded in acoustically challenging farm environments, enabling objective evaluation of bioacoustic models and supporting the development of robust on-farm welfare monitoring.

Efficient Bioacoustic Classification of Goat Vocalizations for Edge-Based Precision Livestock Farming

D. A. Mendez Reyes[1], S. Calvet Sanz[1]
[1] Universitat Politècnica de València, Instituto de Ciencia y Tecnología Animal, Camí de Vera s/n, 46022 Valencia, Spain

Advancing on-farm welfare evaluation requires the development and validation of non-invasive, animal-based measures of emotion that can be deployed at scale using precision livestock farming (PLF) systems. While bioacoustics increasingly leverage deep learning on spectrograms or raw waveforms to monitor animal welfare, these models often require significant computational resources and large datasets, making them difficult to implement on resource-constrained edge devices. This study addresses the practical gap in goat-focused welfare monitoring by proposing a lightweight, interpretable alternative that pairs engineered acoustic features with classical machine learning classifiers to reduce compute, memory footprint, and energy consumption without sacrificing actionable performance. This work utilized the publicly available Goat Bleatings dataset from the VOCAPRA project, comprising 4,147 labeled vocalizations sampled at 44.1 kHz across eight distinct husbandry contexts: heat, feed distribution, parturition, injury or death, social isolation, mother-kid reunion, mother-kid separation, and the presence of unknown visitors. A hybrid feature extraction framework was developed to capture spectral, temporal, and bioacoustic descriptors. This included 20 Mel-Frequency Cepstral Coefficients (MFCCs) and their first and second-order derivatives to encode timbral qualities and temporal dynamics. Additionally, the pipeline extracted spectral flux, temporal centroid, spectral contrast, entropy, and ecoacoustic indices such as the Acoustic Complexity Index (ACI) and Bioacoustic Index. Fundamental frequency (F0) statistics were also derived using the pYIN algorithm to provide critical information for distinguishing between high-pitched distress calls and lower-pitched contact vocalizations. An initial screening of 18 algorithms, including tree-based ensembles, linear models, and SVMs, was conducted. The CatBoost Classifier emerged as the top performer with an accuracy of 82.9% and a Cohen's Kappa of 0.793, followed closely by LightGBM and XGBoost. Feature importance analysis revealed a strong preference for MFCC properties, particularly the lower-order coefficients (indices 0–4), which exhibited the highest discriminative variance. While the model faced challenges identifying high-population classes like "heat" and "feed distribution" due to feature similarity, the results demonstrate that this straightforward pipeline achieves an accuracy-to-computational load trade-off that outperforms some heavier convolutional neural network (CNN) implementations for edge deployment. This work helps close the deployment gap between laboratory accuracy and field-ready, low-power monitoring. Future research will focus on a real-time inference pipeline utilizing a sliding window ring buffer and majority voting to reduce temporal "flickering". Furthermore, we propose a multimodal system where the audio engine is gated by visual object tracking, triggering processing only when specific behaviors are visually identified to further optimize edge resources. This work was supported by the "Ayuda a Primeros Proyectos de Investigación" program [grant number PAID-06-25], Vice-rectorate for Research of Universitat Politècnica de València (UPV)

Sound levels during unloading, in lairage and in the stunning area in cattle slaughterhouses

S. Lühken[1], C. Nyanzi[1], K. Kauselmann[1], L. Schrader[1]
[1] Friedrich-Loeffler-Institut, Institute of Animal Welfare and Animal Husbandry, Dörnbergstraße 25/27, 29223 Celle, Germany

High sound levels in slaughterhouses can cause stress in animals, impair their willingness to move during unloading or to the stunning area and worsen conditions for rest and recovery in lairage. It is reported that noise levels above 70 decibels (dB) can have negative effects on cow welfare. Others describe thresholds for discomfort in cattle at 90–100 dB. Reducing noise in slaughterhouses is also beneficial for occupational safety and employee health protection, and it is recommended to wear ear protection when exposed to levels above 80 dB. The sound level [dB(A)] was measured using a calibrated sound level meter (Optimus Green CR:171B, Cirrus Research) during unloading, at different locations in lairage and in the stunning area in five medium-sized cattle slaughterhouses in Germany (slaughter rates: 20 to 60 animals per hour). Depending on the size of the slaughterhouse and the number of unloaded lorries/trailers, one to six measurements of up to five minutes each were taken. At one slaughterhouse it was not possible to make measurements during unloading. The measurements were taken during routine slaughterhouse operations, with ongoing slaughtering and unloading of animals, and at the height of or up to one meter above the animals' heads. Sound levels during unloading and in the stunning area were recorded up to a distance of 5 m in front of the ramp or point of stunning. The overall equivalent sound level ranged from 76.9 dB to 81.6 dB during unloading (mean: 79.1), from 74.6 dB to 78.3 dB in lairage (mean: 76.7 dB) and from 77.4 dB to 79.3 dB in the stunning area (mean: 78.6 dB). The maximum peak level was highest during unloading at 123.5 dB, was 118.1 dB in lairage and 116.7 dB in the stunning area. The equivalent sound levels were mostly above 70 dB(A) and in some cases even above 80 dB(A), which can be considered critical for cattle. In addition, it must be taken into account that the commonly used filter 'A' simulates human hearing sensitivity. However, while the frequency of human hearing ranges from 20 Hz to 20 000Hz, cattle can hear frequencies from 23 Hz to 35 000 Hz. Thus, the measurements may underestimate the effect of higher-frequency sounds on the animals. Sounds mainly came from the machines in the slaughter hall, the handling of the animals and equipment by employees, and sometimes from animals' vocalizations. It is recommended to reduce the noise in slaughterhouses in order to improve animal welfare. This could be achieved, for example, with structural modifications such as noise protection between lairage and the unloading/stunning area, use of plastic barriers, gates with rubber stoppers or rubber flooring. In addition, appropriate handling of the animals and barn equipment without yelling and banging is important to reduce noise in slaughterhouses.

Relationship between claw health and increased activity during milking as a supportive trait for lameness detection in dairy cows

P. Savary[1], D. Schönberger[1], M. Bodmer[2]
[1] FSVO / Agroscope, Centre for Proper Housing of Ruminants and Pigs, Route de la Tioleyre 4, 1725 Posieux, Switzerland, [2] Vetsuisse Faculty, University of Bern, Clinic for Ruminants, Langgassstrasse 120, 3012 Bern, Switzerland

Cows affected by lameness often exhibit increased stepping and weight shifting in order to relieve painful limbs during prolonged standing on hard ground, e.g., at the feeding rack. The objective of this study was therefore to compare the behavior of lame and non-lame cows in milking parlors and to determine whether lameness is associated with increased hind leg movements during milking. Data were collected from 647 cows on 20 Swiss dairy farms. Lameness assessment was conducted during a morning milking as cows exited the milking parlor. Posture and gait were evaluated using a five-point scoring system (1 = normal, 2 = uneven gait, 3 = mild lameness, 4 = moderate lameness, 5 = severe lameness). For statistical analysis, cows with scores of 3 to 5 were classified as "lame," whereas cows with a score of 1 or 2 were classified as "non-lame." Hind leg movements, such as foot lifting, stepping, or kicking, are transmitted as oscillations to the milking cluster and can therefore be recorded using a 3D acceleration sensor. The sensor was attached to the top of the claw of each milking unit. During one evening milking per farm, cluster balancing movements were recorded continuously. Lateral accelerations along the horizontal x-axis were registered as activity when a predefined threshold value was exceeded. This threshold had been determined in a pre-test in which acceleration data from 36 cows (i.e., milkings) were compared with direct behavioral observations of hind leg movements. Individual movements (e.g., foot lifting or kicking) or phases of repetitive movements (e.g., stepping) were counted and expressed as the "number of hind leg activity phases per minute" (HLA) for each cow and milking. However, some milking units exhibited high intrinsic motion, which would have resulted in excessive false-positive detections of HLA. In total, 257 of 647 milkings (39.7%) showed high intrinsic motion and were therefore excluded from the statistical analysis. Linear mixed-effects models were applied with HLA as the outcome variable. Lameness status (two levels: lame, non-lame) and parity (five levels: 1 to 5+) were included as fixed effects. The random effect structure included the individual milking stall nested within farm. Overall, 27% of the examined cows were classified as lame. The statistical model showed a higher frequency of HLA during milking in lame cows than in non-lame cows ($p = 0.026$). HLA also increased with increasing parity ($p = 0.008$). Considerable inter-individual variability was observed, independent of lameness status and parity. This finding may be partly explained by variability between farms, which accounted for 23.9% of the total variance in HLA. In summary, on farm level, lame cows exhibited increased hind leg activity compared with non-lame cows, likely reflecting attempts to relieve painful limbs while standing on hard ground in the milking parlor. Although HLA was measured indirectly via a 3D acceleration sensor attached to the milking cluster and subject to certain technical limitations, automated and continuous recording of HLA during milking shows promise as a tool for early lameness detection. This approach may be particularly valuable for identifying cows with a lameness score of 3, which are often difficult to detect without time-intensive visual assessment.

Image-based classification of horned and polled Caracu cattle using machine learning

G. Fernandes[1], V. Weber[2], V. Ligori[1], L. Pereira[1], D. Lisboa[1], G. Borges[1], L. El Faro[1]
[1] Instituto de Zootecnia, Beef Cattle Research Center, Carlos Tonani, 94 - Zona Industrial, 14160-900 Sertãozinho, Brazil, [2] Universidade Estadual do Mato Grosso do Sul, Av. Dom Antônio Barbosa, 4155 - Vila Santo Amaro, 79115-898 Campo Grande, Brazil

The automated identification of the polled phenotype is particularly relevant for genetic breeding programs, as this trait is of economic interest and may support selection decisions and directed mating strategies. The identification of polled cattle is traditionally performed during calf handling by trained personnel, through visual inspection of horn presence. Polled animals typically present a more rounded head morphology, whereas horned animals tend to show a more angular head shape, which allows visual differentiation between these phenotypes. The objective of this study was to evaluate the feasibility of using image-based machine learning methods to classify horned and polled Caracu cattle based on head morphology, as a non-invasive alternative to conventional identification. A dataset composed of 69 images of Caracu cattle was used, including horned animals (n = 40) and polled animals (n = 29). Images corresponded to a frontal view of the head, focusing on the region above the eyes and between the ears. Image feature extraction was performed using a pre-trained VGG-16 convolutional neural network as an embedding model. The resulting feature vectors were used to train and compare several supervised machine learning classifiers, including k-nearest neighbors, decision tree, support vector machine, Naive Bayes, artificial neural network, and AdaBoost. Model performance was assessed using leave-one-out cross-validation due to the limited sample size. Classification performance was evaluated using accuracy, F1-score, precision, recall, Matthews correlation coefficient, and area under the ROC curve. Among the evaluated models, the artificial neural network achieved the best overall performance (AUC = 0.94; accuracy = 0.86; MCC = 0.70). To further assess model generalization, the best-performing classifier was applied to an independent set of previously unseen images, resulting in 16 correct classifications out of 21 samples. These results indicate that head morphology contains sufficient visual information to allow the classification of horned and polled Caracu cattle using image-based machine learning. However, the use of a larger and more diverse image dataset is necessary in future studies to improve model robustness and generalization performance. This approach shows potential as an automated and non-invasive tool to support animal identification, with possible applications in breeding programs and cattle management systems.

Benchmarking pig detection and tracking under diverse and challenging conditions

J. Henrich[1,2], C. Post[3], M. Zilke[1], P. Shiroya[1], E. Chanut[1], A. Mollazadeh Yamchi[3], R. Yahyapour[2,4], T. Kneib[1,2], I. Traulsen[3]

[1] University of Göttingen, Chair of Statistics and Econometrics, Faculty of Economics, Humboldtallee 3, 37073 Göttingen, Germany, [2] Campus Institute Data Science, Goldschmidtstraße 1, 37077 Göttingen, Germany, [3] Kiel University, Institute of Animal Breeding and Husbandry, Hermann-Rodewald-Straße 6, 24098 Kiel, Germany, [4] Gesellschaft für wissenschaftliche Datenverarbeitung mbH Göttingen, Burckhardtweg 4, 37077 Göttingen, Germany

Automated monitoring of individual pig behavior is increasingly important for animal welfare assessment, early disease detection, and understanding social interactions. Video-based systems have great potential to help researchers detect behavioral changes indicating health problems, identify harmful behaviors like tail biting or mounting, and quantify activity patterns over extended periods. However, such systems require reliable automated methods to locate and identify individual pigs across time, and under realistic barn conditions with occlusions, variable lighting, and dust. Despite growing research interest, standardized datasets for comparing different automated pig detection and tracking approaches are scarce, and most existing methods have not been made publicly available. This limits progress toward robust, practical tools that could support behavioral research and on-farm monitoring. To address these limitations, we created two annotated, publicly available datasets: PigDetect (2,931 images from 31 different pen setups) and PigTrack (80 videos with 41 minutes in total from 9 pens), specifically including realistic conditions, such as pigs occluding each other, bad lighting or smudged camera lenses, and rapid movements. We then tested several automated detection and tracking approaches, including both fast methods suitable for real-time monitoring and more accurate but slower methods suitable for detailed behavioral analysis. The key findings were: (1) Including challenging training examples substantially improved detection performance. Specifically, selecting difficult cases for training yielded better results than simply using more randomly selected images. (2) Comparing different detection approaches, we found that state-of-the-art models offer substantial improvements in detection quality over real-time alternatives (85.5% average precision versus 83.6%). (3) For multi-object tracking, we observed that SORT-based methods, which partly rely on hand-crafted association metrics, achieve superior detection performance compared to end-to-end trainable models. However, end-to-end models show better association performance, suggesting they could become strong alternatives in the future. Importantly, methods trained on diverse datasets performed well in completely new barn environments without additional training, demonstrating practical generalizability. When tested on publicly available videos from other research groups, the trained models substantially outperformed more specialized methods, highlighting that carefully curated training data covering diverse conditions may be more valuable than custom-designed algorithms. The detection and tracking methods established here provide foundational tools for behavioral analysis systems. The datasets could be extended with action labels for behavior classification research, with PigTrack particularly suited for this purpose as challenging tracking scenarios include behaviorally relevant interactions like mounting and play. All models, code, and datasets are publicly available, enabling result reproduction, direct application to new data, and farm-specific customization. This supports transparent, cumulative progress in automated livestock monitoring.

Automated Sorting of Finishing Pigs Under Commercial Barn Conditions

M. Tufail[1], N. Yeo[1], T. Tayenga[1]
[1] Lacombe Research and Development Centre, Agriculture and Agri-Food Canada, 6000 C & E Trail, T4L 1W1 Lacombe, Canada

Efficient sorting of finishing pigs is a necessary element in pig production facilities. However, in Canada, sorting is still largely based on manual observation and periodic weighing, which can be labour-intensive, stressful for animals, and difficult to apply frequently in large groups. This study presents the development of a portable, non-invasive AI-based vision system for continuous assessment of finishing pigs under practical barn conditions, with the aim of supporting more precise and timely sorting decisions. The study is being carried out at the swine unit of the Lacombe Research and Development Centre. The imaging platform is positioned at the pen drinking station, where pigs naturally pause in a stable standing posture. An RFID panel reads the ear tags for animal identification and triggers automatic image capture when a pig approaches the waterer. This approach reduces interference from crowding and improves repeatability of image acquisition without altering normal animal behaviour. The sensing system combines two Intel RealSense RGB-D cameras and one FLIR thermal infrared camera connected to an edge computing unit for on-site processing. From these images, phenotypic traits relevant to market readiness are extracted, including body dimensions, body volume, and thermal patterns associated with dorsal fat deposition. Markerless body landmark detection is performed using DeepLabCut, while deep learning models such as EfficientNet and YOLO are being evaluated for live-weight estimation using both publicly available and custom barn datasets. Reference live-weight data are obtained from the barn-installed feed intake and weight recording system. The resulting mean squared error in pose-based landmark estimation ranged from 0.5 to 4.7 cm, while the estimated body weight remained within 5% of the true weight. Preliminary results from the study indicate that continuous phenotyping of finishing pigs in group housing is possible and that by combining estimates of backfat cover, body weight and volume, and feed intake, it is possible to estimate lean meat yield to support carcass-value-based sorting before slaughter.

From counting small ruminants with drones and AI to future applications enabled by offered open data and computer vision models

A. Lebreton[1], T. Dechaux[1], E. Nicolas[1], P. G. Grisot[1], L. Helary[1]
[1] Institut de l'Elevage (Idele), 149 rue de Bercy, 75012 Paris, France

"Is my flock complete, or are some animals still out of sight?" This recurring operational question is central to outdoor-based small ruminants farming, where shepherds must frequently verify flock integrity and animal presence, especially at key moments such as gathering, moving animals between paddocks, or bringing them back to shelter. In rangeland systems exposed to predation, this decision is even more critical and can generate substantial stress for shepherds. Conventional approaches, including visual counting and electronic identification, are time-consuming, error-prone, and logistically demanding in real farm conditions, notably because they often rely on handling facilities, and thus rarely implemented. After 2 years of drone testing inside the ICAERUS project, the framework for counting Small Ruminants was described by Lebreton & Helary (2026): focusing on counting animals at key moments and key locations (e.g., along paths, gates, or gathering points) rather than full aerial mapping of entire pastures, in order to reduce technical and regulatory constraints while maximizing counting performance. Our computer vision pipeline relies on 3 core components: (i) small ruminants detection on each video frame, (ii) individual tracking across frames, and (iii) counting through a virtual counting line. We fine-tuned YOLO-based detectors using drone-acquired datasets compiled from open sources and enriched them with additional data to address gaps identified during initial analyses. We targeted data collection in high-density flock flows and for under-represented coat colours (e.g., dark-coloured sheep) that, even at low frequency, occur in many commercial flocks and can degrade detection robustness. For animal tracking and counting on the virtual line, we integrated the algorithm. Detection performance was evaluated on a dedicated dataset (428 images) covering diverse conditions within our defined scope, and assessed the full counting pipeline on three external videos recorded on new farms. The YOLOv8n fine-tuned detection model achieved state-of-the-art performances with 97% precision and 96% recall. End-to-end counting pipeline tests on these new videos further confirmed the capacity to generalize to novel farm conditions, producing counting accuracy considered acceptable by interviewed farmers. This highlights that focusing on key location and key moment improves the overall performance while errors of detection are most likely not located in the virtual counting line and are often not affecting the overall counting performance. Beyond excellent performance, our work highlights the duality of computer vision for livestock farming: high promise, but challenging deployment. Data collection needed for model fine-tuning is slow, annotation is labour-intensive, and real-world variability continues to test model robustness. To help overcome these barriers and accelerate reuse, ICAERUS releases open resources that can support a broader range of applications: more than 4,500 images and 50 videos (with and without bounding-box annotations), representing more than 30,000 small ruminants bounding boxes, along with baseline detection and tracking models. These assets can be reused, fine-tuned, or potentially combined with additional sensors or farm data to build decision-support tools for extensive systems, including animal presence verification, lambing-related alerts, and activity monitoring in outdoor conditions. By making these resources openly available, we aim to lower the entry barrier for researchers and industry developers for robust proof-of-concepts and deployable solutions.

Feasibility of Pulse Oximetry and Infrared Thermometry for Monitoring Vital Signs in Dairy Goats

J. Muñoz-Quirós[1], B. Sosa-Marrero[1], M. González-Cabrera[1], A. Morales-Delanuez[1], A. Argüello[1], N. Castro[1], L. E. Hernández-Castellano[1]
[1] IUSA-ONEHEALTH 4 Animal Production and Biotechnology Group, Institute of Animal Health and Food Safety, Universidad de Las Palmas de Gran Canaria, Trasmontaña s/n, 35413 Arucas, Spain

Monitoring physiological parameters such as body temperature, heart rate, and respiratory rate is essential for assessing animal health and welfare in dairy production systems. However, conventional measurements, such as rectal thermometry and stethoscope recordings, require animal handling, which may induce stress, compromise animal welfare, and reduce the reliability of physiological data collection. This study evaluated the potential of non-invasive technologies, including an infrared thermometer and a pulse oximeter, to assess vital signs in dairy goats. The experiment was conducted on 56 multiparous Majorera dairy goats in mid-lactation (between the fifth and sixth month of lactation). Measurements were performed in the milking parlour immediately after milking. Infrared temperature was recorded at different anatomical locations and compared with rectal temperature obtained using a digital thermometer. Heart rate and respiratory rate were determined manually using a stethoscope and by visual observation, respectively, and compared with values obtained from a finger pulse oximeter placed on the right teat. The Pearson correlation coefficient was calculated using the CORR procedure of SAS 9.4, and statistical significance was set at $P \leq 0.05$. No correlations were found between rectal temperature and temperatures measured at the horn, mouth, or udder. A positive correlation was observed between anus temperature and rectal temperature ($r = 0.322$; $P = 0.016$). In contrast, heart rate recorded by the pulse oximeter showed a strong positive correlation with manually recorded heart rate ($r = 0.829$; $P < 0.001$). Respiratory rate obtained with the pulse oximeter could not be reliably analysed due to the limited number of measurements displayed by the device. These results indicate that a pulse oximeter may represent a practical non-invasive tool for measuring heart rate in dairy goats under farm conditions. However, additional research is required to identify reliable non-invasive approaches for monitoring body temperature and respiratory rate in this species. Project carried out with a 2025 Leonardo Grant for Scientific Research and Cultural Creation from the BBVA Foundation

Effect of Heat Stress on Heart Rate Variability in Dairy Sheep at Pasture Using a Smartex Textile Sensor

L. Turini[1], L. Whatford[2], G. Foggi[1], A. Mantino[1], F. G. Cella[1], T. Malizzi[1], M. Mele[1]
[1] University of Pisa, Department of Agriculture, Food and Environment, Via del Borghetto 80, 56128 Pisa, Italy, [2] Royal Veterinary College, Department: Pathobiology & Population Sciences, Hawkshead Lane, AL9 7TA Hatfield, United Kingdom

Climate change represents a major threat to the sustainability of livestock farming, particularly in rural areas where production systems are closely linked to environmental conditions and farm economic viability. Its impact is expected to be especially severe in the Mediterranean area, posing significant challenges to dairy sheep farming systems that are largely pasture-based. Among the main environmental stressors associated with climate change, heat stress is a critical factor affecting grazing ruminants, with potential consequences for autonomic regulation, welfare, and productivity. This study investigated whether heat stress at pasture influences Heart Rate Variability (HRV) in dairy sheep, using the Smartex textile monitoring system. Six Massese dairy sheep were fitted with textile bands and monitored on four summer days (13 May, 31 May, 25 June, and 25 July 2024) for approximately eight hours during the first two days and four hours on the remaining days. During each session, air temperature, humidity, solar radiation, and wind speed were recorded using an on-site weather station, and the Temperature-Humidity Index (THI) was calculated. Flexible regression models accounting for time of day and repeated measures were applied to test the association between Temperature-Humidity Index (THI) and HRV parameters. THI was significantly associated with heart rate ($p = 0.0328$) and RR interval, the interval between successive heartbeats ($p = 0.0384$), showing a non-linear trend. No significant associations were observed for heart rate variability indices reflecting autonomic regulation, including short-term variability and sympathovagal balance. Smoothed effect plots indicated gentle curvature rather than linear responses, suggesting that predicted differences across typical THI ranges provide the most meaningful effect estimates. The findings indicate that Massese dairy sheep exhibit early physiological adjustments to pasture heat stress, reflected by variations in heart rate and RR interval, while maintaining stable autonomic balance. These adaptive responses may represent effective short-term mechanisms that allow animals to preserve homeostasis under moderate thermal load. Further studies on prolonged or extreme heat conditions are warranted to evaluate potential welfare and production impacts, and to assess whether similar patterns are observed in other breeds, which may have different thermotolerance and sheep systems exposed to different environmental and management pressures.

Accelerometer-based behavioural classification in grazing alpacas in the Andes: effects of sensor location and temporal window length

K. Salazar-Cubillas[1], S. Pizarro Carcausto[2], M. Zarria Samanamud[3], J. L. Contreras Paco[3]
[1] Institute of Animal Nutrition and Physiology, Faculty of Agriculture Sciences, Ludewig-Meyn-Straße 9, 24118 Kiel, Germany, [2] Santa Ana Agricultural Experiment Station, Directorate of Strategic Agricultural Services, National Institute of Agricultural Innovation (INIA), Fundo Santa Ana s/n Huancayo km 8 El Tambo Huancayo, 12006 Huancayo, Peru, [3] Animal Nutrition and Food Evaluation Laboratory, Faculty of Engineering Sciences, National University of Huancavelica, Av. Agricultura Nº 319-321. Sector – Paturpampa, 09001 Huancavelica, Peru

Behavior monitoring provides indicators of grazing activity, locomotion, and resting behavior associated with pasture use and nutritional status in grazing. Accelerometers combined with machine learning are increasingly used to classify livestock behaviors. However, alpacas exhibit locomotor patterns and grazing behavior that differ from other pseudo-ruminants, limiting the direct application of models developed for other species. This study evaluated tri-axial accelerometers to classify alpaca behaviors in high-altitude Andean production systems. It was hypothesized that accelerometer-derived features enable accurate classification of major behaviors and that sensor placement and temporal window length influence classification performance. Behavioral observations were conducted on six 2-year-old female alpacas grazing in high-altitude Andean production systems in Peru. Eighteen sessions were performed over 3 days in July 2025 (~30 min each) during daytime grazing (10:00, 12:00, and 14:00). Behavior was recorded by continuous focal video sampling, annotated using BORIS® software, and classified into 12 behaviors grouped into four classes: oral activity, locomotion, resting, and mixed activity. Body acceleration was recorded using two tri-axial HOBO® accelerometers on the jaw and forefoot, with signals synchronized to behavioral annotations and resampled to 1 Hz, generating 33,130 labeled observations. Accelerometer data were aggregated using temporal windows of 3, 5, 10, 20, and 30 s. For each window, tri-axial features including mean acceleration, variance, signal magnitude area, energy, overall dynamic body acceleration, vectorial dynamic body acceleration, and mean inclination angles were extracted. Each window was assigned the most frequent behavior within the interval. Classification used Random Forest models (500 trees) trained with features from the jaw sensor, the forefoot sensor, or both sensors combined. Model performance was evaluated using leave-one-animal-out cross-validation with class weights to correct class imbalance. Behavioral observations were unevenly distributed, with oral activity representing most observations, followed by resting, locomotion, and mixed activity. Classification performance increased with window length, with overall accuracy ranging from 0.75 at 3 s to 0.85 at 30 s. Sensor configuration had limited influence: single-sensor models achieved accuracies of 0.75–0.84, while the combined configuration reached 0.85. The best performance was obtained with both sensors and a 30 s window. The Random Forest model achieved a training accuracy of 0.98, while leave-one-animal-out validation yielded 0.85. Tri-axial accelerometers combined with machine learning reliably classify alpaca major behaviors under field conditions, with improved accuracy using both sensors and longer temporal windows. This approach provides a non-invasive tool for monitoring behavior in grazing alpacas in high-altitude Andean production systems. Future research should improve discrimination of individual behaviors and validate the approach across broader animal groups and environmental conditions.

Lambing Detection in East-Friesian Dairy Sheep Using Pen-Level Acoustic Monitoring

N. Westendorff[1], B. Puppe[1,2], B. Eusemann-Keller[3], K. Helffenstein[1], B. Kuhla[1], C. Manteuffel[1]
[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [2] University of Rostock, Faculty of Agricultural and Environmental Sciences, Behavioural Sciences, Justus-von-Liebig-Weg 6b, 18059 Rostock, Germany, [3] Leipzig University, Faculty of Veterinary Medicine, Institute of Animal Hygiene and Veterinary Public Health, An den Tierkliniken 1, 04103 Leipzig, Germany

Lambing is a critical phase in sheep farming, associated with high mortality in lambs and ewes. Automatically detecting the onset of parturition may help to improve management of obstetric measures and potentially reduce losses. This study aimed to evaluate whether the onset of lambing in East-Friesian dairy sheep can be predicted using area-specific acoustic activity recorded by permanently installed sensors in lambing pens. Twelve East-Friesian dairy ewes were housed individually in wooden lambing pens (1.3 × 4.0 m) equipped with beamforming microphone arrays (Respeaker, 4mic-array) and video surveillance. Acoustic activity was defined as the frequency of sound events (caused by movement and vocalization) detected within a 45°–90° angular range relative to the sensor plane, with a minimum sound pressure level of −89.5 dBFS. The number of acoustic events varied between pens, but patterns were consistent across them. We found that the acoustic activity increased one hour ante partum and remained higher in the immediate peripartal and postpartal timespan. The data was accumulated hourly, normalized to individual 24-hour baselines, and analyzed using a cumulative sum of differences to the day before. Receiver operating characteristic (ROC) analysis was performed to assess the parameters predictive performance, within 1 hour prior to and in the hour of complete expulsion of the first lamb obtained from the video recordings. Finally, the parameter acoustic activity achieved an area under the ROC-curve of 0.87 (maximum sensitivity: 92%, specificity: 75%) for predicting lambing within one hour before birth. Previous studies on lambing detection using animal-attached sensors achieved good detection rates with reasonable advance warning. Pen-level acoustic monitoring provides a reliable, non-invasive method for lambing detection in sheep, with performance comparable to animal-attached systems. A permanently barn-installed system reduces animal handling, operational costs, and minimizes stress for the animals. On the other hand, the barn-installed approach requires pre-lambing relocation of the ewes to the lambing pens. Future studies should validate the system under commercial conditions across diverse breeds and flock sizes, and assess its impact on perinatal mortality and farm management efficiency. Furthermore, the use of the sensor could be examined in other species and contexts.

Prediction of milk metabolites from mid-infrared spectra and estimation of genetic parameters in dairy goats

C. Brosse[1,2], M. Calmels[3], M. Bonnet[1], N. Friggens[4], T. Fassier[5], J. Pires[1], R. Rupp[2]
[1] INRAE UCA, UMRH, Rte de Theix, 63122 Saint-Genès-Champanelle, France, [2] INRAE, GenPhySE, 24 chemin de Borde-Rouge, Auzeville-Tolosane, 31326 Castanet-Tolosan, France, [3] Seenovia, 126 rue de Beauge, 72000 Le Mans, France, [4] INRAE, PEGASE, 65 rue de Saint-Brieuc, 35042 Rennes, France, [5] INRAE, P3R, Domaine de Bourges, 18174 Osmoy, France

Milk metabolites have been associated with resilience, nutritional stress and energy balance, but their laboratory measurement remains costly, time consuming and difficult to implement in routine. The aim of this study was to predict 13 milk metabolites and one enzyme activity from mid-infrared (MIR) spectra in dairy goats and to estimate genetic parameters for these predicted milk metabolites. Prediction equations were developed for choline, cholesterol, triacylglycerol, glucose, glucose-6-phosphate, galactose, glutamate, malate, free amino groups (NH2), isocitrate, beta-hydroxybutyrate, urea, urate and lactate dehydrogenase activity. The full dataset for prediction included 2,720 milk samples from 160 Alpine goats collected on two geographically distinct experimental farms over three years. To increase milk metabolite variability, goats were subjected to a 2-day nutritional challenge consisting of a straw-only diet during two periods: March in early lactation (mobilization phase) and September in late lactation (repletion phase). The dataset was divided at the animal level into a calibration set (112 goats; 1,820 milk samples) and an independent validation set (48 goats; 900 milk samples). Prediction equations were developed using 212 selected MIR wavenumbers with partial least squares or support vector machine methods. Among the 14 prediction equations, eight showed a coefficient of determination (R^2) greater than 0.64 in validation. Four metabolites exhibited $R^2 > 0.80$: triacylglycerol ($R^2 = 0.81$), cholesterol ($R^2 = 0.84$), isocitrate ($R^2 = 0.85$) and urea ($R^2 = 0.91$). To estimate genetic parameters of predicted milk metabolite concentrations, MIR spectra from routine milk recording collected over seven years on one of the experimental farms were used. The dataset comprised 11,568 MIR records from 880 Alpine goats. Genetic parameters were estimated using a test-day approach with a repeatability animal linear mixed model. The analysis was restricted to the seven metabolites and the lactate dehydrogenase activity because of a validation R^2 greater than 0.64. Heritability ranged from 0.18 (± 0.03) to 0.59 (± 0.04). These heritabilities show the potential of MIR-predicted metabolites for selecting metabolic resilience in commercial farms. The PhD grant of C.B. was funded by Clermont Auvergne Metropole, and the work was funded by the French funding bodies APIS-GENE and CASDAR, under the project names 'Resilait' and 'Casmire', respectively.

A Multi-Stage, Data-Driven Welfare Assessment Framework for Small Ruminants under Intensive Feedlot Conditions in a Hot-Arid Environment

E. Emsen[1], B. Odevci[3], A. Alkaabi[1], D. Alketbi[1], M. Kutluca Korkmaz[2]
[1] United Arab Emirates University, Integrative Agriculture, College of Agriculture and Veterinary Medicine, Department of Integrative Agriculture (CAVM), 15551 Al Ain, United Arab Emirates, [2] Malatya Turgut Ozal University, Department of Animal Science, Faculty of Agriculture, 44210 Malatya, Turkey, [3] Imona Technologies, ITU ARI Teknokent, 34396 Istanbul, Turkey

Animal welfare monitoring across livestock supply chains remains limited in hot-arid production systems, despite its importance for sustainable food production and transparent value chains. The objective of this study was to develop and pilot-test a multi-stage, data-driven welfare assessment framework for lamb production under intensive feedlot conditions and to evaluate the feasibility of translating biological welfare measurements into blockchain-compatible digital records for traceable welfare certification. The framework was applied to 41 Awassi ram lambs (4–6 months of age) raised under an intensive feedlot system with individual pen feeding in the United Arab Emirates. Welfare assessments were conducted across three sequential stages of the production chain: on-farm (feedlot), transport and loading, and immediate pre-slaughter conditions under Halal processing. On-farm welfare was evaluated using standardized animal-based and resource-based indicators structured into four domains: behaviour and mental state, health, nutrition, and environment. Stage-specific indicators were applied during transport and slaughter to evaluate handling, vehicle suitability, and stress-related responses. Welfare scores were generated using a standardized scoring framework and subsequently structured into digitally verifiable data units compatible with blockchain-based traceability systems. On-farm welfare outcomes ranged from moderate to good, with nutrition representing the highest scoring domain, while environmental and behavioural indicators revealed constraints associated with bedding hygiene and restricted movement related to individual housing. Transport and loading conditions achieved a Good welfare classification, characterized by adequate space allowance, appropriate vehicle design, and low incidence of slipping or falling. Immediate pre-slaughter Halal conditions also resulted in Good welfare, with calm handling, minimal vocalisation, and limited behavioural indicators of stress. The study demonstrates that multi-stage welfare assessment can generate structured biological data suitable for digital recording and blockchain-based verification, enabling transparent welfare communication across the supply chain. Such frameworks provide a practical foundation for integrating Precision Livestock Farming data streams, digital traceability, and welfare-based labeling systems in small ruminant production systems operating under hot-arid environmental conditions.

Artificial neural networks outperform partial least squares models for fatty acids estimation using FT-MIR spectrometry on bovine milk: a first step towards transfer learning on small ruminants.

Fourier transform mid-infrared (FT-MIR) spectrometry in milk can improve production, milk quality and animal welfare among others. Nevertheless, this technology remains underused in dairy ewes and goats, despite it becoming increasingly common in the dairy cattle sector. To reduce the cost of developing equations, transfer learning could be used to adapt FT-MIR models from dairy cattle to dairy sheep and goats. However, this transfer requires artificial neural networks (ANN) but these bovine ANN models do not yet exist. This study aims to develop a multi-layer perceptron ANN for fatty acids to see if we can reach at least the same performance as the ones obtained with commonly built partial least squares (PLS) regressions. The ANN models developed for bovine milk were then directly applied to goat milk to evaluate the potential of transductive learning, the simplest transfer learning method. The database (n=1942) contained 42 individual and groups of fatty acids measured by gas chromatography and their associated standardized bovine milk spectra. A total of 80% was used to train models and 20% used for validation. Validation R^2 values ranged from 0.1223 to 0.9890 for PLS models and from 0.2050 to 0.9886 for ANN models. Compared with PLS models, ANN reduced prediction errors (RMSE) by 0.08 to 47.27% for 39 fatty acids, while an increase in errors ranging from 1.74 to 3.38% was observed for 3 fatty acids. These results highlight an overall improvement in the predictive performance of neural networks compared to PLS models on the validation dataset. After applying the built ANN models on the goat dataset (n=345), only 10 fatty acids have a positive R^2 from 0.1228 to 0.9410, one fatty acid showed an R^2 equal to zero, while the remaining 28 fatty acids have aberrant R^2 values, highlighting the lack of model generalization across species. In conclusion, these results highlight an overall improvement in the predictive performance of ANN compared to PLS models to estimate fatty acids by FT-MIR spectrometry for dairy cattle. Furthermore, transductive transfer learning confirms that models created specifically for dairy cattle cannot be applied as they are to small ruminants and opens the door to testing more sophisticated transfer learning methods.

Early-life milk intake and drinking behaviour as predictors of growth and first-lactation performance in dairy goats

J. Caetano De Sousa[1], J. F. Ettema[1]
[1] Goat Improvement Company, Hoofdveste 10, 3992 DG Utrecht, Netherlands

The pre-weaning period represents a biologically sensitive phase that may influence lifetime productivity in dairy ruminants. While associations between pre-weaning milk intake and later milk yield are well documented in dairy calves, comparable evidence in dairy goats remains limited. This study evaluated the relationships between milk consumption behaviour, early growth and first-lactation milk production using large-scale automatic feeder data. Data were collected from 1,686 Saanen goat kids on a commercial dairy goat farm in the Netherlands equipped with an automated milk feeding system. A total of 361,024 feeder visit records were processed to derive two behavioural indicators during the suckling period: total milk intake and drinking speed. Growth was assessed using Average Daily Gain (ADG) and estimated body weight at 50 days of age (est50). First-lactation milk yield data were available for 1,376 animals. Relationships were analysed using linear regression models ($p < 0.05$). Total milk intake showed a strong positive association with ADG ($\beta = 0.0575$, $p < 0.001$). Drinking speed independently increased ADG ($\beta = 0.0078$, $p < 0.001$), corresponding to approximately 11 g/day higher growth per 1 ml/s increase in speed. Early growth was positively associated with first-lactation milk yield: each additional gram of ADG increased milk yield by 0.0063 kg/day ($p = 0.045$), and each additional kilogram of body weight at 50 days increased milk yield by 0.11 kg/day ($p = 0.030$). This amounts to 40 kg more milk per year, which is around 3.3% and has an impact of €24 per goat per year. Drinking speed showed no direct association with milk yield, indicating that its contribution to adult performance is mediated through growth. No significant relationship was observed between drinking behavior and age at first kidding. Estimated body weight at 50 days emerged as the central biological indicator linking pre-weaning nutrition to adult productivity. Seasonal variation further suggested that environmental conditions and month of birth may modulate early growth potential. In a complementary analysis ($n = 899$), milk replacer formulations differed significantly in ADG. When biological performance was combined with economic evaluation (gain per unit cost), the formulation promoting higher growth also yielded superior economic efficiency, demonstrating that product price alone is not an adequate decision metric. These results demonstrate a clear biological pathway connecting early-life milk intake, juvenile growth and subsequent milk production in dairy goats. Automatic feeding systems provide robust phenotypic indicators for early performance prediction. Future research should determine whether enhanced pre-weaning growth influences lifetime productivity and health outcomes. Additionally, the potential physiological consequences of high drinking speed should be evaluated, particularly whether reduced salivation associated with rapid milk intake may act as a limiting factor for growth performance and overall physiological development. We gratefully acknowledge the support from Urban GmbH and the GIC nucleus farm of Harm and Ankie van der Veen-Meijer for providing the data used in this study.

SNP-guided prediction of feed conversion ratio in Latvian sheep: machine learning models for marker-assisted selection.

M. Martins[1], N. Paramonova[1], S. Plavina[1], D. Malakovska[1], N. Krasnevska[1], J. Paramonovs[1], D. Kairisa[2], I. Trapina[1]
[1] The University of Latvia, Genomics and Bioinformatics Centre, Department of Pharmaceutical Sciences, Faculty of Medicine and Life Sciences, Jelgavas iela 1, LV-1004 Riga, Latvia, [2] Latvian University of Life Sciences and Technologies, Department of Animal Sciences, Faculty of Agriculture and Food Technology, Liela iela 2, LV-3001 Jelgava, Latvia

The economic benefit of sheep farmers depends on the quantity and quality of lamb meat produced, which is directly related to the feed conversion ratio. Improving breed selection for feed efficiency would promote the production of high-quality lambs for meat production and breed improvement. Marker-assisted selection (MAS) uses genetic markers associated with specific traits, but these markers must be determined individually for each breed/population. The research seeks to identify molecular markers from the GeneSeek® Genomic Profiler™ Ovine 50K (Lansing, MI, USA) associated with the Feed Conversion Ratio (FCR) in Latvian sheep breeds and to employ these markers in machine-learning-based genomic predictions. DNA genotyping data from 261 controlled fattening lambs across eight prevalent breeds indicate that 135 (51.72%) are of the national breed Latvian Darkhead (LT). The average computed Feed Conversion Ratio (FCR) for the 60-day period (from day 90 to 150) for all lambs was 4.74±0.80 kg, whereas for the LT breed, it was 4.85±0.84 kg. In the Genome-wide association study (GWAS) investigation, one SNP, rs413876950, had a p-value of 3.46 x10-8, alongside 1665 SNPs with $p<0.01$ and 3549 SNPs with $p<0.05$ identified across all breeds. In contrast, the LT breed revealed 478 markers with $p<0.01$ and 1994 markers with $p<0.05$ detected independently. Machine learning methods were employed to integrate lamb birth rates and GWAS significant loci (5215 for all breeds and 2472 for LT) to ascertain the most effective predictors of lamb feed conversion ratio prior to the fattening phase. The resultant MAS prediction would facilitate the identification of prospective breeding candidates before they mature. The results illustrated the predictive powers of machine learning algorithms. The study revealed the potential to integrate machine learning algorithms with genotyping results to enhance breeding efforts in Latvia, particularly for the LT variety, consequently improving breed advancement and competitiveness. Acknowledgments: Funded by UL Faculty of Medicine and Life Sciences internal student grant MG-2026/XXXX, grant No. XXXX and by the Latvian Council of Science, Latvia, projects LZP-2021/1-0489 and LZP-2024/1-0092.

Exploring a data-driven approach to evaluate general resilience in lambs through cumulative feed intake

F. Barchet[1,2,3], A. Oliveira Rocha[3], G. Ciappesoni[1,2], M. S. Aktar[3], L. F. Brito[3], I. De Barbieri[1]
[1] Instituto Nacional de Investigación Agropecuaria, Sistema Ganadero Extensivo, Ruta 5 km 386, 45000 Tacuarembó, Uruguay, [2] Universidad de la República, Facultad de Agronomía, Garzón 780, 12900 Montevideo, Uruguay, [3] Purdue University, Department of Animal Sciences, 610 Purdue Mall, 47907 West Lafayette, IN, United States

Animal resilience is a key concept in livestock production, as more resilient animals are able to better cope with short-term environmental challenges. As resilience is not a directly measured trait, many efforts have been made over the past few years to develop resilience indicators that capture the animals' response to perturbations and may become target traits of selection in breeding programs. In this context, the main objectives of this study were to (1) derive lamb resilience indicators based on variability in cumulative feed intake, (2) evaluate potential differences on resilience phenotypes between sheep breeds and sexes, and (3) investigate the phenotypic correlation between resilience indicators and performance traits in Uruguayan Corriedale, Texel, and Creole sheep. High-frequency individual feed intake data from 439 lambs (176.2 ±47.4 days of age) of three breeds (Corriedale, Creole, and Texel) and offspring of 45 rams (7 Corriedale, 35 Texel, and 3 Creole), collected across seven feeding trials conducted between 2020 and 2024, were used in this study. The animals' average initial body weight (BW) was 37.1 ±9.9 kg for Texel, 30.3 ±7.7 kg for Corriedale, and 22.3 ±2.2 kg for Creole. Feed efficiency trials lasted 53.1 ±6.0 days and animals were conducted at the post-weaning phase. These data were used to estimate target trajectories (in the absence of perturbations) of cumulative feed intake using a smoothing function. Deviations between the observed and predicted cumulative feed intake trajectories were associated with potential perturbations and subsequently used to derive eleven resilience traits. The resilience indicators derived captured different aspects of the perturbation shape, including amplitude, variance of deviation, log variance of deviation, autocorrelation, recovery ratio, recovery time, perturbation time, number of perturbations, average velocity, maximum velocity, and area under the curve. Most of the perturbations occurred at the beginning of the trials (61.9%), which indicates potential challenges involving the adaptation to the facilities. Animals had an average of 1.89 ±0.91 perturbations ranging from one to five across individuals. Differences in estimated marginal means were found for sex in the Texel breed, where males were generally more resilient. Additionally, differences were found between the three breeds inside the male group, where Creole male lambs exhibited improved resilience as compared to Texel and Corriedale. Unfavorable phenotypic correlations were observed between some resilience indicators and production traits such as average daily gain and rib eye area. A favorable correlation was observed between resilience and fat thickness which suggests that fat deposition plays an important role in adaptation and resilience. No unfavorable association was found for residual feed intake, suggesting that, at a phenotypic level, an increase in feed efficiency does not affect animals' resilience. Results indicate that this data-driven approach is a useful tool to evaluate animals' trajectory and responses to unknown environmental challenges. The phenotypic correlations highlight an anticipated pattern of potential trade-offs between resilience and production that warrants further investigation based on genetic analyses and larger datasets. More balanced breeding strategies will likely be needed when selecting for more productive animals.

Combining multi-sensor data and machine learning for automated behaviour classification and disturbance detection in sheep

S. Gerwin[1], J. Henke-Von Der Malsburg[1], A. Vernunft[1]
[1] Research Institute for Farm Animal Biology, Animal Husbandry and Health, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

Sheep production systems are frequently considered low-input and robust, particularly under extensive pasture conditions. However, intensive grazing dynamics, seasonal fleece growth, and the high incidence of lameness, injuries, and predation events require continuous oversight to safeguard welfare and productivity. In self-managed pasture systems, animals may not be visually inspected on a daily basis, increasing the probability that health disorders, mortality, or abrupt behavioural disturbances remain undetected. Early identification of such events is critical for welfare assurance, economic stability, and adaptive predator–livestock management in regions with increasing large carnivore presence. The aim of this study was to integrate multi-sensor technology and algorithm-based behavioural inference in group-housed, pastured sheep. As a result, the high-quality sensor data yielded a comprehensive characterization of small ruminant behaviour. Particular emphasis was placed on detecting rapid, synchronized movement bursts, spatial dispersion events, and orientation shifts indicative of external disturbances such as predator encounters or acute stress responses. Therefore, individual behaviours as well as herd dynamics were considered. Data were collected by equipping eight sheep with VERTEX Plus collars (Vectronic Aerospace GmbH), a multi-sensor system recording tri-axial acceleration, GPS position, magnetometer-based orientation, and proximity to conspecifics at high resolution. Simultaneous direct behavioural observations provided ground truth for supervised model development. Based on these synchronized datasets, a random forest classifier was trained to distinguish core behavioural states (rumination, grazing, resting, locomotion, vigilance, and social interaction) and to identify sudden deviations from established activity patterns. Initial model validation indicates clear separability of primary activity states and promising potential for identifying abnormal movement clusters. Individual deviations may indicate reduced welfare, whereas herd-level deviations may reflect external disturbances. Further work will establish automated scoring coupled with real-time alert functions. The envisioned system architecture aims to notify shepherds of welfare-relevant anomalies such as injury or predator threat and enable rapid on-site intervention. In addition, this approach supports evidence-based livestock-wildlife-coexistence strategies by objectively documenting disturbance events. Ongoing work focuses on evaluation across alternative sensor configurations and parameter optimization throughout the pipeline of data analysis. Practical implementation of the system must further address requirements for data transmission, and scalability across diverse pasture systems. The project is supported by funds of the Federal Ministry of Agriculture, Food and Regional Identity (BMLEH) based on a decision of the Parliament of the Federal Republic of Germany via the Federal Office for Agriculture and Food (BLE) under the innovation support programme.

Assessment of Optimum Drying-Off model on Milk Yield in Assaf Ewes

I. Contreras-Solís[1], D. López-Carbonell[2], C. Palacios[3], J. A. Abecia[4]
[1] Public University of Navarre, Department of Agronomy, Biotechnology and Food, Arrosadia Campus, 31006 Pamplona, Spain, [2] IA2, University of Zaragoza, C/Miguel Servet, 177, 50013 Zaragoza, Spain, [3] Faculty of Agricultural and Environmental Sciences, University of Salamanca, Animal Production Area, Department of Construction and Agronomy, Avda. Filiberto Villalobos, 119, 37007 Salamanca, Spain, [4] IUCA, University of Zaragoza, C/Miguel Servet, 177, 50013 Zaragoza, Spain

Drying-off in the dairy sheep industry is an important management practice with impact on productivity and farm profitability. Proper timing of drying-off allows the mammary gland to recover before the next lactation and can influence subsequent milk yield. Therefore, optimizing the drying-off process may improve production performance while reducing potential economic losses. Additionally, this process influences the health and welfare status of animals, which has become a key aspect in modern production systems. The aim of this study was to explore, using regression analysis, the effect of drying-off timing on subsequent total milk yield in Assaf dairy sheep and, consequently, to determine the optimal drying-off timing as a recommended management practice. To achieve this, a mixed model was applied to account for both fixed and random effects in the analysis. The analysis was based on 152,609 milking records from 52,263 ewes belonging to 36 Assaf dairy farms in Castilla y León, Spain, collected between 2001 and 2023. Records were collected by the Spanish Assaf Sheep Breeders' Association (ASSAFE) as part of routine milk recording activities. After filtering out outliers, 149,003 milking records from 52,615 ewes remained for the analysis. Multiple nonlinear mixed models were fitted to explain the total milk yield after drying-off (TMY2). Variables considered in the analysis were: drying-off days before parturition (DRY), TMY1 (total milk yield prior to TMY2), lambing season (LS), drying-off season (DS), and number of lambings (NL2 = 1 vs. ≥2 parturitions), included as independent variables; and farm (FA), ewe nested within farm (FA:EWE), and lambing year (LY), included as random effects. TMY1 was standardized using the scale function (TMY1z) and subsequently categorized into two levels: high and low total milk yield (TMYLH). The DRY variable was modeled using nonlinear functions, including natural splines and orthogonal polynomials implemented in the splines and stats R packages. Multiple non-linear mixed models were fitted using the lme4 package in the R environment. An ANOVA test was performed to compare models and assess statistical differences, while model fit was evaluated using the Akaike Information Criterion. The analyses indicated that the best-fitting model included the effects:TMY2 = ns(DRY, df = 9) × DS + TMY1z + LS + DS + NL2 + FA + EWE(FA) + LY + Error. This model suggests that the interaction between DRY and DS improves the accuracy of predicting the most suitable drying-off timing, indicating that management decisions regarding drying-off should not rely solely on the number of days but also on the season in which drying-off occurs. Thus, the optimal drying-off point differs across seasons, ranging from slightly more than 50 days for ewes dried in winter and spring to approximately 200 days when drying occurs in summer. These results should be interpreted in the context of the seasonality of sheep reproduction, and more specifically within Assaf production systems in Spain. Overall, the results of this analysis show that non-linear mixed models can be an effective tool for determining optimal management practices for drying-off in dairy sheep, thereby maximizing the total milk yield of subsequent lactations using routinely collected production data, as illustrated in this case with Assaf flocks in Spain.

Mineral requirements of Tenebrio molitor larvae: magnesium, potassium and phosphorus needs

A. Moradei[1], P. Premarajan[1], M. Ottoboni[1], L. Pinotti[1,2], T. Spranghers[3]
[1] Università degli studi di Milano, Veterinary Medicine and Animal Sciences, Via dell'Università 6, 26900 Lodi, Italy, [2] Università degli studi di Milano, Coordinating Research Centre: Innovation for Well-Being and Environment, Via Festa del Perdono 7, 20133 Milano, Italy, [3] VIVES University of Applied Sciences, Research Group Food Processing, Oostnieuwkerksesteenweg 113, 8800 Roeselare, Belgium

Minerals represent a minor proportion of livestock diets; however, they are indispensable for optimal livestock health and performance. Deficiencies in mineral intake may result in impaired growth and reproductive issues, consequently, the mineral requirements of livestock are well documented. In contemporary legal contexts, insects are categorized as farmed animals. However, their rearing practices typically involve the utilization of substrates designed for other species, such as chicken feed, or circular substrates composed of by-products that are not balanced in their nutritional composition. There is limited knowledge about the nutritional requirements of insects, and improvements can be made to their substrates to maximize their performance. It has been demonstrated that, when sufficient protein is provided, the amino acid concentration of the substrates had a limited influence on the growth performance of mealworms (Tenebrio molitor) (MW), but their mineral requirements have not yet been investigated. Therefore, the present trial aimed to analyze the mineral needs of MW. The focus was on the requirements of magnesium (Mg), potassium (K) and phosphorus (P), based on the mineral content of wheat bran, the gold standard for rearing MW. Semi-artificial diets based on at least 25% wheat bran supplemented with sucrose, casein and inorganic minerals were tested. The diets were isoenergetic and isoproteinous. Each mineral was administered in four different doses per experiment (from 25% to 100% of the mineral content of wheat bran) and the other minerals were given in inorganic form at a concentration of 100%. The growth performance of the MW larvae was measured using two key metrics: weight gain and survival. The collected data were then analyzed in SPSS using a univariate ANOVA for final total weight and survivability, and a linear mixed effects model for individual larval weight measured over time. The groups demonstrated a comparable survivability rate (>90%), with the exception of the Mg 50% and Mg 75% groups, which exhibited a numerically lower survivability rate of 89.25%. Considering the average larval weight, differences have been observed between the different mineral groups. Specifically, the K 25% group demonstrated a lower mean individual weight in comparison with the Mg 50%, Mg 75%, P 50%, P 75% and P 100% groups. K 75% larvae showed a lower individual weight in comparison with Mg 75%. The differences observed were partially confirmed in the final total larval weight. Indeed, the K 25% group showed a significantly lower value in comparison with most of the other groups. These results indicate that several minerals are supplied in excess to MW using traditional substrates, and that a quantity higher than 25% of the K present in wheat bran seems to be crucial for MW growth. However, further studies are needed to understand the observed growth differences and to design a substrate that completely fulfils the nutritional requirements of MW.

Effects of structural fibre ingredients on black soldier fly (Hermetia illucens L.) larval growth at industrial and laboratory scales

S. Naser El Deen[1], E. De Lange[2], L. Francuski[3], S. Karanjit[3], T. Veldkamp[1]
[1] Wageningen University and Research, Livestock Research, De Elst 1, 6700 AH Wageningen, Netherlands, [2] Wageningen University and Research, Food Safety Research, Akkermaalsbos 2, 6708 WB Wageningen, Netherlands, [3] Protix, Van Konijnenburgweg 86, 4612PL Bergen op Zoom, Netherlands

Optimising structural fibre components for Black Soldier Fly larval (BSFL) diets is essential for scaling insect-based bioconversion systems. This study evaluated the impact of three fibre-rich materials, reed-ditch grass mix, nature straw, and sawdust (control) on BSFL growth and composition. The reed–ditch-grass mix and natural straw were composted with ammonia-washer fluid on a small scale, while sawdust was used untreated; all materials were incorporated at approximately 20% of the total substrate mass. Trials were conducted under industrial crate conditions using 55,000 four-day-old larvae per replicate (n = 6) over a six-day rearing period. The larval growth performance and biochemical profile were analysed. A complementary laboratory-scale experiment (200 larvae per replicate; n = 5) was performed to confirm substrate-specific performance trends and assess additional fibre variants composted at a larger, industrial scale. Although the diets differed only slightly in biochemical composition, their structural properties had a clear impact on larval performance outcomes at the large-scale. Larvae reared on the reed-ditch grass mix and on the sawdust control achieved the highest total larval biomass (both 4.33 kg), while nature straw yielded the lowest biomass (3.45 kg). Individual larval weights showed the same pattern, with reed-ditch grass producing the heaviest larvae (89.7 mg), followed by nature straw (84.0 mg) and the control (75.2 mg). The survival rate ranged from 75% (nature straw) to 100% (control). Residual substrate weight also varied, with nature straw leaving the highest residue. The larval biochemical composition remained relatively consistent across treatments. Crude protein content (N×4.76) ranged from 8.7% in larvae reared on the reed-ditch grass mix to 9.1% on nature straw, while fat content varied from 1.88% (reed–ditch grass mix) to 2.10% (control diet). In the small-scale experiment, the measured parameters, including larval final weight, survival, and frass output, confirmed the substrate-dependent growth trends observed at the large scale. The survival rate was above 95% for all diets. The highest harvested larval biomass and individual larval weight were for larvae reared on reed-ditch grass mix (22.1 g and 111.8 mg, respectively) and reed alone (21.9 g and 109.8 mg, respectively). Together, the two experiments demonstrate that fibrous substrates can support robust BSFL growth, but their effectiveness varies with fibre type and composition. Reed-based diets showed the most consistent performance across scales, highlighting their strong potential for industrial application.

Protein-to-soluble carbohydrate ratio in the diet for Tenebrio molitor imagoes modifies their reproduction, egg viability and young mealworm survival

T. Añón[1], M. Cambra-López[2], J. Just[1], J. J. Pascual[2]
[1] Feedect, Calle de la Buitrera, 6, 46180 Valencia, Spain, [2] Institute for Animal Science and Technology, Universitat Politècnica de València, Camino de Vera s/n, 46022 Valencia, Spain

Mealworms (Tenebrio molitor larvae) are one of the most relevant species for feeding birds, multiple captive reptiles, amphibians and even mammals due to their high nutritional value for insectivores. To optimise industrial mealworm production, it is essential to maximise egg production and viability, as well as further mealworms survival. However, information on the nutrition of imagoes to optimise egg production is limited. The aim of this study was to evaluate the effect of different protein-to-soluble carbohydrate (P:SC) ratios on the development of T. molitor imagoes, their egg-laying productivity and further survival of the young mealworms. To this end, four experimental diets with the following P:SC ratios were designed: 1:1.7, 1:1, 1.7:1 and 1.7:1F (the latter of which contained 2% fat-F), changing the proportion of wheat bran, soyabean meal and soyabean oil, but maintaining the carrot content. A total of 20 60×40 cm trays (5 per diet) with 350 g of imagoes housed at 27ºC and 70% relative humidity were used for 24 days. The feed intake, weight and mortality of the imagoes during the reproductive period was monitored two times per week, as well as the oviposition and hatching rates of the eggs and the survival rate of the young mealworms during the first month of life. Results indicate high-protein diets (1.7:1 and 1.7:1F) reduced the dry feed intake of imagoes, but they significantly increased the intake of wet feed (carrot) and of the total diet. This is probably due to the greater water requirement needed to process excess nitrogen and form protein retention. Although no significant differences were observed in average daily weight gain, imagoes fed a high-protein, high-fat diet (1.7:1F) reached a higher final weight, suggesting greater nutrient accumulation. Furthermore, these higher-protein diets increased egg weight linearly (by +9.5% from a P:SC ratio of 1:1.7 to 1.7; $P<0.001$), although decreased daily egg production (by -10% from 1:1.7 to 1.7:1 P:SC ratio; $P<0.001$). This trend was partially reversed with the inclusion of fat. The age of imagoes also affected egg production and size. With increasing imago's weight, egg weight also increased by +0.014 mg per day ($P<0.001$), but daily egg production decreases by -0.52 eggs per female per day ($P<0.001$). There were no significant differences in the hatching rate of the eggs depending on the diet provided to the imagoes (on average 84%). With regard to the mortality of young mealworms during the first month of life, mealworms from imagoes fed the 1:1 diet showed greater mortality than those fed the other diets (on average +3.11 percentage points; $P<0.05$). These results suggest that, depending on the production objective, the optimal protein-to-soluble carbohydrate ratio could differ. Richer protein diets promote heavier eggs, while diets with a higher energy content increase the number of eggs obtained. In addition, the diet supplied to the imagoes affects the survival of the mealworms in the early stages of their life.

The effect of tomato leaf waste handling on the growth performance, nutritional composition, and glycoalkaloids content in the desert locust Schistocerca gregaria

Y. Luo[1], N. Förster[1], M. Bogdanova[2], S. Schulz[1], I. Mewis[1], C. Ulrichs[1], W. Yakti[1]
[1] Humboldt-Universität zu Berlin, Urban Plant Ecophysiology Division, Faculty of Life Sciences, Thaer-Institute of Agricultural and Horticultural Sciences, Lentzeallee 55, 14195 Berlin, Germany, [2] Technische Universität Berlin, Institute of Food Technology and Food Chemistry, Charlottenburg, 10623 Berlin, Germany

Abstract^Tomato leaves are an abundant agricultural waste stream, but their utilization as feed is limited due to their high fiber content and the presence of toxic glycoalkaloids. However, using tomato leaves as feed for desert locusts can be a feasible approach to produce insect protein for food and feed applications. In this study, desert locusts were reared on freshly harvested leaves, leaves stored for varying durations, and on leaf cuttings kept in water to maintain freshness. Feeding on leaf cuttings kept in water reduced α-tomatine and dehydrotomatine contents in the locusts, despite the high alkaloid content in the leaves. The chemical composition of the produced locusts varied across treatments, with the leaf cutting method resulting in higher accumulation of Cu, Zn and Pb compared to feeding with fresh leaves. The crude protein content of the locusts remained stable across treatments (59.37–60.51%), so was their fatty acid composition. These findings highlight the impact of leaf storage conditions on the production performance of desert locusts, which is crucial for developing an efficient and low-labour entomoponic cultivation system.

From olive waste to insect biomass: evaluating increasing levels of olive pomace in black soldier fly production

R. Sorayani Bafqi[1], S. Bellezza Oddon[1], A. A. Melis[1], Z. Loiotine[1], I. Biasato[1], R. L. Passaro[1], L. Gasco[1]
[1] University of Turin, Department of Agricultural, Forest and Food Sciences, largo Braccini 2, Grugliasco, 10095 Turin, Italy

Several studies on black soldier fly (Hermetia illucens; BSF) have demonstrated the suitability of agro-industrial residues as substrates for larval development. However, many studies evaluated heterogeneous substrates, making it difficult to isolate the specific effect of individual by-products on larval performance. Experimental approaches using increasing inclusion levels of a single by-product within a constant basal diet allow a more precise evaluation of ingredient suitability. Additionally, most trials are conducted at laboratory scale using relatively small quantities of substrate, whereas rearing scales may influence larval density and substrate conversion efficiency. The objective of the present study was to evaluate the effect of increasing inclusion levels of olive pomace on larval survival and substrate conversion performance of BSF under pilot rearing conditions. Six experimental diets were formulated with increasing olive pomace (0, 10, 15, 20, 25 and 30%; named D0, D10, D15, D20, D25, D30, respectively), while maintaining similar composition for the remaining ingredients (brewers spent grain and yeast, eggs, whey, dry and liquid distillery stillage, rice husk, water, breading and vegetable waste). Each treatment was replicated four times (10kg of substrate/replicate, 14,000 6 days old larvae [average weight: 8.7 mg ± 0.169]/replicate). Larvae were reared at 28°C and 60% RH. The end of the trial was set when 3 replicates/treatment reached at least 5% of prepupae. After that, the larval biomass and residual substrate weight were recorded and the following indicators were calculated: reduction rate (RR), waste reduction index (WRI) and bioconversion efficiency corrected for residue (BER). Larval average weight and survival rate (SR) were also estimated. Data were analyzed using One-Way ANOVA (SPSS, v28; $P<0.05$). The larvae of D0 reached the highest final average weight ($P<0.001$), followed by D10 and D15 that were statistically equal ($P>0.05$). No differences were observed among D15, D20 and D25 ($P>0.05$), and the last two groups were also equal to D30 ($P>0.05$). Olive pomace inclusion also affected larval survival, with the D20, D15 and D10 treatments showing higher SR than D30 and D25 ($P<0.001$), while D0 was intermediate and comparable only to D15 ($P>0.05$). The highest RR was observed in D30 ($P<0.001$) and the lowest in D10 ($P<0.001$), which was statistically equal to D0 ($P>0.05$). The best WRI was recorded in D0 and D10 ($P<0.001$). In contrast, D25 and D30 showed the poorest values ($P<0.001$), while D15 and D20 showed intermediate values ($P<0.001$). This outcome may be referred to the development time that was 8 days for D0 and D10, 10 days for D15, 11 days for D20, 15 days for D25 and 16 days for D30. The D0 and D10 displayed the highest BER, while D25 and D30 showed the lowest values ($P<0.001$). In conclusion, moderate olive pomace inclusion levels (up to 15%) provided the most balanced performance in terms of larval survival, growth and bio-conversion performance. Although higher inclusion levels improved waste reduction, they negatively affected larval viability, maybe due to the phenolic compounds present in olive pomace. The research is part of the OLIWA project, founded by the PRIMA program supported by the European Union's Horizon 2020 Research and Innovation program under Grant Agreement N2432

Integrating Insect Production Into Greenhouse Systems: Using Tomato Leaf Biomass as Insect Feed

W. Yakti[1], Y. Luo[1], S. Bisch-Knaden[2], I. Mewis[1], C. Ulrichs[1]
[1] Humboldt-Universität zu Berlin, Lentzeallee 55, 14195 Berlin, Germany, [2] Max Planck Institute for Chemical Ecology, Hans-Knöll-Straße 8, 07745 Jena, Germany

The Closed Urban Modular Energy- and Resource-Efficient Agricultural System (CUBES), built at the Humboldt University of Berlin (Germany), integrates insect production into a circular production model alongside fish and plant cultivation, mirroring natural ecosystems. The presented work focuses on establishing nutrient synergies between plant (greenhouse) production and insect production systems mainly by exploring the potential use of tomato leaves as feed for insect rearing. Experiments were done using different insect species: the black soldier fly (Hermetia illucens), yellow mealworms (Tenebrio molitor), desert locusts (Schistocerca gregaria), and the tobacco hornworm (Manduca sexta). Tomato leaves commonly grown in greenhouses are not suitable for black soldier fly or mealworm rearing, with negative effects even with partial usage. However, these effects are variety-dependent and differ based on the toxic glycoalkaloid content of the tomato leaves. Herbivorous insects such as the desert locust and the tobacco hornworm can consume and grow efficiently on these leaves but toxic glycoalkaloids can be present in their biomass. The content of toxic plant glycoalkaloids can be reduced with proper downstream processing. A comparison between the production of desert locusts and the tobacco hornworm using tomato leaves as feed will be presented, in addition to challenges in their rearing.

Turning Waste into Value: Effects of olive fragments on Black Soldier Fly Larvae Performance

T. Gogou[1], R. Nakirya[2], P. Soulioti[1], E. Valli[3], C. Rumbos[4], M. Capucchio[5], C. Athanassiou[1]
[1] University of Thessaly, Department of Agriculture Crop Production and Rural Environment, Fytokou Street, 38446 Volos, Greece, [2] University of Bologna, Department of Biological, Geological and Environmental Sciences, Via Irnerio, 42, 40126 Bologna, Italy, [3] University of Bologna, Department of Agricultural and Food Sciences, piazza Goidanich, 60, 47521 Cesena, Italy, [4] International Hellenic University, Department of Agriculture, Alexander Campus, 57400 Thessaloniki, Greece, [5] University of Turin, Department of Veterinary Sciences, Largo Paolo Braccini, 2-5, 10095 Grugliasco, Italy

Olive oil production generates significant amounts of agricultural by-products, particularly in Mediterranean regions. Among these residues, olive fragments, consisting mainly of leaves and small branches, remain largely underutilized despite their potential nutritional value. Black soldier fly larvae (BSFL) are known to efficiently convert organic residues into valuable biomass. Thus, the aim of the present study was to evaluate the effects of different inclusion levels of olive fragments in BSFL diets on their growth and overall performance. Diets were formulated to fall within the reported protein (16–20%) and lipid (2–6%) requirements of the larvae , with the exception of the diet containing the highest level of olive fragment inclusion, in which the protein content was slightly lower. More specifically, the control diet consisted of wheat bran, whey, and brewer's spent grain. Based on this formulation, three additional diets were prepared by incorporating olive fragments at different inclusion levels: 5%, 12%, and 25%. Larval weight and survival were recorded every three days, and the experiment was terminated when 10% of the larvae had reached the prepupal stage. At the end of the experimental period, Feed Conversion Ratio (FCR) and Bioconversion Ratio (BCR) were calculated, while the nutritional composition of both larvae and diets was determined through chemical analyses. Statistical analysis revealed no significant differences in survival rates, which remained higher than 90% across all dietary treatments. In terms of larval performance, the control diet and the 5% inclusion diet yielded the most favorable results, whereas the 25% inclusion diet resulted in the poorest performance. The diet containing 12% olive fragments exhibited intermediate performance. Furthermore, nutritional analyses indicated high protein levels, ranging from 50% to 56%, as well as satisfactory lipid content (2–9%) for larvae reared on the control and 5% inclusion diets, respectively. Overall, the results suggest that BSFL can tolerate the inclusion of olive fragments in their diets at low to moderate levels without negatively affecting feed efficiency or larval performance. Valorizing Apple and Olive Pomaces: How Density and Substrate Shape Hermetia illucens Larval Performance

P. Soulioti[1], T. I. Gogou[1], R. H. Nakirya[3], E. Valli[4], C. I. Rumbos[2], M. T. Capucchio[5], C. G. Athanassiou[1]
[1] University of Thessaly, 1Department of Agriculture, Crop Production and Rural Environment, Phytokou Str., 38446 Volos, Greece, [2] International Hellenic University, 2Department of Agriculture, Alexander Campus, 57400 Sindos, Thessaloniki, Greece, [3] Università di Bologna, 3Department of Biological, Geological and Environmental Sciences, Alma Mater Studiorum, Via Irnerio, 42, 40126 Bologna, Italy, [4] Università di Bologna, 4Department of Agricultural and Food Sciences, Alma Mater Studiorum, piazza Goidanich, 60, 47521 Cesena, Italy, [5] University of Turin, Department of Veterinary Sciences, Via Verdi, 8, 10124 Turin, Italy

Vast quantities of agro-industrial wastes are generated every year and, in many cases, proper management is limited or entirely absent. Apple and olive pomaces are seasonal by-products produced during apple processing and olive-oil extraction, respectively. Although black soldier fly (BSF) larvae have been widely studied, the combined effects of larval density and diet on their performance remain unclear. This study examined how different larval densities and substrates influence BSF growth and development. Four iso-nitrogenous and iso-energetic diets were prepared using brewer's spent grains, wheat bran, apple pomace, and olive pomace. The first diet contained 30% apple pomace (30AP) with brewer's spent grains and wheat bran. The second contained 30% olive pomace (30OP) with the same base ingredients, while the remaining two diets included both apple and olive pomace along with wheat bran and brewer's spent grains. Three larval densities were tested (1, 2.5, and 5 larvae/cm²). Larval weight and survival were monitored every three days, and the trial ended once 10% of larvae reached the prepupal stage. Chemical analyses were conducted to determine crude protein, crude fat, and ash, and feed performance indicators such as feed conversion ratio (FCR), waste reduction rate (WRR), and specific growth rate (SGR) were calculated. The results showed clear differences among treatments across most parameters, except for survival that remained above 90% for all treatments. The highest density (5 larvae/cm²) showed the fastest development on the 30AP diet, whereas the 30OP diet showed the longest development time for all densities. Individual larval weight also varied significantly across diets and densities, with 30OP having the lowest weight across all densities. Protein content exceeded 45% in all cases, with the highest value being recorded for the 30AP diet. Overall, the density of 5 larvae/cm² for all diets appeared to be the most favorable under these conditions, suggesting that larval density and diet strongly influence outcomes. Acknowledgments: This research is supported by the EU-PRIMA program – project OLIWA- Repurposing OLIve WAste in circular economy solutions for feeds, additives, packaging, and biogas – GA 2432, Call 2024 Section 1 Food Value Chain in Nexus.

The effect of the growth substrate on the content of essential amino acids in Hermetia illucens larvae

M. Matvieiev[1], V. Dzhus[2], I. Doroshenko[1], O. Borshch[2], V. Lykhach[1], A. Getya[1]
[1] National University of Life and Environmental Sciences of Ukraine, Heroiv Oborony, 15, 03041 Kyiv, Ukraine, [2] Bila Tserkva National Agrarian University, Soborna Sq. 8/1, 09117 Bila Tserkva, Ukraine

The black soldier fly (Hermetia illucens) is a widely distributed insect that would be considered a novel food for human consumption. The species is used for food waste disposal, contributing to greenhouse gas reduction, and is considered an alternative nutrient source for farm animals. The chemical composition of the substrate on which Hermetia illucens larvae are grown determines their chemical composition and biological value. Therefore, this study aimed to investigate how different substrates affect the essential amino acid content of the larvae. Five groups of at least 1,000 larvae were reared in separate 90-litre containers containing different food industry waste substrates with no commercial value. Different substrates have been used: 1 – vegetable and fruit waste (potatoes and apples); 2 – grain (wheat and corn); 3 – raw chicken processing waste (intestines, skin and internal organs); 4 – mixture of raw pork and beef by-products (intestines, skin and internal organs); 5 waste river fish. The substrates differed in chemical composition. Vegetable and fruit substrate had high moisture (82%) and low protein (1.2%), while grain substrate had low moisture (9.9%) and high carbohydrates (72.8%). Animal by-product substrates (groups 3–5) contained higher protein (19–22.4%) and fat (11.1–20%) levels. Larvae samples were analysed for amino acid composition using capillary electrophoresis. Statistical analysis was performed using ANOVA with Duncan's multiple range test at $p \leq 0.05$. Results showed that larvae grown on chicken by-products (Group 3) had the highest total essential amino acid content (23.15 mg/100 g). Their total content significantly exceeded that of larvae from Groups 5, 4, 2 and 1 by 0.37, 0.57, 0.63 and 3.83 mg/100 g, respectively. Group 3 larvae also had higher levels of isoleucine, leucine, tryptophan and arginine compared to other groups. Larvae grown on grain substrate (Group 2) had the highest phenylalanine, methionine and histidine content. Vegetable and fruit substrate (Group 1) resulted in the highest threonine content. Pork and beef by-products (Group 4) produced larvae with the highest valine content. Larvae grown on waste river fish (Group 5) did not show the highest value for any amino acid, but their total essential amino acid content was second only to Group 3. The study demonstrates that substrate composition significantly influences the essential amino acid profile of Hermetia illucens larvae. To obtain larvae with the highest overall essential amino acid content, poultry slaughterhouse waste is recommended as a substrate. Moreover, substrate composition can be modified to produce larvae with a targeted amino acid profile.

Dietary fat sources modulate growth performance and lipid composition of black soldier fly (Hermetia illucens) larvae

L. Schneider[1,2], N. Stoehr[1], G. Dusel[1]
[1] University of Applied Sciences Bingen, Department of Agriculture, Animal Nutrition and Health, Berlinstreet 109, 55411 Bingen am Rhein, Germany, [2] Justus-Liebig-Uustus Liebig University Giessen, Animal Nutrition and Nutrition Physiology, Heinrich Buff Ring 26-32, 35392 Giessen, Germany

The growing demand for sustainable fat sources in animal nutrition has increased the need for alternatives to conventional vegetable oils such as palm oil, whose production is associated with substantial environmental impacts. Insect-derived lipids from black soldier fly larvae (BSFL, Hermetia illucens) represent a promising option because larvae efficiently convert low-value organic side streams into protein- and fat-rich biomass. The fatty acid composition of BSFL fat influences energy supply and exerts functional effects, such as antimicrobial activity, making it a strategic component for animal feed formulations. Yet, the mechanisms by which dietary fatty acids modulate lipid deposition and fatty acid composition in BSFL remains poorly understood. A total of 420,000 six-day-old larvae were reared under controlled conditions (28 °C; 55 % rH) for 8 days and assigned to five isonitrogenous diets containing 6 % fat (DM basis) from beef tallow (BT), olive oil (OO), sunflower oil (SO), or linseed oil (LO), or a Gainesville diet (GD; 1.8 % fat, DM basis) (n = 6). Feed and larvae were analyzed for gross energy, fat, nitrogen, ash, and fatty acid composition. Diet significantly affected BSFL performance. BSFL fed the GD diet showed the lowest average daily weight gain (201.2±6.4 g/d/box; P=0.024) and survival rate (87.2±1.6 %; P<0.001), while BSFL fed BT had the highest values (245.7±4.7g/d/box; 96.3±2.2 %). Regardless of diet, the fat composition of the BSFL was characterized mainly by lauric acid (LA) and other saturated fatty acids (SFA), which were synthesized de novo, as LA was not present in any of the five feed substrates. BSFL reared on SO and LO substrates showed the lowest level of SFA (SO:46.4±3.1 and LO:48.1 ±3.7 g/100 g of total lipids, respectively, P<0.001), while the inclusion of animal-based fat in the diet (BT) increased the SFA level (62.3±2.5 g/100 g of total lipids). Larvae fed SO and LO had the highest (SO:23.0±0.2 and LO:24.2±0.7 g/100 g of total lipids; P=0.004) levels of polyunsaturated fatty acids (PUFA), whereas larvae fed BT and OO had the lowest (BT:11.2±1.4 and OO:15.3±0.9 g/100 g of total lipids). However, there were no significant differences in GE, fat or nitrogen concentrations among larvae fed diets with added fat. Ash content was highest in BSFL fed GD and lowest in BSFL fed BT (9.1±0.3 and 6.2±0.5 g/kg DM; P<0.001). These results demonstrate substantial metabolic plasticity in BSFL lipid metabolism. Dietary fatty acids can therefore be used to strategically modulate insect lipid composition, enabling the targeted production of insect-derived fats for sustainable feed formulations.

Trentinsect: insects and sustainability in feed production

A. Resconi[1], M. Baker Ala Eddine[1], G. Benassi[2], S. Dabbou[1]
[1] University of Trento, C3A, Centro Agricoltura Alimenti Ambiente, via Edmund Mach 1, 38009 San Michele all'Adige, Italy, [2] Kinsect s.r.l., via Fortunato Zeni, 8-Corpo, P-52, 38068 Rovereto, Italy

One of the future challenges for the agri-food sector will be to reduce the waste it generates. The combination of reutilisation of unutilised by-products and waste streams with the creation of more sustainable agro-industrial systems allows to reduce the environmental footprint of the food and feed production. Insect bioconversion is a perfect candidate for circular economy systems, by absorbing organic waste and byproducts and converting them into animal protein. The Trentinsect project is the result of a collaboration between the industrial and academic sector: the University of Trento (Italy), and the company Kinsect. The project aims to develop and optimise, within a circular economy framework, the mass rearing of the black soldier fly (Hermetia illucens) larvae using locally available plant-based residues and agro-industrial byproducts from the Trentino-Alto Adige region, in the north of Italy. The objective is to identify and characterise agro-industrial byproducts and plant-derived waste streams into optimised multi-ingredient diets that meet larval nutritional requirements with the ultimate goal of producing sustainable protein ingredients for animal feed. Locally sourced substrates will undergo comprehensive physicochemical characterisation, including nutrient profiling, assessment of dry matter, granulometry, viscosity, water retention capacity, and contaminant screening. These data will support the formulation of scalable diets, which will be validated through experimental trials evaluating larval growth kinetics, substrate reduction efficiency, bioconversion rates, and biomass nutritional quality. To ensure year-round operational feasibility, innovative storage and stabilisation strategies for seasonal byproducts will be developed. The project will compile a structured database of substrate characteristics and establish a predictive substrate performance impact model linking feed formulation, larval productivity, economic viability, and environmental footprint indicators, thereby enabling to estimate technical and economic outcomes based on locally accessible resources. By improving the management of organic residues, reducing waste disposal burdens, and enhancing resource efficiency, the project aims to strengthen the sustainability of the local agri-food sector.

Use of ergot (Claviceps purpurea) - contaminated rye in the rearing of black soldier fly (Hermetia illucens) larvae

N. Stöhr[1], L. Schneider[1], K. Schuh -Von Graevenitz[1], W. Markert[2], T. Priesmann[3], G. Dusel[1]
[1] University of Applied Sciences Bingen, IFR, Berlinstrasse 109, 55411 Bingen, Germany, [2] DSM Nutritional Products, Emil-Barell-Strasse 3, 79639 Grenzach-Wyhlen, Germany, [3] DLR Eifel, Westpark 11, 54634 Bitburg, Germany

Sustainable protein production depends on the valorization of biomass streams that are excluded from conventional food and feed chains. Ergot-contaminated grain represents one such underutilized resource, caused by the fungal pathogen Claviceps purpurea, which proliferates under humid conditions during flowering and harvest, as observed in Germany in 2024. Contaminated rye cannot be processed for flour or animal feed due to toxic ergot alkaloids (EA), even at low concentrations. Black soldier fly larvae (BSFL, Hermetia illucens) exhibit broad substrate plasticity and high bioconversion efficiency, transforming heterogeneous organic residues, including manure and agro-industrial by-products, into protein- and lipid-rich biomass. Yet their ability to tolerate or accumulate EA remains largely unknown. This study investigates whether dietary inclusion of ergot-contaminated rye affects larval growth, biomass yield, and EA accumulation in BSFL. A total of 336,000 7-day-old larvae (DOL) with an initial larvae weight of 6 mg/larvae, were allocated equally to 4 treatments with six replicated each (14,000 larvae per box (40x60cm)). Larvae were reared for 8 days in a climate chamber under controlled conditions (28-30 °C, 55-65% rH). The basal diet consisted of 50% rye, 40% wheat bran, 7% concentrates, and 3% apple pomace. Treatments differed in ergot contamination level in the rye: T1 (CON) contained uncontaminated rye and formed the control group. T2 (LOW) contained contaminated rye with ergot bodies removed by sieving, T3 (MID) contained low contamination (0.67 g ergot/kg), and T4 (HIGH) contained high contamination (2.34 g ergot/kg). Larval growth was monitored every two days by weighing subsamples of 50 larvae per replicate. Substrate pH and temperature were recorded at the same intervals. Composite samples of rye, substrate, frass, and larvae (DOL 15) were analyzed for EA content. Data were analyzed using one-way ANOVA ($p<0.05$) followed by post-hoc-Tukey HSD. After 8 days of trial, no significant differences in larval growth performance were observed among the treatments. MID-fed larvae showed the highest weight (155 mg/larvae), while HIGH-fed larvae the lowest (144 mg/larvae, $p>0.05$). A similar trend was observed for biomass yield. The dietary treatment had no effect on biomass yield; however, LOW was numerically higher (2.18 kg larvae FM/box), while HIGH was the lowest (1.96 kg/box; $p>0.05$). Dietary ergot inclusion had no effect ($p>0.05$) on larval survival rate. EA were detected in rye, substrate, and frass but were not detected in larval biomass. In conclusion, the inclusion of ergot-contaminated rye (up to 50% of the diet) appears to be a suitable feed for BSFL without compromising performance or resulting in detectable transfer of EA into larvae. Further research is required to confirm these findings and assess long-term effects. Acknowledgement: The study was conducted as part of Project BSFL meets MycoGrain and financed by the Ministry of Economics, Transport, Agriculture, and Environment of Rhineland-Palatinate, Germany. We would also like to thank DSM Nutritional Products GmbH (Dr. Wolfgang Markert) for supporting the mycotoxin analyses.

Methodological approach for multi-trait information pooling into single-trait using deregression: a study case on boar taint

A. Markey[1], N. Gengler[1]
[1] University of Liège, Gembloux Agro-Bio Tech, TERRA Teaching and Research Center, Passage des Déportés, 2, B-5030 Gembloux, Belgium

The current study proposes a pre-treatment designed to condense information from a multi-trait (MT) model into a single reference pseudo-phenotype that can be used in a single-trait (ST) model for routine evaluation. This need arises from the current context of selection, which is constantly evolving by incorporating an increasing number of new traits (i.e., emergent traits) to characterise complex phenotypes that can be costly to measure, heterogeneous, poorly heritable, or limited in availability, complicating MT analyses. For example, boar taint is a complex phenotype, multiplying potential phenotyping methods, each with their own limitations, such as sensory analyses vs. quantifications of skatole and androstenone. 2169 Piétrain × Landrace boars were measured for three boar taint traits (sensory score, i.e., the reference trait, skatole and androstenone). These traits were evaluated in a MT evaluation. Then, their estimated breeding values (EBV), accompanied by their reliabilities (REL), were deregressed and obtained pseudo-phenotypes were evaluated in an ST evaluation. The used scalar deregression method had two limitations: a reduction in variance and a loss of reversibility. To solve this, an expansion factor and a reliability-alignment factor were iteratively applied in the pre-processing. The results are based on a comparison of EBV and REL from evaluations of the reference trait (i.e., in MT) and of the pseudo-phenotypes (i.e., in ST) according the two approaches: (1) standard deregression (DRP) and (2) adjusted deregression (ADJ_DRP). They showed that standard deregression indeed underestimates genetic variance, while adjusted deregression have (almost) identical distributions as in MT. The EBV(MT)~EBV(ADJ_DRP) regressions have slopes close to 1 and intercepts close to 0, confirming reversibility. REL remained stable. Therefore, pre-processing allows to effectively synthesise genetic information into single reference pseudo-phenotype while preserving essential genetic signal. The proposed method provides an extended reversible system adjusting deregression and generates pseudo-phenotypes compatible for subsequent use in routine genetic evaluation. Potential use includes the integration of pseudo-phenotypes into carcass evaluations in the framework of the Walloon Genetic Evaluation System for Piétrain boars. More theoretical studies are ongoing, as different partial data configurations including missing records for the reference trait, the application of higher-dimensional datasets and its transfer into a genomic context.

Selection for birth weight uniformity and its effects on subsequent weights in SRC Iberian pigs

I. Cervantes[1], N. Formoso-Rafferty[2], F. Sánchez-Esquiliche[3], L. Ramírez[3], M. Muñoz[4], J. M. García-Casco[4,5], J. P. Gutiérrez[1]

Agropecuaria, Sánchez Romero Carvajal-Jabugo, 21290 Huelva, Spain, [4] Dpto. Mejora Genética, INIA-CSIC, 28040 Madrid, Spain, [5] Centro de I+D del cerdo Ibérico-Zafra, INIA-CSIC, 06300 Badajoz, Spain

Sánchez Romero Carvajal (SRC) company is implementing a breeding selection scheme focused on the Iberian purebred animals, and its production system in open-air includes a finish-fattening period known as montanera based on an ad libitum intake of acorns and grass. This population has been selected for maternal traits since 2011 combining two traits: piglets born alive and total litter weight at 21 days, being the weight for each trait 80% and 20% respectively since 2019. Furthermore, the selection program for this population prioritized the genetic improvement of meat quality traits. Homogeneity in the weights at different steps in the breeding program is economically important and advantageous in farm management. Selection for birth weight (BW) uniformity has become an interesting selection criterion to be included in pig breeding programs. Within-litter variation of BW is of great importance in breeding practice for animal survival. In SRC breeding programs weights at different ages are collected. They routinely collect a preweaning weight around 21 days (PW), and since 2022 they have implemented the BW data collection and the weight around 90 days of age (AW). The objective of this study was to evaluate the impact of selection of BW uniformity in subsequent weights in the SRC population. Data contained 12,589 records of BW and PW and 1,589 of AW from two linked farms recorded between 2022 and 2024. The pedigree file contained 2,827 individuals. Univariate and multivariate heteroscedastic models were applied including age of weight for PW and AW, sex (2 levels), parity number (12 levels), litter size (13 levels), batch (23 levels) and sow feeding system (2 levels, for BW and PW) as fixed effects. The litter effect (for BW and PW) beside the maternal genetic effect were included as random effects. Same effects were included for the mean trait and its variability. The analysis was performed using ASReml 4.2. The maternal genetic variance affecting the environmental variability was 0.075 (0.024) for BW and 0.064 (0.024) for PW in univariate models. The litter effect variance was 0.265 (0.025) and 0.336 (0.027) for BW and PW variability, respectively. The genetic correlation between the trait and its environmental variance was not different from zero for both traits indicating the possibility of selecting for the mean traits and their variability independently. This is the opposite of what is seen in other commercial pig populations where this correlation is moderate and positive. This may be because the population has not been subjected to strong selection pressure to increase litter size, unlike the commercial populations. In the multivariate analysis, the genetic correlation between BW and PW environmental variabilities was 0.93 (0.05). AW trait seems not to be impacted by the environmental maternal genetic component. Applying BW uniformity to this population seems favourable for PW. Even though more data seems necessary for such complex models, other traits or other models should be essayed to deal with uniformity on latter weights after weaning.
This study was funded by a grant from the Spanish Ministry of Science, Innovation, and Universities: CPP2023-010423 (iberTOP).

Potential to increase additive genetic variance in pigs by changing crossover count

O. Katz[1], Y. C. J. Wientjes[1], A. C. M. Jansen[1], M. P. L. Calus[1]
[1] Wageningen University & Research, Animal Breeding and Genomics, Droevendaalsesteeg 1, 6708PB Wageningen, Netherlands

The goal of animal breeding is to select the best animals to reproduce to create genetic gain for multiple breeding goal traits in future generations. The rate of genetic gain increases when additive genetic variance is higher. One suggested way to increase genetic variance is by changing the number of meiotic crossovers (CO) that individuals transmit. CO allow homologous chromosomes to exchange DNA, generating novel allele combinations, which can release additive genetic variance. Hence, this study aimed to estimate additive genetic variance for breeding goal traits for different groups of individuals based on CO count in a sow pig line that was mainly selected for reproductive traits. We used 72,456 sire–offspring pairs with CO count observations, and observed CO count ranged between 5 and 34. We split the data in five bins based on the CO count and used bivariate sire mixed models to estimate the sire genetic variance in each of the bins. The bins were approximately of equal size and the CO ranges in each bin were: 5-14; 15-16; 17-18; 19-20 and 20-34 CO. Overall, results showed that sire additive genetic variance was not constant across bins, suggesting that CO may influence additive genetic variance for these traits. For the traits number of total born and number of born alive, the additive variance was maximized for intermediate CO ranges (~15-20). For number of stillborn piglets, additive variance was higher in lower CO counts. These results suggest that CO count might affect additive genetic variance between traits, and that CO ranges that could maximize additive genetic variance differs across breeding goal traits.

Heritability and Genetic Correlations of Crossover Count in Two Commercial Pig Lines

A. C. Jansen[1], O. Katz[1], M. P. Calus[1], T. Druet[2], A. Boshove[1,3], Y. C. Wientjes[1]
[1] Wageningen University & Research, Animal Breeding and Genomics, Droevendaalsesteeg 1, 6708 PB Wageningen, Netherlands, [2] University of Liège, Unit of Animal Genomics, Avenue de l'Hôpital 1, 4000 Liège, Belgium, [3] Topigs Norsvin, Research Center B.V., Meerendonkweg 25, 5216 TZ 's-Hertogenbosch, Netherlands

The aim of animal breeding is to select the genetically best animals in the current generation to achieve genetic gain in future generations regarding a breeding goal. This genetic gain increases with a greater genetic variance. Crossover count (CC) is currently not directly selected for in animal breeding programs, but it might be beneficial to do so. Crossing-over between homologous chromosomes during meiosis generates variation in gametes, and can create more variable offspring. Crossovers can break linkage between alleles, resulting in new possible allele combinations in gametes and potentially increase additive genetic variance. It is therefore expected that selection for a higher crossover count can increase the genetic variance of other breeding goal traits, thereby resulting in a higher genetic gain. The number of crossovers is found to be variable between individuals, sexes, and species, and this variation is at least partly heritable which makes it feasible to change CC with selection. But before a new trait can be added to the breeding goal, it is important to know if there are correlations to other breeding goal traits. For CC, there are indications that its variation is directly associated with variation in fertility, because the formation of crossovers is a necessary step for successful completion of meiosis. In addition, variation in CC may be indirectly correlated to other breeding goal traits. Therefore, the main objective of this study is to estimate the heritability of CC and its genetic correlations with important breeding goal traits in two pig lines: a sow line and a boar line. Both lines consisted of >100,000 animals genotyped for ~20,000 SNP markers. The sow line was mainly selected for reproduction traits, and the boar line mainly for production traits. Phenotypic records are available on a number of breeding goal traits, including fertility, growth/feed efficiency traits, and the number of teats. The genotypes were phased to determine the number and locations of crossovers using LINKPHASE3. The autosomal CC was determined for 91,371 parent-offspring pairs in the dam line, and 150,228 parent-offspring pairs in the sire line. The first results showed that CC of the sow line was on average 23.9 for females and 18.1 for males. For the boar line, this was on average 22.4 for females and 17.4 in males. The higher CC in the sow line compared to the boar line is possibly an effect of selection on fertility traits. We expect to present the heritabilities of CC and their correlations to important breeding goal traits at the time of the conference, which will provide insight in the possibility of targeted selection on CC in the breeding goal, and whether CC may already be implicitly selected for, as a correlated response to the current breeding goal.

Methods for joint genetic prediction of multiple ordinal categorical and continuous traits

M. Bermann[1], A. Legarra[2], A. Alvarez Munera[1], I. Misztal[1], D. Lourenco[1]
[1] University of Georgia, 425 River Road, 30602 Athens, United States, [2] CDCB, 4201 Northview Dr, 20716 Bowie, United States

The landscape of animal breeding is rapidly evolving. Data on health, disease, welfare, and fertility, which are key fitness traits for sustainable production, have been extensively collected. The categorical nature of these traits violates the normality assumptions of traditional linear mixed models, requiring threshold or threshold-linear models. These models can be fitted either via Gibbs sampling or by maximizing the posterior density (maximum a posteriori, MAP). While Gibbs sampling is flexible and can handle multiple-trait models with several categorical and continuous traits, its computational and memory demands, and the need to evaluate whether the Markov chain converged limit its applicability in genetic evaluations. MAP methods are computationally efficient and suitable for large-scale datasets. However, existing MAP methods are restricted to a single categorical trait and many continuous ones, making them insufficient for the new generation of data. The lack of proper methods to fit threshold-linear models to real-life applications has persisted for two to three decades. Failing to model categorical traits accurately can lead to reduced genetic gain and deterioration of the traits over time. This study aimed to develop the first theoretically sound and computationally efficient framework for jointly analyzing multiple categorical and linear traits, specifically multi-trait threshold-linear models, under BLUP and single-step genomic BLUP (ssGBLUP). The proposed methods are based on Newton-Raphson and Expectation-Maximization schemes. Using a simulated dataset and treating Gibbs sampling as the benchmark, we show that the breeding values estimated by our methods agree nearly perfectly with those obtained from Gibbs sampling, while greatly reducing computational cost and allowing scalability to very large datasets. As expected, the Newton-Raphson iteration outperformed the Expectation-Maximization algorithm in terms of computational time. Our results demonstrate that routine genetic evaluations incorporating multiple categorical traits are now feasible using the presented methodology. Solving this decades-old enigma enables accurate, large-scale genetic and genomic predictions of key categorical fitness traits under multi-trait models.

xyBnG.jl: A Julia package for scalable, GPU-accelerated stochastic simulation of complex national livestock breeding schemes

X. Yu[1], L. Cao[1], J. Jakobsen[2], G. Difford[1], P. Berg[1], B. Åby[1]
[1] Norwegian University of Life Sciences, Department of Animal and Aquacultural Sciences, Oluf Thesens vei 6, 1433 Ås, Norway, [2] The Norwegian Association of Sheep and Goat Breeders, Moerveien 2A, 1430 Ås, Norway

Stochastic simulation of national livestock breeding programmes is a vital tool for evaluating the integration of novel traits, such as enteric methane emission (CH4), and optimizing complex multi-trait breeding objectives before field implementation. However, existing simulation tools often face computational bottlenecks in scale, speed, and memory when attempting to fully mimic national schemes that feature tens of thousands of animals, genomic selection, and intricate mating structures over multiple generations. We present xyBnG.jl, an open-source Julia package designed for the large-scale, full-complexity stochastic simulation of livestock breeding programmes. The software overcomes traditional constraints through advanced memory management and parallelization. It features a flexible BitArray-based genotype storage system capable of holding over 4.5 million individuals with 60K SNPs entirely in 64 GiB of RAM, drastically minimizing disk I/O. Furthermore, it incorporates CUDA-accelerated gene dropping, utilizing GPU power to exponentially speed up the processing of massive offspring populations. Analytically, xyBnG.jl seamlessly integrates Fisher-Wright historical population modeling, multi-trait maternal-effect PBLUP, and single-trait/multi-trait SNPBLUP for genomic prediction. To demonstrate its capabilities, we developed a digital twin of the Norwegian White Sheep (NWS) breeding scheme, accurately replicating its 12-trait Total Merit Index (incorporating growth, fleece, carcass, maternal, and CH4 traits), genomic selection pipeline, and complex ram circle mating system. We evaluated ten scenarios varying the selection weights for CH4 (0%, 2%, 5%, 10%) and the annual number of ewe CH4 phenotypes (0, 2K, 4K, 6K) added to the genomic prediction. The model simulated 12 years (5.5 generations) with 20 replicates, successfully generating and evaluating 120,000 lambs annually under realistic breeding conditions. The WCGALP simulation results verified by xyBnG.jl proved that incorporating CH4 into the national sheep breeding objective effectively reduces methane emission corrected for live weight, whilst simultaneously improving carcass and fleece weight. The most intensive scenario (10% weight, 6K phenotypes/year) achieved an emission reduction of 0.032 g CH4/hour per ewe over 12 years (0.37 genetic standard deviations). Larger selection weights and phenotyping intensity synergistically improved selection efficiency, but the benefits of additional phenotypes were constrained if the index weight for CH4 was insufficient (<5%). xyBnG.jl provides an efficient, reproducible, and highly scalable framework for simulating sophisticated national livestock breeding programmes. Its application to the NWS demonstrates that breeding strategies for reduced CH4 and improved production can be harmonized, underlining the necessity of strategic phenotyping investments. The package is freely available to the community to facilitate complex breeding programme analyses.

EVOGEN: A novel tool for large-scale simulation and optimization of breeding programs

V. Milkevych[1], A. Bouquet[1], H. Liu[1], B. Grove Poulsen[1], M. Sandø Lund[1]
[1] Aarhus University, Center for Quantitative Genetics and Genomics, C.F. Møllers Allé 3, 8000 Aarhus, Denmark

Animal breeding is a complex task as many factors such as prediction models, and the structure of breeding programs can influence the long-term genetic gains of focal traits. At every iteration it involves a sophisticated methodological toolchain that may include the methods of phenotypic and genomic evaluation. Therefore, simulation tools that are flexible while remaining user-friendly are useful for predicting responses to selection and for adapting breeding plans to achieve defined breeding objectives. EVOGEN software is a novel computational tool allowing in silico studies of general evolutionary processes (changes in natural populations, artificial selection/breeding, evolutionary computations) on population and individual levels. The software can be used for simulation, design, and optimization of a variety of selective breeding schemes of different levels of complexity. The software can simulate crossbreeding between any number of populations and traces genetic changes in these populations under different scenarios. It allows flexibility in simulation various population structures and accounts for different genetic models (with additive, dominance and environmental effects). It can be used to test different phenotyping and/or genotyping strategies, estimate breeding values, evaluate different selection and mating strategies, and generate genetic data to test statistical tools. EVOGEN differs from other simulation tools mostly by the implemented design principles, software interfaces, and the targeting environment while keeping similar levels of functionality and implemented features. EVOGEN is programmed in C++ and compiled into a shared library, which is interfaced to Python. Therefore, it allows scripting and interactive simulation in external environment to incorporate any other external tools to perform genomic evaluations, selection and mating. The software is designed for simulation of large-scale breeding schemes with many iterations, individuals, and genotypes. The software is well suited for a dedicated Linux based high performance computational environments. The software's design provides convenient interfaces that allow a user-defined low-level construction of simulation scenarios of different degree of dualization and complexity. Among others features, the most unique are a multiple-allelic genomic architecture and possibility of use the same interfaces for both tasks: design/simulation of breeding schemes and solving optimization problems using evolutionary computations, with genetic algorithms approach.

Beekeepers' preferences for breeding goals: how can the results from a French on-line survey feed the design of relevant breeding programs?

T. Kistler[1,2], B. Basso[2,3], A. Lauvie[2,4], F. Phocas[1,2]
[1] Université Paris-Saclay, INRAE, AgroParisTech, GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [2] UMT ETTAP, 228 route de l'Aérodrome, 84914 Avignon, France, [3] INRAE, UR 406 Abeille et Environnement, 228 route de l'Aérodrome, 84914 Avignon, France, [4] SELMET, INRAE, CIRAD, L'Institut Agro Montpellier SupAgro, Univ Montpellier, Campus de La Gaillarde Batiment 22,2 Pl. Pierre Viala, 34060 Montpellier, France

Honey bee breeding initiatives are emerging worldwide. France is seeing the emergence of diverse small-scale breeding groups. Researchers are involved to support some of those bottom-up setups. The motivations of these beekeepers, the sizes, orientation and functioning of their production systems are highly diverse. Yet, little is known about what these diverse beekeepers would envision as fitting breeding goals in this context of relative novelty of bee breeding endeavours. In complementarity to comprehensive approaches of beekeepers' breeding practices, which often rest on context specific case studies, large scale inquiries are a useful way to get data on the diversity of breeding goals considered by beekeepers at a larger scale. However, relevant outputs of such large-scale surveys to support breeding programs design seemed lacking in honeybees. To fill this gap, an online survey was launched during most of 2023. We obtained about 250 complete answers, mostly from professionals. Answers gathered basic information about their beekeeping profile, including their main production and services offered, their bees' genetic background, their operation size, and more. Beekeepers were then asked to rate the importance they attributed to including certain traits in a breeding goal, choosing from a list of twenty possible traits and a three-levels importance scale: essential, useful, or useless. For useful or essential traits, they further were asked to indicate whether they wished to genetically see these traits improve, or only be maintained at their current level. Our findings revealed a strong inclination toward multi-trait breeding goals, with a median of 13 traits deemed as useful or essential. Such a result confirms the key role of multicriteria assessment processes in the design of relevant breeding programs. Honey yield, disease resistance, swarming tendency, gentleness, and summer feed autonomy (no emergency feeding required), stood out as the traits attributed the highest importance, with nearly 90% of beekeepers considering these traits at least useful.However, in a perspective of feasibility, including in terms of achievable genetic improvement, it is also key to know the nature of changes expected for those traits. In this survey. Around 40% or more of beekeepers stated they would prefer to see these traits maintained at their current level, as opposed to directionally improving them. A clear exception to this was disease resistance, with 75% of beekeepers wanting to directionally improve it.Regarding how beekeepers' profile shaped these preferences, the most significant characteristic was the genetic background of bees they kept, while other beekeeping profile characteristics only appeared to have marginal effects.Moreover, these results highlight several understudied traits, such as summer and winter feed autonomy, winter diapause, and longevity, that are regarded as at least useful in a breeding goal by over 70% of beekeepers, and for which nothing or only little is known about their measurement feasibility and potential to respond to selection. Consequently, such results are also useful to guide future research to identify and evaluate possible selection criteria for these traits.

Deriving cow methane traits and their genetic relationships with feed intake, energy balance and nitrogen utilisation efficiency

M. Stassen[1], K. Brügemann[1], C. Grelet[2], M. Calusinska[3], S. König[1]
[1] University of Giessen, Ludwigstr. 21b, 35390 Giessen, Germany, [2] Walloon Agricultural Research Center, Chée de Namur 24, 5030 Gembloux, Belgium, [3] Institute of Science and Technology, Rue Bommel 5, 4940 Hautcharage, Luxembourg

Modern dairy cattle breeding goals suggest consideration of trait categories reflecting methane emissions, energy balance (EB) and nitrogen utilisation efficiency (NUE). However, detailed direct trait recording implies tremendous logistics and financial costs. Furthermore, for the development of an overall breeding goal for resource efficiency, the availability of genetic parameters and genetic correlations among all traits from all trait categories is imperative. EB and NUE indicators from routine monthly milk recording of 1107 German Holstein cows were energy corrected milk (ECM), fat-to-protein-ratio (FPR) and milk urea nitrogen (MUN). Based on calibration and prediction equations from milk mid-infrared (MIR) spectroscopy, NUE and EB traits were N-loss as the difference from nitrogen intake and nitrogen output in milk, NUE as their ratio, residual feed intake (RFI), and EB as energy intake minus the sum of milk energy and maintenance energy requirements. Methane traits were derived considering patterns of CH4 respiration and eructation from laser methane detector measurements and applying developed data analysis protocols. The generated methane traits included the arithmetic means (AllMean, RespMean, ErucMean) and the respective sums of emissions per minute (AllSum, RespSum, ErucSum). In a sub-sample of four research herds, the microbiome composition was characterized based on faeces analyses considering 237 faecal samples. 16S rRNA sequencing was performed to determine bacterial and archaeal community composition. Nanopore sequencing was applied to characterize the community of anaerobic fungi. Animal models were applied to estimate variance components and heritabilities for all "conventional" and MIR-based EB and NUE traits, and for all methane traits. Genetic correlations for all trait combinations were approximated based on estimated breeding value correlations of 43 sires with at least 10 daughters and corrections of breeding value accuracies. In enhanced mixed models, we defined the "milk traits" as explanatory variables, to infer their effects on all methane traits. Phenotypic association analyses indicated a significant effect of MUN on methane emissions, with significantly lower least-squares means for all methane traits of cows allocated to MUN classes < 150 ppm. FPR alterations as indicator for EB displayed only minor effects on CH4 traits, and respective genetic correlations were close to zero. For all CH4 traits, additive-genetic variation was identified, but the large residual component contributed to small heritabilities in the range from 0.001 to 0.02. Moderate heritabilities were estimated for the MIR-based traits with 0.28 for RFI, 0.24 for EB, 0.31 for N-loss and 0.13 for NUE. Genetic correlations between CH4 traits with EB and NUE indicators from routine milk recording (MUN, FPR, ECM) were close to zero, but stronger with the derived MIR traits, especially with N-loss in the range from 0.33-0.55. Consequently, CH4 emissions, EB and NUE displayed differing genetic mechanisms, indicating the need to include these trait categories separately into an overall breeding goal. CH4 emissions were weak indicators for EB and NUE, and vice versa, suggesting the implementation of detailed recording schemes. Microbiome-derived traits (relative abundance of key taxa, diversity indices, microbial community profiles) were phenotypically correlated with CH4, EB and NUE traits, suggesting the predominant role of the rumen microbiome composition regarding methane emissions and feed efficiency.

Statistical and genetic analysis of udder conformation traits recorded by automatic milking systems in Fleckvieh cows

S. Hosseini[1], B. Zumbach[2], T. Shabalina[3], R. Emmerling[1], J. Ertl[1], A. R. Sharifi[4]
[1] Bavarian State Research Center for Agriculture, Institute of Animal Breeding, Prof.-Duerrwaechter-Platz 1, 85586 Grub-Poing, Germany, [2] University of Goettingen, Division of Plant Breeding Methodology, Carl-Sprengel-Weg 1, 37075 Goettingen, Germany, [3] LKV Bayern e.V., Landsberger Straße 282, 80687 Munich, Germany, [4] University of Goettingen, Animal Breeding and Genetics, Albrecht-Thaer-Weg 3, 37075 Goettingen, Germany

Udder conformation traits play a critical role in functionality and health of dairy cattle. Recent advances in automatic milking systems (AMS) have enabled precise, high-frequency recording of udder traits, providing valuable data for genetic analysis. Estimating genetic parameters of udder conformation traits allows breeders to ameliorate udder morphology genetically, ultimately improving functionality in both AMS and conventional milking systems, longevity and animal welfare. The present study aims to estimate the heritabilities and genetic correlations of udder conformation traits derived from AMS and classifier evaluations. This study utilised a comprehensive dataset comprising 3,006,575 observations of 78,458 Bavarian Fleckvieh cows across three parities, recorded over the period from 2019 to 2025 by Lely AMS. Data preparation and statistical analysis were performed using the SAS programme. The genetic parameters were estimated using the BLUPF90+ software. Five udder conformation traits were investigated in this study: front teat distance (FTD, mm), rear teat distance (RTD, mm), udder depth (UD, mm), udder balance (UB, mm), and distance front rear (DFR, mm). The descriptive statistical analysis of the AMS data is based on the exclusion of data outside the 1% and 99% quantile limits, in order to avoid extreme observations. The descriptive statistics of the conformation traits showed the following average values for the first three parities (P): FTD (P1=175; P2=178; P3=182), RTD (P1=91; P2=94; P3=98), UD (P1=587; P2=536; P3=501), UB (P1= 4.0; P2=-1.7; P3=-5.2), and DFR (P1=111; P2=128; P3=136). The results of analytical statistics revealed significant differences in least squares means based on 1–350 days in milk among parities in all five traits. The heritability was estimated solely for parity one, since classifier scorings were available only for first calving cows for the traits front and rear teat placement and udder depth. The estimated heritabilities of AMS conformation traits, including FTD, RTD, UD, UB, and DFR, were 0.54, 0.42, 0.47, 0.38, and 0.58, respectively. The phenotypic and genetic correlations between the FTD and front teat placement were negative (rp=-0.60; rg=-0.84). The negative correlations are plausible with regard to opposite definitions of AMS and classifier teat traits and consistent, when considering both RTD and rear teat placement (rp=-0.66; rg=-0.94). Conversely, positive correlations were identified between UD and udder depth recorded by classifiers (rp=0.66; rg=0.92). The estimated heritabilities for classifier evaluations for traits front and rear teat placement and udder depth were 0.33, 0.26, and 0.39, respectively. In conclusion, the present study revealed a higher heritability for udder conformation traits derived from AMS and promising genetic correlations with classifier evaluations. These results suggest a potential advantage by including AMS-based udder conformation traits in genetic evaluations, which should be further investigated.

Development of a new recording scheme for calf-health related traits

B. Fuerst-Waltl[1], C. Fuerst[2], C. Rehling[2], C. Egger-Danner[2], K. Linke[2]
[1] BOKU University, Department of Agricultural Sciences, Institute of Livestock Sciences, Gregor-Mendel-Str. 33, 1180 Vienna, Austria, [2] ZuchtData EDV-Dienstleistungen GmbH, Dresdner Straße 89/B1/18, 1200 Vienna, Austria

Calf health and consequently mortality has long been a cause for concern with respect to animal welfare. More recently, circular economy considerations and consumers' desire to reduce food waste have additionally led to more attention being paid to losses along the food production chain. Apart from stillbirth, and lately, rearing losses, traits related to calves, youngstock and replacement heifers have largely been neglected in dairy and dual-purpose cattle breeding. In the joint Austrian-German-Czech genetic evaluation, the vitality value (VIW), which includes any stock losses including stillbirths in the first 10 months for male and the first 15 months for female youngstock, has been published since 2016. The VIW's relative economic value in the total merit index (GZW) is 5% in Fleckvieh and 4% in Brown Swiss. To further strengthen calf-related traits in the breeding objective, additional traits for health and mortality are to be added to the VIW within the ENSURE (Data driven strategies to enhance sustainability, resilience, and resource efficiency of cattle farming) project. In terms of breeding, using various data sources in addition to the existing ones is beneficial for representing different facets of calf health and survival, and for achieving higher reliabilities in potential breeding values. One such source is information on why calves left the herd, were culled or died, in line with the recording of disposal reasons for cows. The latter are used for management purposes but also as indicator traits in several genetic evaluations, since they are widely available in large quantities at little or no additional cost. Thus, the first step was to elaborate reasons for disposal or culling of youngstock. The focus is on young calves of both sexes until day 30 post-partum, and on female calves (i.e. replacement heifers) until their first calving. Apart from the categories "sold for breeding" and "sold for fattening", 14 disposal reasons were defined. These include e.g. respiratory problems, diarrhoea, umbilical hernia or septicaemia which mostly occur in younger calves, but also reasons relevant in youngstock, such as fertility problems or spastic paresis. Farmers can now record the codes in an upgraded app, allowing them to document the reasons for the disposal of calves and youngstock. In 500 farms taking part in the ENSURE project, recordings are monitored and supplemented by performance recording personnel during routine inspections, which take place eight to eleven times per year. Additionally, the app has been updated to include observations of contracted tendons and the sucking reflex. These are each recorded by farmers in five categories within 24 hours of birth. Similar to the disposal reasons, monitoring is accomplished by performance recording personnel in the 500 project farms. In next steps, the potential extension of existing data on individual calf health (i.e., veterinarian diagnoses) by information that currently cannot be linked to individuals (e.g., slaughterhouse or rendering reports), will be evaluated.

Genome-Wide Association Study of Navel Length at Weaning in Brangus Cattle

T. De Melo[1], D. De Oliveira[1], S. Rocha[1], S. Lazaro[2], H. De Oliveira[3]
[1] Federal University of Santa Maria, Animal Science, Av. Roraima nº 1000 Cidade Universitária Bairro - Camobi, 97105-900 Santa Maria, Brazil, [2] University of Guelph, Animal Biosciences, 50 Stone Road East, N1G 2W1 Guelph, Canada, [3] Purdue University, Animal Sciences, 270 S Russell Street, IN 47907 West Lafayate, United States

Navel length (in females) and prepuce length (in males) are phenotypes that have been used in genetic evaluations of beef cattle more frequently in the last decade. These morphological traits are closely associated with the adaptation and functionality of the animals. Animals with long navels or prepuces are more susceptible to lesions from contact with pasture, which is undesirable in pasture-based farming systems. The objective of this study was to identify genomic regions associated with navel/prepuce length evaluated at weaning age in Brangus cattle. The dataset was provided by Gensys Consultores Associados, and it included phenotypes recorded from 182,937 Brangus (i.e., 3/8 Brahman and 5/8 Angus) animals raised at Brazil (south, southeast and midwest), Paraguay, and Bolivia. A total of 715,130 animals were included in the pedigree file, of each 11,592 animals were genotyped using a SNP panel containing 93,150 SNPs. The single-step GBLUP (ssGBLUP) method was used to predicted animals genomic breeding values (GEBVs), which were then back solved to estimate the SNP effects in the genome-wide association study (GWAS). The general model used include contemporary group (concatenation of sex, year, and farm of birth) and season in which the trait was evaluated (i.e., spring or fall) as categorical fixed effects, age of the animal at the time of evaluation as covariates (linear and quadratic effects), and the random effect of animal. Categorical phenotypes were used in the evaluation, ranging from 1 (short) to 5 (long length navels/prepuce). The Gibbsf90+ program was used to estimate the GEBVs using a threshold model, and PostGSf90 was used to predict marker effects. False discovery rate (FDR) was used to account for multiple testing. To select α values producing an FDR lower than 0.05, the p-value rank position procedure was used. The GWAS resulted in 103 significant single-nucleotide polymorphisms (SNPs), at an empirical threshold P-value of 3.38×10^{-5} (FDR < 0.05). Those SNPs were located at 28-60Mb at BTA5, with the majority around of 40-55Mb (70%). This region contains the WIF1 gene (48.6-48.7 Mb), which is known to be related to navel length in cattle. In addition, other QTLs associated with milk protein production in dairy cattle and kidney fat weight in Brangus cattle were identified in the top region identified. Studies on navel length are still scarce in the literature, but our results point to an important genomic region possibly regulating this trait, reinforcing previous studies focused on other breeds.

Phenotyping strategies to enhance genetic gain for animal health and welfare in dairy cattle – from the past to future perspectives

C. Eggerdanner[1], A. Köck[1], C. Fürst[1], H. Schwarzenbacher[1], K. Schodl[1], J. Himmelbauer[1], B. Fürst-Waltl[2]
[1] ZuchtData, Dresdner Straße 89, 1200 Vienna, Austria, [2] 2BOKU University, Vienna, Department of Agricultural Sciences, Institute of Livestock Sciences, Gregor-Mendel-Str. 33, 1180 Vienna, Austria

Sustainable cattle breeding requires the integration of new data sources and technologies to improve the resilience, efficiency and environmental performance of production systems. One of the expected main results of the ENSURE project is the revision, further development and optimisation of breeding strategies for Fleckvieh and Brown Swiss to increase sustainability and resilience. This includes novel phenotypes for traits related to resilience, reproduction and health derived from technological advances and new data sources; the evaluation of different phenotyping strategies; the development of a breeding goal that considers biological, economic, environmental and consumer aspects; and the optimisation of the entire breeding process. In genetic improvement programmes, traits can be broadly classified as either direct or indirect. Indirect traits, often referred to as indicator traits, are genetically correlated with the trait of interest, but are usually cheaper or easier to measure. This is particularly important for traits with low heritability, such as many health-related traits, for which large datasets are required to achieve reliable breeding values. However, direct traits are generally more efficient for achieving genetic progress when comparable data quantities are available. They are also essential for developing and validating indicator traits. Currently, phenotypes within breeding programmes for health and welfare are traditionally based on diagnoses from veterinarians and hoof trimmers, farmer observations and recordings within dairy herd improvement programmes, and laboratory results, with a growing interest in mid-infrared (MIR) predictors. Technological advances offer new possibilities for novel phenotypes. This presentation will discuss different approaches, the requirements and challenges of various traits, and strategies for genomic breeding programmes. It will focus on genetic improvement in terms of health and selected welfare traits in general, as well as different direct and indirect traits relating to claw health and lameness. Direct traits include diagnoses from veterinarians and claw trimmers. Other data sources include information on lameness and hind claw position, as well as changes in milking and behaviour (e.g. activity, eating and lying down). Novel technologies provide information to assist with management decisions. The presentation will present existing research results, as well as ongoing research within the ENSURE project.

An impact of including methane emission into the Polish Holstein-Friesian cattle breeding program

G. Cieleń[1], M. Pszczola[1,2], L. Büttgen[3]
[1] Poznań University of Life Sciences, Department of Genetics and Animal Breeding, Wołyńska 33, 60-637 Poznań, Poland, [2] Centre for Genetics, Polish Federation of Cattle Breeders and Dairy Farmers, J. H. Dabrowskiego 79A, 60-529 Poznań, Poland, [3] Wageningen University & Research, Animal Breeding and Genomics, P.O. Box 338, 6700 AH Wageningen, Netherlands

The genetic progress in dairy cattle breeding depends on the balancing of multiple selection criteria. In the Polish Holstein-Friesian (PHF) population, the current selection index integrates production, conformation, and functional traits. However, the dynamic nature of the dairy industry – particularly the increasing demand for environmental sustainability – requires re-evaluation of trait weightings and the introduction of new selection objectives, such as methane emissions (CH4), to ensure long-term genetic gain. This study aimed to evaluate and compare several alternative scenarios of including CH4 trait into breeding objective and compare the effects with the current PHF breeding goal. We simulated the complex population structure of Polish dairy cattle, using the Modular Breeding Program Simulation (MoBPS) framework in R,. The simulation involved a multi-generational approach, where different selection strategies were tested by varying: 1) relative weights assigned to specific sub-indices (production vs. functional traits); 2) inclusion of methane emission as an additional trait; 3) intensity of selection within the sire and dam pathways, and the impact of genetic correlations between methane traits and performance traits. The performance of each scenario was assessed based on predicted genetic response, inbreeding rate, and overall environmental efficiency. The findings illustrate how reallocating selection pressure affects the long-term genetic correlation structure, showing that methane reduction can be achieved while maintaining stable genetic gains in production and functional traits. This comparative analysis provides objective selection criteria foundation for future modifications of the national selection index, ensuring that breeding goals remain aligned with both industry requirements and global climate targets. The European Union's Horizon Europe research and innovation program provided funds for this work under grant agreement no. 1059609 (Re-Livestock project).

Genetic background of Navel Length in Brangus Cattle

T. De Melo[1], D. De Oliveira[1], S. Rocha[1], S. Lazaro[2], H. De Oliveira[3]
[1] Federal University of Santa Maria, Animal Science, Av. Roraima nº 1000 Cidade Universitária Bairro - Camobi, 97105-900 Santa Maria, Brazil, [2] University of Guelph, Animal Bioscience, 50 Stone Road East, Guelph, Ontario, Canada, N1G 2W1, N1G 2W1 Guelph, Canada, [3] Purdue University, Animal Sciences, Creighton Hall 270 S. Russell Street, IN 47907-2041 West Lafayette, United States

Genetic background of Navel Length in Brangus Cattle Thaise Pinto de Melo1, Daniele Alves de Oliveira1, Saymon Rocha1, Sirlene Lazaro2, Hinayah Rojas de Oliveira3 1Federal University of Santa Maria, Departament of Animal Science, Santa Maria, Rio Grande do Sul, Brazil. 2University of Guelph, Departament of Animal Biosciences, Guelph, Ontario, Canada. 3Purdue University, Departament of Animal Sciences, West Lafayette, United States. Navel length has recently been considered as an important trait in genetic evaluations of beef cattle. Its importance lies in its relationship with animal welfare and the adaptability of cattle raised in pasture-based systems. Navel length is considered as a categorical trait, generally evaluated based on five classes. Animals with greater navel length tend to have more problems with inflammation in the navel and prepuce regions, and are therefore undesirable. Due to past selection pressures, animals in classes four and five (i.e., with longer navels) are often underrepresented. The objective of this study is to evaluate navel length phenotype as categorical (using either five, four, and three categories), and linear models, based on both BLUP and ssGBLUP methods, and to assess their impact on heritability estimates, accuracy, bias, and dispersion of breeding values. The database contained information from 182,937 animals, as well as pedigree information for 715,130 individuals. A total of 11,592 animals were genotyped using a SNP panel containing 93,150 SNPs. Of the 182,937 animals, 6,437 (3.52%) belonged to the phenotypic classes four or five, i.e., presented the longer navel phenotype. The BLUP and ssGBLUP models were tested using the BLUPF90 program family. The results showed that the variability for the results for evaluated parameters among the different scenarios was generally low. Among all, heritability was the parameter that varied the most, ranging from 0.52 to 0.38 in the models and scenarios tested. The scenarios using with five or four classes produced higher heritabilities and were closer to the literature, with low variation between BLUP and ssGBLUP. In the scenario using only three classes, there was a slight reduction in the heritabilities to 0.48 (BLUP), and a greater decreasing was observed when the trait was treated as linear (0.38 for BLUP). Overall, accuracies ranged from 0.35 to 0.38; bias ranged from 0.02 to 0.06, and dispersion ranged from 0.83 to 0.88. The small variation and little difference between scenarios can possibly be explained by the low number of animals in classes four and five, only 3.52% of the total number of phenotypes, and only 654 of these were in the validation population (younger animals with genotype). Therefore, the different methods of dealing with navel length in cattle did not have a major impact on the parameters evaluated, except for heritabilities.

Genome-Wide Association Study for Hair Coat Score in Brangus Cattle

D. De Oliveira[1], S. Rocha[1], S. Lazaro[2], H. De Oliveira[3], T. Melo[1]
[1] Federal University of Santa Maria, Department of Animal Science, Av. Roraima nº 1000 Cidade Universitária, Bairro Camobi, 97105900 Santa Maria, Brazil, [2] University of Guelph, Department of Animal Biosciences, 50 Stone Road East, N1G 2W1 Guelph, Canada, [3] Purdue University, Department of Animal Sciences, 270 S Russell St, IN 47907 West Lafayette, United States

Hair coat score is a key adaptive trait for tropical and subtropical cattle breeds, influencing heat dissipation, ectoparasite resistance, and overall fitness in Brangus (Bos taurus × Bos indicus). Despite its economic importance, genomic regions underlying weaning coat score remain poorly characterized. This study aimed to perform a genome-wide association study in order to identify important genomic regions associated with hair coat score in Brangus cattle at weaning. The analysis used Natura-Gensys® Brangus data (from Brazil/Paraguay/Bolivia): 70,045 phenotypes of hair coat scores evaluated at weaning (1-3 scale, ~205 days), 11,592 genotyped animals for 93,150 SNP markers, 715,130 pedigree records. We used the single-step GBLUP (ssGBLUP) method in order to predict the genomic breeding values (GEBVs), which were then back solved to estimate the SNP effects in the genome-wide association study (GWAS). Contemporary groups were formed by concatenating information of year, farm, season and management group. BLUPF90 family programs were used to perform the analysis. Windows of 1 Mb were constructed and the percentage of variance explained by each window was evaluated, ordering the top windows that explained 10% of the total genetic variance together. A total of 36 windows collectively explained ~10% of the additive genetic variance. BTA9 showed the highest number of windows (four), whereas BTA4 concentrated three of the most informative windows, jointly explaining about 1.5% of the variance: BTA4_69 (69.93–70.90 Mb; 0.868%), BTA4_9 (9.40–10.39 Mb; 0.378%) and BTA4_10 (10.75–11.75 Mb; 0.216%), with BTA4_9 and BTA4_10 forming a consistent cluster at 9–11 Mb. BTA20_35 (35.83–36.77 Mb; 0.349%) covers the SLICK region, including SKP2 (38 Mb), SPEF2 (38.3 Mb), and nearby PRLR, AGXT2 and DNAJC21 (~39 Mb) – major players in hair coat and heat tolerance. Cumulative variance reached 3.72% in the top 10 windows. These results indicate that weaning coat score in Brangus has a complex, highly polygenic architecture, controlled by many loci of small effect rather than a single pronounced peak, with BTA4 emerging as a relevant hotspot for future fine-mapping and functional studies in the 9–11 Mb and 69–71 Mb regions.

Genomic evaluation of weaning coat score in Brangus cattle using BLUP and ssGBLUP

D. De Oliveira[1], S. Rocha[1], S. Lazaro[2], H. De Oliveira[3], T. De Melo[1]
[1] Federal University of Santa Maria, Department of Animal Science, Av. Roraima nº 1000 Cidade Universitária Bairro Camobi, 97015900 Santa Maria, Brazil, [2] University of Guelph, Department of Animal Biosciences, 50 Stone Road East, N1G 2W1 Guelph, Canada, [3] Purdue University, Department of Animal Sciences, 270 S Russell St, IN 47907 West Lafayette, United States

Hair coat score at weaning is a key adaptive trait for thermoregulation and ectoparasite resistance in Brangus cattle maintained under tropical and subtropical heat stress. Short slick coats (score 1) enhance radiative heat loss while reducing tick harboring capacity, critical for this Bos indicus-influenced breed in low-latitude production systems. In genomic prediction, the single-step genomic best linear unbiased prediction (ssGBLUP) method allows the inclusion of information from genotyped and non-genotyped relatives in the analysis. This study aimed to perform BLUP and ssGBLUP genomic evaluation in commercial Brangus populations, estimating prediction accuracy, bias, and dispersion for both methods. The analysis used Natura-Gensys® Brangus data (from Brazil/Paraguay/Bolivia): 70,045 phenotypes of hair coat scores evaluated at weaning (1-3 scale, ~205 days), pedigree (n=715,130 animals), and genotypes from 11,592 animals. Contemporary groups were formed by concatenating information of year, farm, season and management group. BLUPF90 family programs were used to perform the analyses with fixed contemporary group and age-at-weaning covariate, plus random additive and residual effects. Both methods estimated moderate heritability (0.45) for weaning hair coat score. Forward validation (2020-2024 cohorts) used linear regression of full-dataset EBVs/GEBVs against deregressed breeding values from validation animals only, with ssGBLUP based on 6,846 genotyped animals and BLUP on 9,522 animals. The accuracies with ssGBLUP were higher than those from traditional BLUP, with accuracy of 0.40 and 0.35, dispersion of 0.80 and 0.81, and bias of −0.010 and −0.009 for ssGBLUP and BLUP, respectively. Despite the smaller genotyped validation set, ssGBLUP showed a 15% increase in accuracy with comparable dispersion (b_1≈0.80; mild under-dispersion typical without metafounders) and stable heritability, supporting its use for genomic selection of tropical adaptation traits at weaning in Brangus cattle.

Supporting dairy cows breeding practices using historical fertility data and MIR spectra : a deep learning approach

T. Przybylski[1], C. Grelet[1], L. Dale[2], Y. Ben Mohamed[3], J. Leblois[5], H. Soyeurt[4], F. Dehareng[1]
[1] Walloon Agricultural Research Center, 24 Chaussée de Namur, 5030 Gembloux, Belgium, [2] LKV Baden-Württemberg, 1-3 Heinrich-Baumann-Str., 70190 Stuttgart, Germany, [3] Eliance – Maison Nationale des Eleveurs, 149 Rue de Bercy, 75595 Paris, France, [4] Gembloux Agro-Bio Tech, University of Liège, 2 Pass. des Déportés, 5030 Gembloux, Belgium, [5] Walloon Breeders Association Group, 4 Rue des Champs Elysées, 5590 Ciney, Belgium

Holicow is an Interreg North-West Europe (NWE) project dedicated to the development of a holistic herd management tool for dairy farmers. The project capitalizes on an extensive transnational database comprising more than 60 million milk recording samples and over 500 existing predictive models based on Mid-Infrared (MIR) spectroscopy. In addition, more than 19 million reproductive events (primarily inseminations, pregnancy diagnoses, and calvings) have been collected by the project partners. The primary objective of this work was to integrate MIR spectral data and derived predictions with fertility records in order to develop robust models capable of predicting key reproductive traits directly from routine milk recordings. A first major step consisted in identifying fertility traits that are both relevant for on-farm decision-making and available, either directly or indirectly, within the transnational database. The main traits investigated were pregnancy status, probability of success at the time of insemination, and probability of embryonic loss. Subsequently, predictive models were developed for these traits using either raw MIR spectra or MIR-based predictions as input variables. Both classical machine learning approaches and deep learning techniques were implemented and evaluated. Combined with existing methodologies for assessing milk production, milk processing characteristics, animal welfare, environmental impact, and heat stress, this approach contributes to the development of a comprehensive and collaborative decision-support tool accessible to farmers and advisors.

GEDA: A novel software for automated processing of sniffer-based gas emission measurements

L. Ashayeri[1], S. Annadatha[1], R. B. Stephansen[1], T. M. Villumsen[1], N. Saedi[1], M. S. Lund[1], V. Milkevych[1]
[1] Aarhus University, Center for Quantitative Genetics and Genomics, C. F. Møllers Allé 3, 8000 Aarhus, Denmark

Accurate estimation of methane (CH_4) and carbon dioxide (CO_2) emissions is essential for genetic evaluation of environmental impact and supporting mitigation strategies. In this context, sniffer-based measurements play substantial role for upscaling number of records in a cost-effective manner. Sniffers integrated into Automatic Milking Systems (AMS), provide continuous gas concentration records; however, these data are often affected by sampling irregularities, sensor noise, time misalignment between data streams, and environmental drift. Therefore, the quality of such records is a well-known challenge and alongside emissions' phenotypes estimation is critical to address. This study introduces the GEDA software representing a unified framework for processing raw sniffer data into aligned, quality-controlled gas emission data and reliable emission phenotypes. The pipeline implementation is based on a stochastic model that represents noisy gas emission signals as a function of AMS data. This formulation enables the workflow that integrates data quality control, errors correction, synchronization of AMS and sniffers data following reliability assessment. The background concentrations are estimated through a weighted regression model following data corrections. Extreme outliers are identified and bounded according to parameter-based statistical criteria. Optional denoising is implemented using singular spectrum analysis. After visit-level filtering, emission phenotypes are calculated as mean concentrations [ppm] or emission intensities [ppm/min] at visit-level or daily-level. The quality of the phenotypes is evaluated using linear mixed models to estimate the intraclass correlation coefficient as a localized quality metric. A comprehensive case study based on four years data from 38 Danish commercial farms assessed the pipeline's efficiency and the quality of estimated phenotypes. In this analysis, records were filtered using thresholds of the local quality metric, and heritability and repeatability were subsequently estimated for each dataset. Heritability estimates for daily average phenotypes ranged from 0.13 – 0.16, while repeatability values were in the range of 0.32 – 0.41. The pipeline parameter sensitivity was assessed for sampling frequency, signal length, scaling, denoising, visit constraints, outlier filtering, and phenotype definition. Maximum repeatability was observed at a data sampling interval of 1 s. Repeatability was highest at a minimum visit duration of 2 min and decreased as the exclusion window increased. Among filtering parameters, the upper outlier bound had the largest effect on repeatability. Finally, visit-based intensity phenotypes provide more stable (to the changes in data sampling rates) repeatability estimations than daily or concentration-based alternative. On average, processing approximately 1 million records required 2.74 min using 6 CPU cores. Overall, GEDA provides a theoretically grounded framework for processing sniffer-based gas emission data under commercial farm conditions. By addressing data heterogeneity, noise, and misalignment, the pipeline enables the generation of aligned AMS and gas concentration datasets and emission phenotypes suitable for genetic evaluation and greenhouse gas research in dairy cattle.

Should she stay or should she go now? Ranking of cull cows based on Net Present Value implemented in Dairy Management Software

B. Hoejlund Nielsen[1], L. A. Hjort Nielsen[2], N. H. Schneider Nielsen[3], J. Ettema[1], S. Oestergaard[4]
[1] SimHerd A/S, Niels Pedersen Allé 2, DK-8830 Tjele, Denmark, [2] SEGES Innovation, Agro Food Park 15, DK-8200 Aarhus N, Denmark, [3] VikingDanmark, Agro Food Park 12, DK-8200 Aarhus N, Denmark, [4] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, DK-8830 Tjele, Denmark

Decisions regarding culling dairy cows are complex and many factors influence the decision. Farmers may aim to keep the most profitable cows, but profitability can be difficult to assess and are often made in a nonprogrammed fashion, relying partly on intuition. To support the day-to-day decision of which cows are candidates for culling, ranking of the cows based on the Net Present Value (NPV) has shown to be useful. The NPV estimates the discounted, future cash flows of a cow, including both revenues and costs. The objective of this project was to implement an NPV ranking of cows in the Danish Dairy Management Software, DMS, supplementing the existing data on performance with an estimation of each cow's future economic outcome. A dynamic, stochastic and mechanistic simulation model (the SimHerd Model) was used in a large simulation study of cash flows of different cow types. The SimHerd Model simulates a dairy herd in weekly steps; representing production, events and state of each individual cow in the herd. The simulated cow types were based on parity, lactation stage, milk yield, plus reproductive and health status. All cow types were simulated in different herd types characterised by milk yield, culling level and reproductive performance. Based on the simulated data, response surface models (RSMs) were developed to predict the NPV of individual cow type in the different herd types. In the Danish DMS, the cow level data on milk recordings, reproduction events and health registrations are used as input for the RSM models. As the RSM models are tailored to different herd types, The individual NPV is calculated after each monthly milk recording for all lactating cows with milk recordings >70 DIM. The herd and cow specific NPV are converted into values on a ranking index from -100 to +100. In January 2026, all dairy farmers with access to DMS were presented with the ranking index in a dashboard together with supplemental information regarding the cow's performance in the current lactation. Cows not eligible for culling, due to medicine use or near calving, are marked. The user can filter which group of cows are of interest. The dashboard has been well received with predominantly positive response to the new tool from the farmers. Ranking of culling candidates based on the NPV was successfully implemented in a dairy management software with national reach. Farmers find the add-on with the future economic value useful in combination with the historic data on the cows.

High-throughput video phenotyping of sow activity around farrowing and its association with piglet mortality

A. Poublan-Couzardot[1], T. Cochou[1], F. Laperruque[1], W. Hébrard[2], M. Bonneau[3], L. Canario[1]
[1] INRAE, GenPhySE, 24 chemin de Borde-Rouge, 31326 Castanet-Tolosane, France, [2] INRAE, GenESI, Le Magneraud, 17700 Surgères, France, [3] INRAE, ASSET, Prise d'eau, 97170 Petit-Bourg, Guadeloupe

Sow postural activity is an overall indicator of maternal behaviour and health status of sows, both of which have a strong influence on piglet survival. The aim of this study was to develop and apply a high-throughput video phenotyping approach to characterize sow activity around farrowing and to evaluate its association with piglet mortality. A total of 134 Large White sows kept in farrowing crates in the INRAE experimental facility were video recorded. The database included 221 farrowing events between April 2021 and April 2024. A YOLO convolutional neural network was trained for automated image classification to predict sow posture. The network was trained on diverse images to ensure high predictive accuracy. The algorithm achieved a global accuracy greater than 95% on all postures but one. The model identified eight postures that were predicted at one-second resolution: udder left/right, lateral left/right, sternal, sitting, kneeling and standing. Analyses focused on −3 days to +5 days relative to the onset of farrowing (birth of the first piglet). After filtering, 1,099,545 posture change events were used for analysis. Sow activity was characterised by posture duration, frequency of posture changes, and posture sequences using a sliding-window approach across periods before, during (6 hours after onset of farrowing), and after farrowing. Features were summarized using mean, SD, area under the curve, peak-to-mean ratio (PTM), and PTM_SD. Of the 35,161 generated activity traits, 27,506 were retained. On average, activity increased during the 24 h preceding farrowing, peaked shortly before onset, and declined immediately afterward. Mean posture duration decreased toward farrowing and increased post-partum. Inter-individual variability was observed in activity intensity and posture transitions across different time periods. To identify activity traits most strongly associated with mortality traits, we applied Elastic Net regression within a multi-response linear model using the glmnet package in R software. Piglet mortality traits comprised 23 continuous variables (e.g., stillborn (SB), crushed (CR), weak (WE), savaged (SA), killed (KI, i.e., CR + SA), number of piglets born alive, litter sizes at days 0 to+3), corrected for parity, batch, and total number born. Elastic Net selected 150 activity traits among which 19 key traits were significantly correlated with SB, CR, WE, and KI ($p < 0.01$). SB showed the strongest mean correlation ($|r| = 0.38$, 11 traits, mostly post-farrowing), followed by killed (0.26, 7 traits before and during farrowing), CR (0.20, 3 traits during farrowing), and WE (0.18, 1 trait during farrowing). Duration in kneeling posture before farrowing was associated with KI and CR. Increase in sequences of active postures during farrowing were positively associated with KI and CR and negatively with WE. The strongest association ($r = 0.62$) was between SB and mean frequency of short (<60 s) udder-left postures measured over 4-hour sliding windows, starting 6 hours after the onset of farrowing. These findings show that high-throughput video phenotyping can reveal moderate to strong associations between maternal activity patterns and piglet mortality. Automated, continuous, and standardized quantification of activity traits offers strong potential for precision monitoring, integrating sow activity into breeding strategies, and anticipating farrowing or health issues.

Seasonal adaptation is associated with systemic metabolic remodelling in heavy pigs: a molecular phenomic approach

S. Agyabeng[1], S. Bovo[1], M. Gallo[1], G. Schiavo[1], L. Fontanesi[1], F. Bertolini[1]
[1] University of Bologna, Animal and Food Genomics Group, Viale Guiseppe Fanin 46, 40127 Bologna, Italy

Seasonal thermal conditions represent a relevant environmental challenge for finishing pigs, potentially influencing metabolic regulation, physiological homeostasis, and performance outcomes at high slaughter weights. In heavy pigs (approx. 160 kg), environmental conditions may influence systemic metabolic status, with potential implications for physiological robustness and carcass characteristics, which may in turn affect the subsequent seasoning of ham. Molecular phenomic approaches, including plasma metabolomics, provides a valuable tool to characterise integrated physiological responses to environmental variation under field conditions. However, seasonal metabolic variation in heavy pigs has never been characterised using plasma metabolomics. The objective of this study was to characterise seasonal metabolic differences in performance-tested Italian Large White heavy pigs at slaughter using untargeted plasma metabolomics and to evaluate systemic metabolic adjustments associated with pre-slaughter temperature conditions. A total of 193 Italian Large White pigs were included in two seasonal groups: summer, collected across four slaughtering days (n = 87), and winter, collected across three slaughtering days (n = 106), balanced between males and females. Pre-slaughter thermal exposure differed markedly between seasons, with higher 10-day average minimum and maximum temperatures in summer (average min 20.92 °C; max 33.90 °C) compared to winter (average min -3.77 °C; max 3.2 °C). Plasma was collected at slaughter, which was performed in the early morning. Untargeted metabolomics detected 670 metabolites. After quality control, exclusion of xenobiotics, and removal of metabolites with >25% missing values, 580 metabolites were retained for downstream analysis, which included imputation using Multivariate Imputation by Chained Equations. Seasonal comparisons were performed using the Wilcoxon rank-sum test and linear regression. Only metabolites with a Bonferroni-corrected p-value < 0.01 in both analyses were considered significant. Enrichment analysis of significant metabolites was performed using MetaboAnalyst, considering the Relational Database of Metabolomic Pathways and requiring at least three entries per cluster. A total of 193 and 187 metabolites were detected by the Wilcoxon and linear regression analyses respectively, with an overlap of 177 metabolites. Enrichment analysis (RaMP DB) indicated that discriminant plasma metabolites clustered in pathways related to membrane transport, lipid metabolism/signaling, amino acid and branched-chain amino acid catabolism, and nucleotide/pyrimidine metabolism, with additional enrichment for mitochondrial biogenesis (FDR < 0.01). These findings indicate that seasonal temperature variation is associated with coordinated systemic metabolic remodelling in heavy pigs, detectable at slaughter, and identify potential plasma biomarkers of thermal adaptation under field conditions. Research funded by the European Union – NextGenerationEU under the National Recovery and Resilience Plan (PNRR) – FEEDTHEPIG, proposal code P2022FZMJ9 – CUP J53D23018310001 and the European Union's Horizon Europe research and innovation programme under the grant agreement No. 101059609 (Re-Livestock).

Comparison of classification models to estimate lifetime productivity of Murciano-Granadina goats from first-lactation records

M. P. Torralbo-Muñoz[1], Á. Sevilla-Molina[2], M. J. García-García[1], E. Padrón-Tejera[1], F. Maroto-Molina[1], D. Guijo-Rubio[3], P. A. Gutiérrez-Peña[3], J. Fernández-Álvarez[4]

[1] University of Córdoba, Department of Animal Production, Rd. km 396, 14071 Córdoba, Spain, [2] International Chair on AI and Agriculture, M. Azahara 5, 14071 Córdoba, Spain, [3] University of Córdoba, Department of Computer Science and Artificial Intelligence, Rd. km 396, 14071 Córdoba, Spain, [4] National Association of Murciano-Granadina Goat Breeders, Rd., km 1.5, 18340 Granada, Spain

Lifetime productivity is a key driver of the economic and environmental sustainability of dairy goat systems. However, culling and replacement decisions are still largely based on current milk yield without considering lifetime production, although an increased longevity may improve herd efficiency. Milk recording programmes routinely provide detailed individual data, creating an opportunity to predict lifetime performance at an early stage and support more informed farmer decisions. The aim of this study was to compare classification modelling approaches to predict individual lifetime performance indicators in Murciano-Granadina (MG) goats using information available at the end of the first lactation. Data were obtained from 76 MG dairy goat herds and included 24,459 goats with complete productive life records. The database integrated three data sources: (i) milk recording data (e.g., 270-days milk yield and composition, lactation length, etc.), (ii) morphological evaluations (e.g., general structure, udder system, etc.), and (iii) lifetime performance of the dams. Target variables were lifetime milk yield, total days in milk (DIM), longevity and total number of lactations. Each target trait was discretised into four ordered groups using percentile-based cut-offs (P25, P50 and P75). After data cleaning and standardisation, models were trained using different combinations of predictor sets, all of them including milk-recording variables. Four classification approaches were evaluated: (1) logistic regression (LR), a well-known linear model for nominal classification; (2) ridge regression (RR),), a regression-based approach trained on continuous targets, whose continuous predictions are subsequently mapped to classes; (3) ordinal ridge regression (ORR), a naïve ordinal classifier trained on categorical data that produces continuous outputs, which are then converted into class labels; and (4) a logistic model with all-threshold variant (AT), specifically designed for ordinal outcomes. Model performance was assessed as classification accuracy (ACC) and mean absolute error (MAE) for each data-model combination. The former evaluates the proportion of correctly classified goats, without considering the magnitude of the errors, whereas the latter measures the average number of categories by which the prediction deviates from the target category. Combining milk-recording and morphological data yielded the lowest MAE, whereas models based on milk-recording data alone showed the highest error. AT achieved the lowest MAE for lifetime milk yield (0.74), longevity (0.81) and number of lactations (0.93), with only minor reductions in accuracy compared with the maximum observed values (−0.04, −0.05 and −0.09, respectively). In contrast, RR provided the best results for total DIM (MAE=0.65; ACC=0.42, the highest observed). Overall, modelling lifetime traits as an ordinal classification problem reduced MAE with only a modest loss of accuracy. This is particularly relevant for decisions at farm level, where avoiding misclassification of individual animals is critical. These results support the use of routinely collected lactation data, complemented with morphological and maternal information, as an early decision-support tool to improve farmer decision making.

Is gut microbiome information to be considered as part of the animal phenomic realm?

F. Tiezzi[1], C. Maltecca[2]
[1] University of Florence, DAGRI, Piazzale delle Cascine 18, 50144 Firenze, Italy, [2] North Carolina State University, Animal Science, 120 W Broughton dr, 27695 Raleigh, NC, United States

Animal the gut microbiota (GM) has been proposed for its unique potential to describe and interpret complex host phenotypes, reflecting genetic and environmental influences and their interplay. Lastly, the GM has been proposed as the ultimate tool to explain animal resilience, for its nature of representing a dynamic and responsive ecosystem, defined and determined in tight relationship with the animal's physiology, So to give a broad definition encompassing both ruminants' and monogastrics' physiology, GM could be defined as the complex ecosystem of symbiont organisms that inhabits the gastro-intestinal tract. At the same time, animal phenomics (AP) has been developed as its own field. AP can be defined as the ensemble of technologies that can be used to gather, organize and manage data relative to animal phenotypes. AP is receiving strong attention from both the scientific community and the industry, for the unprecedented opportunities it can create in monitoring and controlling animal production system. Economic profit, animal welfare and environmental impact can all be improved thanks to AP. With that being said, can GM be considered as a form of AP? Several studies have attempted to used GM in this sense, which can all be brought to our attention. However, there is probably a lack of conceptual foundation for its proper use as an AP feature. While AP technologies are designed to capture animal variability, GM is an intrinsic characteristics of animal variability. GM is a feature that determines animal variability. This talk will provide a dialectic analysis of why GM can or cannot be used as an AP feature. This will encompass animal management and breeding. As a likely conclusion, GM can't probably be declared as the most appropriate source of information for use as AP, but some applications in animal breeding appear promising.

Exploring European Family Farmers' Attitudes Towards Big Data Tools

E. Eriksson[1], D. K. Mcgrath[2]
[1] EFFAB, Rue Des Treves 61, 1040 Brussels, Belgium, [2] University College Dublin, Belfield, Dublin 4 Dublin, Ireland

Exploring European Family Farmers' Attitudes Towards Big Data Tools Family farms account for the vast majority of farms within Europe (more than 9 out of 10 farms) and their resilience and survival are key to European food security and resilience of rural communities. Therefore, understanding from a bottom-up perspective their needs and expectations from on-farm technologies that could aid in their resilience and survival is critical. The agricultural sector is experiencing its fourth revolution, Agriculture 4.0., – characterized by the use of smart farming tools such as the Internet of Things (IoT), robotics, sensors, machine learning, big data, cloud computing, etc. In recent years, the use of big data tools in farming have increased globally, across all types of farms, and these tools are expected to have a major impact within agriculture and possibly change the way farming is done today. Data from digital tools, like big data tools, both start and end at the farm. From data collection stemming from the farm, it is processed and used in a vast multitude of ways before returning back in various formats (such as data analytics for assisted decision making, livestock health and welfare tracking) to benefit the farm. For example, as EFFAB (the European Forum of Farm Animal Breeders) members wide use of digital tools show, data is utilized to connect genotype to phenotype (G2P), develop and improve sustainable breeding, and much more. This is why collecting this herd and animal level data from farms is important for the whole livestock sector in order to improve resilience and sustainability. As these novel technologies are being developed, employing a co-design process is crucial to ensure fair and practical tools are being created for European family farmers. Additionally, concerns have been raised that these tools could increase the power divide within farming, and in turn be a disadvantage for smaller farms rather than a beneficial addition enhancing sustainability and resilience of their farms. Therefore, this study aimed to inform the development of tools that actively involve family farmers in the creation process by exploring the research questions: What are family farmers' attitudes towards participating in the co-design for big data tools? What skills and support are needed by family farmers to adopt big data tools? What are family farmers' needs and expectations from big data tools? What are family farmers' concerns and perceived benefits towards current and future use of big data tools? This study used a mixed methods approach, with semi-structured interviews employed to explore research questions 1 and 2, and an online survey questionnaire addressed questions 3 and 4. Overall, this study's findings suggest that for farmers who have already adopted big data tools, the tools are having a positive and significant impact on their day-to-day farm work and decision making. As these tools are further developed, it is crucial to engage farmers in the co-design process to address their concerns, needs, and wants (including support and training needs pre- and post-adoption) – which will aid to increase big data tools' usage and uptake. Ensuring fair and just tools, and access to adoption is key to ensure family farms' resilience and survival.

Use of new digital and "omics" technologies data in animal breeding: opportunities and issues

J. P. Bidanel[1], F. Laperruque[4], Y. Billon[3], C. Bertrand[2], M. H. Pinard-Van Der Laan[1]
[1] Université Paris-Saclay, INRAE, AgroParisTech, UMR GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [2] INRAE, CTIG, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [3] INRAE, Animal Genetics Division, Domaine du Magneraud, 17700 Surgères, France, [4] INRAE, Université de Toulouse, UMR GenPhySE, Chemin de Borde-Rouge, 31320 Castanet-Tolosan, France

Animal breeding has long been based on the use of large amounts of data, either phenotypes, pedigrees or genomic data, most often specifically collected for breeding purposes. The explosion in recent years of high-throughput data collected automatically on animals (weights or volumes, data from robots, sensors, accelerometers, cameras, microphones, etc.) and their rearing environment, from animals' tissue samples (genetic markers or sequences, transcriptomes, epigenomes, microbiomes, proteomes, metabolomes, etc.), in vitro (cell cultures, organoids, etc.), and in silico (data generated by imputation, modelling, etc.) offers numerous opportunities for animal breeding. The primary use of some of these data is not breeding, and its use in breeding raises a number of challenges and difficulties. This article presents different potential uses use of these new data to characterise multi-performance, adaptation to climate change and to expected changes in livestock systems, as well as some problems and issues that may arise (data quality, standardisation, interoperability, data ownership, etc.). Authors received financial support from the European Union's Horizon Europe Coordination and Support Action under grant agreement no. 101134866, (project Digi4Live, https://digi4live.eu/) and from French National Rechearch agency,France 2030 program under the reference ANR-22-PEAE-0013, https://www.pepr-agroeconum.fr/.

Economics of smart livestock farming technologies – Current costs and benefits and the need for more harmonised estimation approaches

J. K. Niemi[1], Y. Fu[1], M. Pastell[1], A. Stygar[1]
[1] Natural Resources Institute Finland (Luke), Latokartanonkaari 9, 00790 Helsinki, Finland

Sensor technologies, such as milking robots or accelerometers are widely used on dairy farms, especially to monitor animal health, feeding and milk-related aspects. Although sensor technologies are common, information about the economics of their application is scattered. While existing studies illustrate cases where the use of digital technologies in livestock systems yields economic benefits, comprehensive assessments that capture overarching trends, the consistency of reported effects, and the broader economic implications for both researchers and practitioners remain absent. The aim of this study was to synthesize economic implications of sensor technologies in dairy farming. A literature review on sensors in dairy farming that was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. The Scopus and Web of Science databases were searched using economic, sensor and animal type as search terms. From 1 355 identified publications, only 22 studies provided content that was in accordance with the criteria. In total, 11 studies focused on economic efficiency of automatic milking systems (AMS) for milk production monitoring, seven looked at various sensors (accelerometer, camera and intervaginal) for estrus detection, three examined information of sensor application in lameness detection and one focused on the economics of using sensors for body condition score and animal identification monitoring. The highest variation in the net profit of investment was observed for milk production monitoring with automatic milking systems, followed by estrus detection. The break-even costs of various sensors used for lameness detection varied between €6 and €53, on average. The profitability of sensors is linked with the severity of issues that information obtained by sensors could mitigate, the accuracy of sensor data to measure traits and opportunities to respond to the situation. Comparison between various economic results is hampered by different costs and methods used. To provide more robust evidence on economic impacts of digital and data-integrated solutions, a systematic data collection approach is proposed. In this approach, indicators will be determined using a literature review and consultations with researchers and stakeholders. Data collection instruments will be developed and validated by using a co-creation approach. Finally, we elaborate the importance of a harmonised approach that ensures comparability across studies. Authors received financial support from the European Union's Horizon Europe Coordination and Support Action under grant agreement no. 101134866, (project Digi4Live, https://digi4live.eu/).

Stakeholder Role Differences in the Use of Precision Livestock Farming Technologies in Europe

C. Gao[1], D. Liu[1], Ç. Y. Kaya[2], S. Orlandini[3], M. Ryynänen[4], J. Marchewka[5], J. Niemi[6], A. Tolmačev[7], E. Eriksson[2], D. Čenejac[7], T. Norton[1]

[1] M3-BIORES: Measure, Model & Manage Bioresponses, Division Animal and Human Health Engineering, Department of Biosystems, KU Leuven,, Kasteelpark Arenberg 30, 3001 Heverlee, Belgium, [2] European Forum of Farm Animal Breeders (EFFAB), Rue de Trèves 61, 1040 Brussels, Belgium, [3] ICAR (International Committee for Animal Recording), Arthur van Schendelstraat 550, 3511 MH Utrecht, Netherlands, [4] Digital technologies in agriculture, Production systems, Natural Resources Institute Finland, Halolantie 31A, 71750 Maaninka, Finland, [5] Institute of Genetics and Animal Biotechnology of the Polish Academy of Sciences, Postępu 36A, 05-552 Magdalenka, Poland, [6] Bioeconomy and environment, Business economics, Natural Resources Institute Finland, Kampusranta 9C, 60320 Seinäjoki, Finland, [7] Foodscale Hub, Trg Dositeja Obradovića 8, 21000 Novi Sad, Serbia

Precision livestock farming (PLF) technologies are increasingly recognised as part of broader socio-technical systems linking livestock monitoring technologies, data infrastructures, and actors across the livestock value chain. Stakeholders occupy different structural positions in these systems, which may shape technology deployment, performance perceptions, and data governance. Within the Horizon Europe project Digi4Live, we surveyed 92 stakeholders across EU member states (farmers 33.7%; non-farmers 66.3%) to examine role-based differences in current PLF context. Technology type selection was associated with both stakeholders' roles ($p<0.001$) and livestock species ($p=0.002$). On-animal sensors dominated overall and were reported almost exclusively by farmers, while non-farmers described more diversified portfolios including off-animal and integrated systems. Across species, on-animal and integrated systems were more common in cattle production, whereas off-animal systems were more prevalent in pig production. Activity and motion (n=63, 69.2%) were the most frequently reported monitoring indicators across roles ($p=0.15$), while primary objectives differed ($p=0.01$), with farmers prioritising reproduction management and non-farmers emphasising health monitoring. Respondents reported broadly positive evaluations of technologies performance: data accuracy satisfaction ($M = 3.75 \pm 0.87$), perceived effectiveness ($M = 3.60 \pm 1.05$), and validation realism ($M = 3.61 \pm 0.91$) were all significantly above neutral level (1=poor, 3=neutral, 5=excellent, all $p<0.001$), with no significant role differences (all $p > 0.05$). In contrast, governance perceptions diverged significantly between roles. Farmers more frequently reported being unaware of how technologies were validated (n =21, 67.7%; $p < 0.001$). Differences also emerged in data-sharing preferences ($p=0.026$) and perceived barriers ($p = 0.031$): farmers were more likely to share data for research purposes (n = 15, 48.4%) and more often reported no significant barriers to sharing (n=18, 58.1%), whereas non-farmers more frequently preferred sharing with trusted partners (n=39, 63.9%) and were more likely to cite privacy and ownership concerns as the main barriers (n=31, 50.8%). Respondents perceived an overall positive ROI ($M=3.96 \pm 0.82$, $p < 0.001$; strong negative=1, neutral=3, strong positive=5) with no role differences ($p = 0.8$), although high cost remained the most frequently cited barrier to wider adoption. Overall, despite differences in monitoring priorities, governance transparency, and data-sharing perceptions, confidence in technological performance is shared. Keywords: Precision Livestock Farming, Multi-actor, Technology configuration, Data governance

Connecting the Dots: Interoperability from Regulation to Practice

C. Y. Kaya[1], J. Niemi[2], H. Kayhan[3]
[1] EFFAB, Silkeborg, 2905AT Capelle aan den IJssel, Netherlands, [2] LUKE, Latokartanonkaari 9, FI-00790 Helsinki, Finland, [3] KU Leuven, Sint-Michielsstraat 6, 3000 Leuven, Belgium

The final discussion of the "Connecting the Dots: Interoperability from Regulation to Practice" session will bring together perspectives from phenomics, digital infrastructures, and sector governance to address a central challenge: how to translate rapid advances in livestock data generation into practical, trusted and scalable use. Building on insights from contributions linked to HoliCow, EULIPHE and Digi4Live, this interactive conversation will explore how interoperability can be advanced across tools, platforms and stakeholders, and how regulatory and governance developments are shaping both the opportunities and constraints for data exchange. The panel will reflect on what is needed to connect data across systems and sectors while protecting legitimate interests, strengthening trust, and enabling fair and effective use of data for decision-making. This session fosters a focused exchange on how to move from fragmented data landscapes to workable pathways that support real-world implementation and sector-wide value creation.

Development of Sustainable Dairy Production in Germany - learnings from the "Dairy Sustainability Tool" project

K. Agethen[1], H. Kuhnert[1], B. Lassen[1], T. Lindena[1], A. Raschel[1], H. Nieberg[1]
[1] Thünen Institute, Institute of Farm Economics, Bundesallee 63, 38106 Braunschweig, Germany

Since the 2010s, sustainability has gained increasing importance in the food value chain – in the production, processing and marketing of food, at national and international levels. This also applies to the German dairy industry. Were these sustainability initiatives focused mainly on the dairy processor level in the beginning, the focus progressively shifted along the whole value-added chain. Consumers, society, food retailers and food companies were wondering about the sustainability of milk production at farm level. Including German dairy farms in sustainability concepts poses particular challenges: the large number of farms, some with very different production conditions, the very broad range of sustainability aspects covering economic, ecological, social issues and animal welfare to be recorded at farm level and the fact that dairy farming has a strong linkage with the local environment. The problem: in the 2010s, there were scarcely any workable and cost-effective means to measure sustainability at farm level in its entirety. Against this background, a "basic-tool" for the sustainable development of dairy production in Germany was developed by actors from science and practice in an interdisciplinary approach. The aim was to develop a monitoring tool for dairy farms which measures and assesses a broad range of sustainability criteria in a large number of farms. It should provide information to business partners and society about dairy farms' strengths and weaknesses, and support evidence-based sustainable development of dairy farming. The sustainability criteria were screened for being a) scientifically defined and validated, and b) measurable and collectable at a reasonable cost and time by farmers themselves. To address the latter, mainly categorial indicators were used. The criteria were rated in four performance categories following their attribute value. These ratings based on scientific literature review, international frameworks, existing assessments of sustainability criteria in other measurement systems and relevant legislative frameworks. As a result, the tool consists of (a) a questionnaire covering more than 80 sustainability criteria in the dimensions economy, ecology, social aspects and animal welfare, (b) factsheets with explanations (scientific background and state of knowledge) for each criterion and its rating and (c) a central database. Since its introduction, over 15,000 dairy farms from about 30 dairies in Germany have participated. The project is fully funded by the participating dairies. Incentive schemes at farm level vary across dairies and range from no remuneration, through a flat-rate payment per completed questionnaire, to a condition for inclusion in bonus schemes. In all cases, remuneration is independent of the results; neither penalties nor performance-related fines are imposed. Farm benchmarking was provided to every participant to raise awareness and to serve as a continuous learning and development instrument. Regular reports allowed participating dairy processors to include the findings in the development of their own sustainability pathways and implement fact-based farmer communication and training. In-depth scientific analysis using multivariate statistical analyses informs both the public and the scientific community. After more than ten years, the project ends in 2026. We investigate the farm-level progress based on selected variables and identify persistent challenges in dairy production. Given the recent narrowing of the sector's sustainability focus to climate impact, we discuss lessons learned in the context of a climate-smart development of German dairy farms.

Outlook of a dairy farmer from Northern Germany: Strategies for resilient milk production

J. Riecken[1], R. Loges[2]
[1] Grünhof Dairy Farm, Zum Grünhof, 24245 Grossbarkau, Germany, [2] University of Kiel, Department of Animal Nutrition and Feed Science, Ludewig-Meyn-Straße 9, 24118 Kiel, Germany

Northern Germany is considered a favourable region for milk production in Northwest Europe. Comparatively, mild temperatures and favourable rainfall patterns ensure high and stable forage yields. However, milk production in this region also faces challenges: Intense competition for agricultural land has led to high lease and purchase prices for agricultural area. Farmers here underlay strict regulations with respect to nitrogen and phosphorus fertilisation. Also, in this region societal demands regarding animal welfare have increased, and a lack of sufficient dialogue has led to a decline in public acceptance of modern agriculture. Generally rising wages, exacerbated by a shortage of skilled workers, make it difficult to recruit and retain suitable employees. After a period of high milk prices, these have fallen again, and while production costs have remained high, many farmers are finding it difficult to operate profitably. Anticipating these long-term developments, the Grünhof farm's long-term strategy was to reduce feed and production costs and to become as independent as possible from the labour market. The central strategy is the combination of pasture-based milk production with high-performing animals, automatic milking systems, and a barn designed with animal welfare in mind. Grazing combined with high animal welfare standards ensures high public acceptance and also results in healthy, well-trained cows with few hoof problems, thus reducing veterinary costs. Consistent seasonal calving in autumn allows for targeted feeding of the animals for peak performance during the winter months, when the cows are kept indoors anyway. This also ensures healthy calves, as the calf barn is empty for periods of time, which reduces infection risks. The robust calves can be kept on pasture cost-effectively from their first year. The cows are turned out to pasture at the beginning of April. Day and night grazing is offered to the cows from early Mai to the end of September. Through targeted grazing management, pasture growth covers most of the demand for forage; only straw and limited amounts of concentrates are supplemented, thus reducing feeding costs in this period. The highly digestible, protein-rich pasture grass reduces the need for concentrated feed by 20% compared to the regional average. Twice a day, after visiting the milking robots, the cows receive access to a new area with fresh grass (AB system), thus motivating them to use the milking robot also during grazing season without spending extra time fetching them. Autumn calving allows for optimal utilisation of the generally higher milk prices in the winter months and gives the farm manager the opportunity to focus more on forage production and also to spend holidays and leisure time with the family during spring and summer, as there are no calvings or inseminations during this period, and no calves need to be fed. Instead of the otherwise typical regional strategy of increased herd sizes combined with high lease payments, Grünhof farm is generating a sufficient income with 140 high-yielding Holstein-Frisian cows based on only an equivalent of 2 full-time employees and comparably low feed costs. This approach allows for relative independence from the labour market and simultaneously frees up time for family and leisure. Grünhof acted as pilot-farm in the EU-Horizon2020-project R4D – Resilience for Dairy and a well reported example for future sustainable and resilient milk production.

Key developments and scientific focus fields in European dairy farming systems

G. Van Duinkerken[1]
[1] Wageningen Livestock Research, De Elst 1, 6708 WD Wageningen, Netherlands

Food systems worldwide are undergoing major transformations driven by population growth, climate change, geopolitical tensions, and shifting societal expectations regarding sustainability, health, and ethics. The global demand for animal source food products is still rising. It is projected that global per capita consumption of animal-source foods will continue to increase, particularly in lower-middle-income countries. Also in Europe, livestock production is a major element of the food system. In 2024, approximately 41% of the estimated value of the European Union's agricultural output originated from animals and animal products. At the same time, livestock populations in the EU have declined by 8–16% over the past decade, reflecting structural adjustments driven by economic pressures, environmental regulations, and changing consumption patterns. In contrast, European poultry meat production is following an upward trend for the last 15 years. Dairy production in the European Union has expanded in the last decades, but in recent years stabilised at an annual level of about 160 million tonnes. It is expected that this consolidation will continue in the next few years and that transforming production systems towards increased sustainability and resilience will be a European focal point. In 2025, the European Commission (EC) presented its Vision for Agriculture and Food. The main objective for 2040 is an agri-food system that is attractive, competitive, sustainable and fair for current and future generations. To enable this, the EC puts research, innovation, knowledge and skills at the heart of Europe's agri-food economy. This presentation discusses current challenges related to the food system, the role of livestock within sustainable and circular agri-food systems, and the main trends shaping livestock farming in Europe from both practical and animal science perspectives. The future of European dairy farming systems will be the core element of the presentation. Key themes include climate-smart production, biodiversity, One Health, animal welfare, digitalisation, and incentives for change of human behaviour.

Which livestock systems best address both food insecurity and climate change? Comparing cattle, pig, poultry, rabbit, and snail systems in Cameroon.

L. Germer[1,3], M. Moleman[1,3], J. Tabot[2], C. Van Middelaar[1], S. Oosting[1], E. Kingsley[2], P. Gerber[1,3]
[1] Wageningen University and Research, Animal Production Systems, De Elst, 6708 WD Wageningen, Netherlands, [2] Institute of Agricultural Research for Development of Cameroon, Institut de Recherche Agricole pour le Développement, NA Yaoundé, Cameroon, [3] The World Bank Group, 1818 H Street NW, DC 20433 Washington, DC, United States

Ruminants play a central role in food security, rural livelihoods, and climate resilience across Sub-Saharan Africa (SSA), yet they also contribute substantially to agricultural greenhouse gas emissions and must adapt to increasing climate shocks and variability. While many studies assess productivity, resilience, and mitigation within ruminant systems, there is limited comparative evidence positioning ruminants within the wider livestock sector to clarify how their functions, benefits, and climate vulnerabilities differ from those of other species. The objective of this study is to apply the framework of Germer et al. (2023) to evaluate food security and climate-related outcomes of major livestock systems in Cameroon—specifically cattle, pigs, poultry, and selected non-conventional species (rabbits and snails)—and to clarify the distinctive role of ruminants within this broader context. Using farm-level survey data collected in 2022 in collaboration with Cameroon's Institute for Agricultural Research for Development (IRAD), we construct a structured set of locally validated, expert-informed indicators related to food security, climate vulnerability, and mitigation potential. The analysis spans multiple spatial scales, covering Cameroon's five agroecological zones, and major livestock production systems (pastoral, mixed crop–livestock, and more intensive systems). The selected indicators are designed to capture both short-term system responses to climate shocks and longer-term structural characteristics influencing adaptive capacity and sustainability trajectories. By situating ruminants within the broader livestock portfolio, this study provides comparative insights into how the ruminant sector contribute to food security, income stability, and climate resilience compares to other species, while also highlighting trade-offs in greenhouse gas mitigation potential. These findings support more informed livestock sector planning and identify pathways to strengthen the sustainability of broader food systems under a changing climate.

Current developments in the dairy sector in the USA

A. De Vries[1]
[1] *University of Florida, Department of Animal Sciences, 2250 Shealy Drive, Gainesville, FL 32608, United States*

The dairy sector in the USA continues to undergo tremendous change. This is evident by the rapid reduction in the number of dairy farms, and the growth of the average cow herd size. The average dairy farm now has approximately 400 dairy cows (not including youngstock), but it is quite common to see dairy farms with thousands or tens of thousands of dairy cows. Increasingly, dairy heifers are raised on specialized heifer raising ranches, often in the middle part of the country. Dairy herd sizes in the USA have increased greatly in the last 20 years. Milk production in this period has increased by 31%. While the national dairy herd has been varying between 9 000 and 9 500 thousand cows, the number of licensed dairy farms has decreased from 67 000 in 2004 to fewer than 24 000 in 2025. Consequently, the average herd size is now almost 400 dairy cows (excl. youngstock). There is barely a cap on the maximum herd size, and it is not uncommon to see herds with thousands of dairy cows. Dairy farms with more than 2 500 cows, which represent only 3% of all dairy farms, produce half of the milk in the USA. This consolidation is due to geography (wide open spaces and less strict environmental regulations in many states) and a culture where competition and expansion is welcomed and celebrated. One finds many abandoned older dairy farms. The reduction in the number of active dairy farms, and dairy farm families, means a strain on the viability of small towns in rural USA and a sense of loss of community. These farms are owned by fewer dairy farm families, who may own multiple farms in multiple states. These families may also have (co)ownership of processing facilities. Thus, the dairy sector follows the integration models of the poultry and pig sectors. The milk processing capacity in the country is growing strongly. Consolidation is also occurring in the allied dairy sector, where fewer but larger firms serve the dairy sector. Collectively, there remains a drive to become more productive, more efficient, more environmentally sustainable, and more profitable. Given the large variation in efficiency, some dairy farms are very profitable while many older, smaller, traditional operations struggle to remain viable. The lack of interest of the next generation to take over the dairy farm is often the main factor for farm closure. There remain strong research and investments in improved production, reproduction, genetics, nutrition, health, and labor management. Technologies driven by artificial intelligence are becoming more accepted. For example, these technologies aim to interpret the many data collected through wearable sensors, milking parlors, genomic testing etc. and offer actionable advice such as for animal treatment, replacement, and insemination decisions. Another example is the use of cameras to monitor worker task compliance, such as in milking parlors. The shortage of purebred beef owned by beef producers has led to a boom in the use of beef semen on dairy cows and a sharp increase in the use of dairy sexed semen. About 75% of all dairy heifer calves are born from sexed dairy semen. The price of 1-week old crossbred (beef-on-dairy) calves is more than US$ 2000 in some markets, prices that were unbelievable just a few years ago. The sale of these beef-on-dairy calves is now an important source of income for many dairy farms. Consequently, the number of dairy heifers produced has been reduced, which is leading to a shortage of heifers. It remains to be seen if this shortage will increase cow longevity. “Right sizing” animal inventories, which is the logistics of producing the right number of dairy animals at the right time, receives considerable attention. In conclusion, the US dairy sector is very dynamic with rapid changes, including adoption of modern technologies.

CO2 tax and N-legislation constrain Danish dairy production

N. I. Nielsen[1]
[1] *SEGES Innovation, Livestock, Agro Food Park 15, 8200 Aarhus N, Denmark*

The Danish parliament decided in 2021 that Danish dairy farmers should decrease the enteric methane emission form their cows by 6% in 2025 and increasing to 25% in 2029. Furthermore, a newly established Green Deal in the Danish Parliament obliges Danish dairy farmers to pay a CO2-tax from 2030 on GHG-emissions from cows and their manure. New legislation from 2027 has the purpose to reduce N-leaching markedly by changing the N fertilization from an N-supply quota on crop level to an N-leaching quota on field level. This will especially impact Danish Dairy farms and have consequences for their roughage production, amount of purchased feeds and thereby ration composition. Eventually, it can also limit number of Danish dairy cows.

Regenerative agriculture as an evolving concept: emergent practices and farmer decision-making in Dutch dairy farming

J. Threels[1], E. Bokkers[1], E. De Olde[1]
[1] Wageningen University, Animal Production Systems, De Elst 1, Wageningen, 6708 WD Wageningen, Netherlands

Regenerative agriculture (RA) is increasingly promoted as a response to pressing sustainability challenges, yet its loosely defined and context-dependent nature makes it both broad in appeal and difficult to study rigorously. To address this complexity, this research focuses on regenerative practices within Dutch dairy agriculture, a sector confronting urgent challenges related to biodiversity loss, soil quality, and nitrogen deposition. Specifically, this study aims to identify the emergent characteristics and applied practices of regenerative dairy farming, and to explore how farmer knowledge, discourse, and decision-making shape the transition towards RA. Data were collected through two rounds of in-depth interviews with 28 pioneering RA dairy farms participating in the ReGeNL transition programme, actively applying innovative or alternative practices that distinguish them from conventional Dutch dairy farming. The first round captured farm system characteristics, farmers' conceptualisation of RA, and the underlying reasons why farms are organised the way they are, including motivations and potential situational limitations. The second round gathered detailed dairy farm and herd management data, covering grazing strategies, feed composition, breed choices, and medical intervention plans. Notably, the pioneering farms interviewed tended to manage larger land areas with smaller herd sizes than the Dutch dairy average, reflecting a broader orientation towards extensification. Preliminary analysis of farm interviews revealed that farmers' understanding of RA centred primarily on strengthening natural closed cycles and reducing dependence on external inputs. Soil health was identified as the most important theme in transitioning towards RA, followed by animal health, welfare and production, with biodiversity and farm economics jointly ranked third. Beyond sustainability, farmers consistently cited ease of workload, economic considerations, and personal beliefs as defining factors shaping their management and farm design choices. The second round of interviews further revealed considerable variation in how these principles are translated into practice, spanning grazing strategies, breed composition, and feeding regimes, which reflects the context-dependent and emergent nature of RA. These findings highlight that the transition to regenerative dairy farming is deeply embedded in farmer identity, pragmatic constraints, and local context, consistent with the context-dependent nature emphasised in broader conceptualisations of RA. This conceptual complexity, and the considerable variation observed across farms, underscores the need for research approaches that link tangible farm-level outcomes with farmer discourse to offer a more complete understanding of RA's potential, limitations and trade-offs for the dairy sector.

Producer Mental Health and Wellbeing as a Critical Component of a Resilient and Sustainable Agricultural System: Insights from Canada

H. Watson[1]
[1] *Farm Management Canada, 21 Florence St., K2P0W6 Ottawa, Canada*

The mental health and wellbeing of agricultural producers has emerged as a critical issue for the sustainability of the agricultural sector and all those who rely on it across the globe. Farming is widely recognized as a demanding profession characterized by economic uncertainty, long working hours, social isolation, and environmental and social pressures, all of which can contribute to stress, anxiety, and depression among producers. Studies in Canada and internationally suggest farmers face elevated mental health risks compared with the general population, highlighting the need for sector-specific understanding and support strategies. Canada's dairy sector presents a unique context in which to explore these challenges. Dairy farming systems in Canada vary widely in terms of scale, labour structure, technology adoption, and management practices. These differences can shape the daily experience of producers and influence both risk factors and protective factors associated with wellbeing. Understanding the factors that contribute to and alleviate stress, and how production systems interact with producer management practices and the health and wellbeing of producers is therefore essential to building resilience for livestock systems and the agricultural sector at large. This presentation will synthesize findings from Canadian research initiatives examining producer mental health and wellbeing and management practices, with a particular focus on dairy farmers. Drawing on national surveys of farmer mental health, sector-specific research, and studies examining structural and management practices and characteristics of dairy operations, the analysis highlights key stressors affecting producers and identifies factors associated with resilience and positive wellbeing outcomes. Evidence from Canadian studies indicates that producers experience high levels of stress related to the unpredictability of the agricultural sector, financial pressures, workload demands and the responsibility associated with managing family farms. At the same time, research suggests that farm structure and production systems can influence wellbeing in different ways. For example, labour availability, automation, herd size, and management intensity may affect workload, time flexibility, and social support networks. The presentation will also discuss how broader sector initiatives, including national research collaborations and producer wellbeing programs, are beginning to address mental health challenges in Canadian agriculture. By bringing together insights from several studies and initiatives, this work aims to highlight the importance of integrating human wellbeing into discussions of sustainable livestock production. Supporting the health and wellbeing of dairy producers is essential not only for individual and family wellbeing but also for the long-term resilience and productivity of dairy farming and the agricultural sector as a whole.This synthesis contributes to a growing body of knowledge on farmer wellbeing and provides insights relevant to researchers, policymakers, and industry organizations seeking to design effective, evidence-based supports for producers. Strengthening producer wellbeing must be recognized as a key component of resilient and sustainable agricultural systems.

Milk Quality Driven by Training Programs and Technical Support in Small and Medium Scale Dairy Farms

L. C. Roma Junior[1], L. El Faro[2], M. Perissinotto[3], W. V. B. Soares[1]
[1] Instituto de Zootecnia, Divisao de Pesquisa e Desenvolvimento de Bovinos Leiteiros, Rua Heitor Penteado 56, 13380011 Nova Odessa, Brazil, [2] Instituto de Zootecnia, Divisao de Pesquisa e Desenvolvimento de Bovinos de Corte, Rodovia Carlos Tonanni, SP-333, Km 94., 14174-000 Sertaozinho, Brazil, [3] Coordenadoria de Assistencia Tecnica Integral, Escritorio Regional de Piracicaba, Rua Campos Salles, 507, 13400-200 Piracicaba, Brazil

The quality of milk is directly influenced by management practices, worker training, and the adoption of appropriate technical procedures. Continuous assistance and training programs have emerged as effective strategies to improve microbiological and compositional indicators and to support quality-based payment systems. This study aimed to assess, over a three-year period, the effects of training and monthly technical assistance on milk quality and on bonus indicators received by producers. The study was conducted on 44 dairy farms in Piracicaba, SP, Brazil, from 2017 to 2019. In the first year, farms were only monitored to establish a baseline for milk quality indicators. In the following years, a structured technical assistance program was implemented, including monthly visits, quarterly training sessions, and monthly reports with analytical results and management recommendations. Monthly bulk-tank samples were collected using bronopol vials for composition and somatic cell count analyses, and azidiol vials for standard plate count. All samples were processed following laboratory protocols, and quality-based payment was evaluated using the cooperative's bonus table. A mixed model with repeated measures was used, considering farm as a random effect and year as a fixed effect. The intervention significantly reduced standard plate count (-60%; $P<0.001$) and somatic cell count (-19%; $P=0.033$), while fat, protein, and SNF remained stable. Although overall bonus payments did not change, group-based analysis revealed important contrasts: producers who increased bonuses improved all components, raising the bonus from 2.3% to 5.2%, whereas those who reduced bonuses improved only SPC and SCC, with a decrease from 6.3% to 3.3%, indicating lower adherence to recommendations. Beyond farm-level improvements, the results highlight the broader impact of structured training and technical support on the regional dairy sector. By strengthening producers' technical capacity, promoting consistent adoption of best practices, and improving decision-making based on analytical feedback, these programs enhance production efficiency, reduce avoidable losses, and contribute to more stable and predictable economic outcomes. Such improvements are particularly relevant for small and medium-scale farms, which often face greater vulnerability to market fluctuations and sanitary challenges. From the consumer perspective, the widespread implementation of improved hygiene and management practices results in safer, higher-quality dairy products, reinforcing trust in the supply chain and supporting the long-term development of the sector. Moreover, as milk quality improves at the regional level, processors benefit from more uniform raw material, potentially reducing processing costs and increasing the value of final products. Overall, continuous technical assistance and periodic training led to meaningful improvements in milk quality, especially through reductions in microbial load and somatic cell count. When aligned with quality-based payment systems, these improvements contribute not only to the economic and productive sustainability of dairy operations but also to the broader resilience, competitiveness, and advancement of the regional dairy sector. (FAPESP PDIP 2017/50339-5)

Examination and comparison of measured and scored body conformation traits of German Holstein cows in 2015 and 2025

M. Rozing[1], D. Warder[2], F. Rosner[1], H. Scholz[3], A. Braune[4], C. Schmidtmann[5], M. Wensch-Dorendorf[1]
[1] Martin Luther University Halle-Wittenberg, Institute of Agricultural and Nutritional Sciences, T.-Lieser-Str. 11, 06120 Halle/Saale, Germany, [2] German Livestock Association, Adenauerallee 174, 53113 Bonn, Germany, [3] Anhalt University of Applied Sciences, Faculty LOEL, Strenzfelder Allee 28, 06406 Bernburg, Germany, [4] RinderAllianz GmbH, Am Bullenberg 1, 17348 Woldegk, Germany, [5] vit w.V., Heinrich-Schröder-Weg 1, 27283 Verden, Germany

Conformation traits in dairy cattle are usually recorded as a score from 1 to 9. These traits are typically assessed between the 50th and 100th day of lactation after the first calving. In 2015, in a project involving multiple breeding organizations, the conformation traits of approximately 1,200 Holstein cows were recorded after their first calving in Germany. In addition, eight traits were measured in 2015, six of which were also scored as conformation traits – such as body depth, rear udder height and rump width – and were therefore objectively recorded. In 2025, after approximately 10 years of genomic selection, during which genotyping of cows became standard practice, this objective recording of conformation traits was carried out again on approximately 2,100 Holstein cows, 1,871 of these could be used after a quality check. In 2025, 13 traits were measured, seven of which were also available as scored conformational traits, five of which were the same as in 2015. The differentiation ability (discriminatory power) of the trait scoring system was evaluated at the two time points separately (2015 and 2025) by comparing the LS-means of measured values across score levels, and together. LS-means for the scored traits rump width and body depth were significantly higher in 2025 compared to 2015, while those for rear udder height and median suspensory were significantly lower. The discriminatory power of the scoring system remained adequate, as LS-means mostly differed significantly between score levels for 2015 and 2025. Additionally, LS-means for both timepoints (2015 and 2025) were calculated to assess changes in the traits over the decade of selection. For most of the measured and scored traits, a significant increase in LS-means was observed from 2015 to 2025, reflecting consistent phenotypic changes over the ten-year period. However, these shifts do not necessarily imply optimality with regard to functionality or requirements of modern production systems. Finally, Pearson correlations between measured values and scores were calculated to determine the degree to which the scores reflected the actual trait variation. The correlations were all positive except for rear udder height and ranged between 0.41 and 0.59, or -0.56 for rear udder height in 2025, and thus remained almost unchanged compared to 2015. The observed phenotypic trends likely reflect broader breeding developments in dairy cattle breeding in Germany and other highly developed dairy regions, where genomic selection has accelerated genetic change and breeding goals increasingly emphasize functionality, udder health, and longevity alongside production traits. At this point and from a practical perspective, the results indicate that conventional conformation scoring systems remain a robust and informative tool for breeding programs and herd management even under ongoing genomic selection. At the same time, the moderate correlations between scores and objective measurements highlight the potential of more precise and automated phenotyping approaches to complement existing evaluation systems in the future. Overall, these results support the continued use of traditional scoring while encouraging the integration of high-resolution phenotyping technologies to further enhance dairy cattle evaluation and breeding strategies.

Evaluating greenhouse gas emissions of different breeding sheep pilot farm in Latvia

D. Ruska[1], L. Berzina[2], D. Kairisa[1], D. Barzdina[1], L. Paura[2]
[1] Latvia University of Life Sciences and Technologies, Institute of Animal Sciences, Liela str. 2, LV3001 Jelgava, Latvia, [2] Latvia University of Life Sciences and Technologies, Faculty of Engineering and Information Technologies, Liela str. 2, LV3001 Jelgava, Latvia

Prudent use of natural resources is essential for the quality of life of inhabitants today, tomorrow, and for the future. The Intergovernmental Panel on Climate Change (IPCC) has developed guidelines for national greenhouse gas inventory and monitoring, which require extensive and reliable data. Previous studies on emissions produced by different species of agricultural animals, which form the basis of the IPCC guidelines, need to be updated to reflect the specific conditions of each country. Continuous and reliable data recording is required in all livestock sectors so these data can be used for various forecasts, including the calculation of greenhouse gas (GHG) and ammonia emissions under Latvian conditions. Data collection is an integral part of the development and updating of greenhouse gas inventories and must be adapted to Latvian conditions and periodically reviewed as part of the implementation of good practice. Currently, the volume of research on emission levels from individual agricultural animal species under Latvian conditions and within different livestock farming systems is insufficient. This research aims to verify the findings obtained from IPCC guidelines and related studies under practical farming conditions by monitoring the data required for inventory calculations on farms. Furthermore, the research aims to ensure the continued recording and accumulation of these data and knowledge so that the impact of greenhouse gas and ammonia emission mitigation measures can be incorporated into national emission inventory reports. In 2023, cattle are the largest source of methane emissions from enteric fermentation processes in Latvia, where sheep account for 2.0% of them. In the project, sheep farms in Latvia are divided into two categories according to the type of production: wool–meat farms and meat production farms. The first farm is actively involved in breeding activities, ensuring intensive indoor fattening of lambs of different sheep breeds under conventional or traditional (grazing) conditions. The lambs are fattened and sold for meat production. The fattening process is carried out under controlled conditions, recording all feed placed in the feeders and the amount consumed. The actual consumption of hay and straw cannot be precisely determined, as part of it is scattered on the pen floor and becomes bedding. The farm employs a breeding specialist and a veterinarian; lambs are weighed regularly, and their health is monitored. A study on feed utilization efficiency is also being conducted on the farm. The second sheep farm operates under an organic farming system and raises several sheep breeds. The farm is involved in a breeding organization; therefore, herd monitoring and control are carried out. The farm specializes in meat production. Pastures are intensively used for feed production, with efforts made to extend the grazing period as much as possible by growing catch crops and providing animals with cheaper available feed, mainly roughage from pastures. Regular monitoring of the herd's live weight is carried out on the farm. Sheep of all age and sex groups are weighed using electronic scales. Based on collected data evaluation of GHG from each farm was estimated by used in the country inventory methodology for different farming systems depending on local circumstances. Sheep breeding is not a big source of emissions in Latvia, but it is still important to evaluate its effect on the farm level.

Environmental Sustainability as a Dimension of Sheep and Goat Product Valorization: Preliminary Results from a Carbon Footprint Study of Greek Cheeses

A. Smeou[3], M. Koureas[2], A. Manouras[2], I. Boziaris[3], E. Malissiova[1]
[1] University of Thessaly, Animal Science, Gaiopolis Campus, 41500 Larisa, Greece, [2] University of Thessaly, Nutrition and Dietetics, Argonauton 2G, 42100 Trikala, Greece, [3] University of Thessaly, Department of Ichthyology and Aquatic Environment, Fytokou Street, 38466 Volos, Greece

Sheep and goat dairy products play a crucial role in rural economies across Mediterranean regions, where traditional production systems and quality-label schemes such as Protected Designation of Origin (PDO) contribute to product differentiation and value creation. At the same time, increasing attention to environmental sustainability is reshaping the way these products are evaluated within agri-food systems and markets. Assessing the environmental performance of sheep and goat dairy products can therefore support both sustainable management practices and the valorization of traditional products. This study presents preliminary results on the carbon footprint of cheese production in a small-scale dairy plant in Greece, applying key methodological elements of Life Cycle Assessment (LCA). The case study concerns a dairy facility processing exclusively sheep and goat milk and producing several types of cheese, including PDO products such as feta and manouri, which represent important examples of differentiated small ruminant dairy products in Mediterranean markets. The assessment was conducted for a functional unit of 1 kg of packaged cheese, with system boundaries defined as "cradle to retail store" and a reference year of 2024. The analyzed stages include primary milk production, transport to the cheese plant, industrial processing, packaging, waste management, and distribution of the final product. The consumption phase and end-of-life disposal were excluded. Due to limited availability of primary data and the absence of access to commercial LCA databases, emissions were estimated using secondary emission factors derived from scientific literature and international guidelines. The results indicate a total carbon footprint of 15.42 kg CO_2-eq per kg of cheese. Primary milk production is the dominant stage, accounting for approximately 98% of total emissions (15.05 kg CO_2-eq/kg), confirming previous findings that farm-level processes largely determine the environmental profile of dairy products. In contrast, industrial processing and distribution contribute only about 2% of total emissions (0.37 kg CO_2-eq/kg). Within the dairy plant, energy consumption represents the main emission hotspot (78.40%), followed by packaging materials (19.71%), solid waste management (1.65%), and water use (0.24%). These preliminary results highlight the importance of farm-level management practices in shaping the environmental footprint of sheep and goat dairy value chains. At the same time, documenting the environmental performance of PDO cheeses can support their broader valorization by linking traditional quality schemes with measurable sustainability indicators. Despite several methodological limitations—such as the use of secondary emission factors and aggregated energy data—the study provides useful insights for identifying emission hotspots and guiding mitigation strategies. It also contributes to addressing a research gap regarding the environmental assessment of sheep- and goat-milk cheese production in small-scale Greek dairy plants.

Translational rumen microbiome research to improve cattle production sustainability

L. Guan[1]
[1] The University of British Columbia, Faculty of Land and Food Systems, 2357 Main Mall, BC V6T 1Z4 Vancouver, Canada

Novel and adoptable technologies are needed to improveg feed efficiency while reduce enteric methane (CH4) emission in global ruminant production systems. Methane (CH4) is the second most important greenhouse gas (GHGs) that contributes to climate change, and it is the most significant source of emissions from ruminants in the Canadian agriculture sector. Ruminants have evolved to possess a diverse population of microbes in their rumen that can convert forage into nutrients for animal growth. This symbiotic microbiota can degrade most complex plant polysaccharides to produce short chain fatty acids, proteins, and vitamins, which satisfy the animal's energy requirement for maintenance and growth. However, this process also leads to the production of enteric CH4. There is growing evidence that composition and function of rumen microbiomes have both beneficial and detrimental impacts on cattle productivity, methane emissions, product quality and cattle health. This presents an opportunity to develop translational microbiome solutions to improve productivity and reduce the environmental footprint for cattle production. This presentation will introduce the recent research advances in rumen microbiome and discuss the opportunities to develop novel and industry adoptable microbiome solutions to improve feed efficiency and reduce methane emissions in beef and dairy cattle. Suchmanipulation solutions will lead to novel breeding and dietary supplementation strategies and targeted precision management to lower methane emission from dairy and beef cattle aligning with Canada's goal of Net Zero emissions from Agriculture by 2050.

Genome-wide analysis indicates host genetic control of ruminal microbial traits in Holstein cows

I. T. Vourlaki[1], O. Furman[2], L. R. Porto-Neto[3], I. Tapio[4], D. Fischer[4], L. L. Guan[5], S. M. Waters[6], P. B. Pope[7,8], D. P. Morgavi[9], A. Reverter[3], I. Mizrahi[2], Y. Ramayo-Caldas[1]

[1] IRTA, Animal Breeding and Genetics, Caldes de Montbui, 08140 Barcelona, Spain, [2] Ben-Gurion University, Beerseba, 8410501 Beerseba, Israel, [3] CSIRO, Brisbane, 4067 Queensland, Australia, [4] Luke, Jokioinen, 31600 Jokioinen, Finland, [5] University of British Columbia, Faculty of Land and Food Systems, Vancouver, 2357 Vancouver, Canada, [6] University of Galway, School of Biological and Chemical Sciences, Galway, H91 TK33 Galway, Ireland, [7] Queensland University of Technology, Centre for Microbiome Research, Queensland, 4000 Queensland, Australia, [8] Norwegian University of Life Sciences, Faculty of Chemistry, Biotechnology and Food Science, As, 1432 As, Norway, [9] INRAE, UMR Herbivores, Saint-Genès-Champanelle, 63122 Clermont, France

The bovine rumen microbiota is a complex and dynamic ecosystem that influences many physiological processes, with major implications for cattle productivity and environmental sustainability. Emerging evidence indicates that host genetic variation influences the composition of ruminal microbes; however, the biological mechanisms and metabolic pathways that govern host regulation of these microbial communities are still not well understood. To address this deficiency, we evaluated host genetic control of ruminal microbial communities and their association with host performance by conducting genome-wide association studies (GWAS) on 593 microbial traits in 816 Holstein cows, using 4,549,172 imputed single nucleotide polymorphisms (SNPs) with imputation accuracy $r2 \geq 0.8$ and minor allele frequency ≥ 0.05. Microbial traits included clr-transformed abundances of six Rumino-signatures (RS), 118 microbial genera (102 bacterial, 10 archaeal, and 6 protist), and 469 amplicon sequence variants (439 bacterial, 8 archaeal, and 22 protist). We identified 5,201 significant SNP associations (q-value < 0.05), which clustered into 67 non-overlapping QTLs. Although associations were detected across all microbial domains, QTLs were domain-specific, with 54 linked to bacterial abundance, seven to archaea, and six to protists. Archaeal-associated QTLs predominantly involved members of the family Methanobacteriaceae, while Entodinium and Dasytricha were the most associated protist genera. Bacterial QTLs were mainly associated with the abundance of RS-RF16, Prevotella, Cryptobacteroides, Ruminococcus, Succinivibrio, Treponema, and members of the family Lachnospiraceae. Functional enrichment analysis of genes within QTLs identified pathways related to ion transport and neurophysiological signaling, including ligand-gated ion channels and calcium-dependent processes, as well as muscle contraction–related pathways. Gene ontology analysis further highlighted enrichment of synaptic signaling, regulation of cellular calcium homeostasis, membrane transport activities, and metabolic pathways involving NAD^+ and extracellular matrix components. Notably, pleiotropic associations of lead SNPs within QTLs were primarily observed with host performance traits including methane emissions, milk lactose content, and milk fat composition. In summary, our findings highlight the complexity and polygenic nature of the ruminal microbial ecosystem and suggest that shared host genetic factors may influence both microbial communities and host performance traits. Moreover, we identified candidate genes and pathways involved in host control of the ruminal ecosystem, with potential implications for hologenomics-based breeding strategies.

Host genomic influence on Gut microbiome diversity and composition in Atlantic salmon during Saltwater production phase.

E. O. Odah[1], H. Dvergedal[1,2], J. Ødegård[1], G. Klemmetsdal[1], A. Vera Ponce De Leon[1], S. R. Sandve[1], L. Hall[3], G. F. Difford[1]

[1] Norwegian University of Life Sciences (NMBU), Department of Animal and Aquacultural Sciences, Oluf Thesens vei 6, P.O. Box 5003 Ås, Norway, [2] AquaGen, Breeding and Genetics, Torgard, 7462, Postboks 1240 Trondheim, Norway, [3] University of Birmingham, Institute of Microbiology and Infection, Edgbaston Birmingham B15 2TT, P.O. Box 5003 Birmingham, UK, United Kingdom

The gut microbiome influences nutrient utilization and resource efficiency in Atlantic salmon (Salmo salar). However, the extent to which gut microbiome diversity and composition are under host genomic control in salmon during the saltwater production stage is not well understood. The objectiveof this study was to estimate the additive genomic contribution to gut microbiome diversity and composition. Host genomic contributions to gut microbiome variation were evaluated in 425 Atlantic salmon. Distal intestinal digesta were collected postmortem when fish reached a mean body weight of 1,301.5 g. The fish population consisted of 30 full-sib families reared in eight tanks within a standard recirculating aquaculture system. Gut microbial communities were characterized by sequencing the 16S rRNA gene (V3-V4) region using Illumina MiSeq platform. Sequence data were processed using DADA2 pipeline, yielding 10,069 amplicon sequence variants (ASVs). Taxonomy was assigned using the SILVA v138.1 database (80% bootstrap). Fish were genotyped using AquaGen's custom Axiom® 56K SNP array, and 47,792 SNPs were used to construct the genomic relationship matrix. Genomic linear mixed models were fitted in ASReml 4.2 using REML to estimate additive genomic variance for each microbiome phenotype (alpha diversity, Faith's phylogenetic diversity, beta diversity, and individual taxon abundances). At the ASV level, heritability was estimated for most prevalent taxa (n = 243), and likelihood ratio tests were performed on each ASV additive genomic variance to identify heritable and non-heritable taxa. PERMANOVA was performed on unweighted and weighted UniFrac distances to test the effect of tank on microbial community structure. The gut microbiome of saltwater Atlantic salmon was dominated by Firmicutes (66%), followed by Proteobacteria (10%), Actinobacteriota (8%), and Bacteroidota (6%). At the genus level, Caldanaerobius (42%) was most abundant, followed by Romboutsia (8%), with other genera observed at lower relative abundances. Tank effects were significant but small, explaining 3.9% (unweighted UniFrac) and 3.4% (weighted UniFrac) of the variation. Heritability estimates for alpha (0.00-0.02) and beta (0.01-0.02) diversity phenotypes were low, with no significant genomic contribution. At the ASV level, heritability ranged from 0.00-0.12 (mean 0.02). Seven heritable taxa were identified: Caldanaerobius ($h^2 = 0.11$), Thermoanaerobacterium ($h^2 = 0.08$), Limnobacter ($h^2 = 0.07$), Candidatus Brocadia ($h^2 = 0.06$), Geminicoccaceae ($h^2 = 0.06$), Geitlerinema ($h^2 = 0.06$), and TM7a ($h^2 = 0.06$). Host genomic influence on gut microbiome diversity and community structure was low, with significant additive genetic variance observed only in a few taxa. These results indicate that microbiome phenotypes may exhibit lower heritability in aquaculture systems compared to what is observed in terrestrial livestock species. Keywords: Atlantic salmon, gut microbiome diversity, host genomic control, heritabilityof microbial taxa, microbiome phenotypes.

CowPi 2: Enhanced functional inference from rumen microbiome 16S rRNA data using a comprehensive genome database

C. Creevey[1], J. P. Wilkins[1], L. Dillon[1], N. Dimonaco[1], K. Lawther[1]
[1] Queen's University Belfast, School of Biological Sciences, 19 Chlorine Gardens, BT9 5DL Belfast, United Kingdom

Background and objectivesMetataxonomic 16S rRNA gene sequencing remains the most accessible approach for characterising rumen microbiome composition, yet provides limited insight into functional capabilities. We previously developed CowPi, a rumen-focused implementation of the PICRUSt functional inference tool, which predicts microbial metabolic potential from 16S profiles using a reference database of ~500 cultured rumen genomes (Wilkinson et al., 2018, Front. Microbiol. 9:1095). Whilst CowPi demonstrated improved accuracy over generic PICRUSt for rumen samples, the limited genome database restricted taxonomic coverage and functional resolution. Here we present CowPi 2, which expands the reference database to 63,487 genomes and metagenomically assembled genomes (MAGs) from the HoloRuminant project, and implements the updated PICRUSt2 framework with improved phylogenetic methods and functional prediction algorithms. MethodsWe have constructed CowPi 2 using genomes and MAGs from the Hungate 1000 collection, BV-BRC, MGnify, and rumen metagenomic studies. The database encompasses eight ruminant host species sampled from ten body sites. All genomes underwent quality assessment using CheckM2, with stratification enabling selection of appropriate genome sets. Taxonomic classification employed GTDB-Tk, revealing representation across Bacteroidota, Firmicutes, Proteobacteria, Methanobacteriota, and Actinobacteriota. Functional annotation utilised eggNOG-mapper and Bakta. We extracted 16S rRNA genes using Barrnap, with recovery rates exceeding 90% in high-quality isolate collections and were used to generate a phylogenetic reference tree. Implementation follows the PICRUSt2 framework with improved hidden state prediction algorithms and expanded functional databases including enzyme commission numbers and MetaCyc pathways. ResultsCowPi-2 represents a 127-fold expansion in genome database size compared to the original implementation, with expanded taxonomic coverage including rumen-specific Prevotella lineages previously underrepresented in public databases. Quality metrics demonstrate variable completeness and contamination, with high-quality genomes (>90% completeness, <5% contamination) predominantly from isolate collections, medium-quality genomes (50-90% completeness, <10% contamination) from mixed sources, and draft-quality genomes from MAG collections. This stratification enables users to balance comprehensiveness against accuracy. Functional annotation shows expected enrichment in carbohydrate metabolism, energy production, amino acid metabolism, and cell wall biogenesis. The complete database, including quality assessments, taxonomic classifications, functional annotations, 16S rRNA sequences, metadata, and workflows, has been deposited in an open-access repository. Discussion and conclusionCowPi-2 leverages the improved hidden state prediction algorithms in PICRUSt2 with an extended ruminant-specific microbial genomic dataset. Validation studies with paired metagenomic and metatranscriptomic datasets have quantified improvements. This resource enables improved functional inference from ruminant-associated 16S rRNA datasets, facilitating investigation of rumen microbiome function in relation to animal productivity, health, and environmental sustainability, whilst providing a foundation for hypothesis generation to guide targeted metagenomic studies.

An Expanded Isolate and Genome Collection of Rumen Bacteria Reveals Microbial Signatures of Feed Efficiency in Cattle

L. Scott[1], A. Z. Rahman[1], A. Alizadeh[1], L. L. Guan[1,2], T. A. Mcallister[1,3], H. Derakhshani[1]
[1] University of Manitoba, Animal Science, 12 Dafoe Rd, R3T 2N2 Winnipeg, Canada, [2] University of British Columbia, Faculty of Land and Food Systems, 311A Food, Nutrition and Health building, V6T 1Z4 Vancouver, Canada, [3] Agriculture Agri-Food Canada, Lethbridge Research Centre, 5403 1 Ave S, Lethbridge, T1J 4B1 Lethbridge, Canada

The rumen microbiome is a highly specialized anaerobic ecosystem that depolymerizes complex plant polysaccharides into fermentation products that fuel ruminant's metabolism and influence feed efficiency (FE). However, a mechanistic understanding of rumen microbial function has been limited by the scarcity of large, curated isolate genome resources. To address this gap, we present an expanded genomic resource comprising 1058 high-quality, non-redundant bacterial isolate genomes recovered from the rumen of dairy cattle. Based on Genome Taxonomy Database (GTDB) classification, this collection encompasses 59 bacterial families and includes 65 putatively novel species, substantially expanding the culturable diversity of the rumen-associated microbiota. Genome-resolved annotation revealed extensive diversity of carbohydrate-active enzymes (CAZymes) across taxa, with members of the Bacteroidota phylum encoding the highest proportion relative to total coding sequences of their genomes (~7%). Glycoside hydrolases (GH; 45%) and glycosyltransferases (GT; 33%) dominated the CAZyme repertoire, with GHs exhibiting the greatest family richness (>150 families). Notably, 39 of the predicted CAZyme proteins lacked detectable homology to CAZy or UniProt databases, suggesting putatively novel enzymes primarily identified within the genomes of Caldibacillaceae and Lachnospiraceae. Functional enrichment analysis indicated strong overrepresentation of pectin-targeting activities among CAZymes. To better resolve the genomic context of CAZymes and assess whether they are co-localized within metabolic gene clusters or encoded as discrete loci, we examined their distribution relative to reconstructed metabolic pathways. Across genomes, a large diversity of predicted metabolic pathways was identified, including 64 non-redundant characterized pathways associated with central energy-conserving processes, short-chain fatty acid production, amino acid metabolism, including thiamine-dependent pyruvate oxidation, succinate and propionate formation, and flavin-linked sugar catabolism. However, most CAZymes were not embedded within these pathways but instead dispersed throughout the genome, suggesting a modular organization of carbohydrate degradation and downstream metabolism. Further, to assess the potential of CAZymes as biomarkers of FE, metagenomic reads from an independent cohort of high- and low-FE cattle (n = 24 per group) were mapped to the non-redundant CAZyme catalog. No significant differences were observed in CAZyme abundance, richness, or diversity between groups, and machine learning models based on CAZyme profiles showed only a moderate discriminatory power for FE (AUC = 0.65). However, co-occurrence network analysis revealed distinct functional architectures. High-FE microbiomes exhibited tightly connected hubs centered on hemicellulose and pectin degradation (e.g., GH3, GH39, and Polysaccharide Lyase "PL" Family 12), whereas low-FE microbiomes showed greater centrality of enzymes associated with soluble and storage carbohydrate metabolism (e.g., GH35, GT1, and carbohydrate-binding module CBM48). Together, this work provides a high-resolution genomic framework for linking rumen microbial function to host performance, establishing a foundational resource for mechanistic studies and enabling microbiome-informed strategies to improve livestock productivity.

Persistent Auxiliary Microbiome of Early Colonizers Shapes the Developing Rumen Ecosystem

O. Furman[1], I. Mizrahi[1]
[1] Ben Gurion University of the Negev, Life Sience, Ben Gurion Blvd, 8410501 Beer Sheva, Israel

The early life assembly of the rumen microbiome is a critical developmental process with lasting consequences for host physiology and greenhouse gas emissions. Using high-resolution longitudinal metagenomics in calves tracked from birth to three years (~800 days), we reconstructed 2,873 high-quality metagenome-assembled genomes, including 517 novel genomes predominantly detected in early life. These genomes, spanning 274 genera, define a diverse and functionally distinct auxiliary microbiome. Unlike transient early colonizers described in other ecosystems, this auxiliary community persists into adulthood, retaining ecological and functional relevance despite reduced abundance while contributing to the metabolic capacity of the mature rumen ecosystem. Temporal clustering revealed strong associations with dietary transitions and functional enrichments in environmental sensing, nutrient biosynthesis, and volatile fatty acid metabolism. Metabolic network analyses further demonstrated that auxiliary genomes complement non-auxiliary community members in key biosynthetic and fermentative pathways, indicating coordinated ecosystem-level interactions. These findings suggest that early colonizers act as ecosystem engineers, shaping the developmental trajectory of the rumen microbiome.

Effect of birth delivery method on microbial colonisation of key gastrointestinal regions in neonatal beef calves

M. M. Stafford[1,2], P. E. Smith[1], S. Waters[3], E. O'Hara[4], F. Buckley[2], D. A. Kenny[1]
[1] Teagasc, Animal and Bioscience Research Department, Teagasc Grange, A85 VP65 Meath, Ireland, [2] University College Cork, School of Biological, Earth and Environmental Sciences, Distillery Fields, North Mall, T23 TK30 Cork, Ireland, [3] University of Galway, School of Biological and Chemical Sciences, University Rd, H91 TK33 Galway, Ireland, [4] Canadian Forest Service, Canadian Forest Service, Natural Resources Canada, 5320 122 Street, Edmonton, T6H 3S5 Alberta, Canada

The microbial colonisation of the neonatal gastrointestinal tract is critical for digestive, immune and metabolic development. There is some evidence from human and rodent studies that Method of birth delivery can influence the initial process of microbial colonisation. The aim of this study was to investigate the effect of two birth delivery methods viz (i) transvaginal and (ii) elective caesarean section, on the microbial composition across key regions of the gastrointestinal tract of neonatal calves reared across two commercial research farms. Samples were collected immediately after birth from five gastrointestinal regions (Region); colon, ileum, jejunum, meconium, and rumen (swabs) from Aberdeen Angus calves delivered (Delivery) either transvaginally (TV; n = 11) or by caesarean section (CS; n = 11). Microbial DNA was extracted and subjected to 16S rRNA gene amplicon sequencing. Absolute microbial quantities were measured using 16S rRNA qPCR (Ct values). Alpha (Observed, Shannon, Simpson) and beta (PERMANOVA on Bray–Curtis dissimilarities) diversity were compared between delivery methods within each region, with sex and farm included as fixed effects. Differential abundance (Maaslin2) analyses were conducted with the same fixed effects. Alpha diversity varied significantly among gastrointestinal regions ($p < 0.05$) but did not differ between delivery methods within any region (all BH-adjusted $q \geq 0.78$). PERMANOVA indicated that gastrointestinal region strongly structured microbial community composition ($R^2 = 0.24$, $p = 0.0001$). A strong tendency towards a Region × Delivery interaction was observed ($R^2 = 0.057$, $p = 0.024$), indicating that any influence of delivery method was dependent on anatomical site rather than uniform across the gastrointestinal tract. Farm was not associated with statistically significant variation in community structure ($R^2 = 0.012$, $p = 0.17$), and no overall effect ($P > 0.05$) of delivery method across regions was detected. However, an analysis conducted per region detected no statistically significant treatment effects within individual gastrointestinal regions (all $p > 0.05$), suggesting that the interaction reflected modest, region-specific trends rather than strong site-specific effects. The early microbial establishment within the GIT of neonatal beef calves was therefore primarily driven by anatomical site rather than delivery method, with only weak, region-dependent differences associated with birth method. Microbial load and community composition were comparable between CS and TV calves at birth, indicating that initial gastrointestinal colonisation is largely independent of delivery method. These findings together with previous published data from our group suggest that postnatal environmental exposure and host–microbe interactions may play a greater role than birth method in shaping early gastrointestinal microbial assembly in beef calves.

Impact of pastures composition on calves microbiota in saliva, rumen and feces

C. Lauer-Weich[1,2], G. Mesbahi[3], F. Leiber[3], J. Werner[3], J. Seifert[1,2]
[1] Institute of Animal Science, University of Hohenheim, Emil-Wolff-Str. 8, 70599 Stuttgart, Germany, [2] HoLMiR – Hohenheim Centre for Livestock Microbiome Research, University of Hohenheim, Leonore-Blosser-Reisen Weg 3, 70599 Stuttgart, Germany, [3] Research Institute of Organic Agriculture (FiBL), Ackerstrasse 113, 5070 Frick, Switzerland

Rearing dairy male calves on underused pasture offers the opportunity to solve economic, sustainable and welfare associated tradeoffs. This study deals with assessing how different pasture compositions affect the calves microbiota across time. Understanding the influence on gastrointestinal settlement and development helps to understand ruminal fermentation efficiency. Three contrasting pasture compositions and one indoor system were compared by the effects on bacterial community composition. Buccal swab and feces sampling allowed repeated sampling over calves age (three- to six-month-old). Additionally, rumen fluid was collected once at the end of the experiment via esophageal probe. It is to be assumed that increase of composition and diversity of the pasture lead to higher microbial diversity. Male calves (n=72) were raised on three different composed pastures (intensive, permanent, alpine) and one hay based indoor system in Switzerland. Eighteen animals were examined per feeding system, every six were of the same genotype (Brown Swiss, Swiss Fleckvieh, Crossbreed = Limousin x Brown Swiss). Pasture composition was described by grass type and alongsides like herbs (%). Bacterial communities of buccal swabs (bioinformatically separated in oral- and rumen associated communities), rumen fluid, and feces were characterized by 16S rRNA amplicon sequencing, processed in QIIME 2 (DADA2), and taxonomically assigned using GTDB (v226). Diversity metrics (Shannon index and Bray–Curtis dissimilarities) and statistical tests (Kruskal–Wallis, PERMANOVA) were calculated in R (vegan package). Buccal swabs enabled us to collect rumen-associated samples at three time points on all locations. This challenging experimental design wouldn't allow an intensive sampling via the esophageal probe. In total 3,427 ASVs were revealed from buccal swab samples and 3,937 ASVs from rumen fluid at the end of the trial, with 1,726 ASVs overlapping in both sample sets and defined as rumen-associated ASVs in buccal swab samples. Thus, an impressive recovery of rumen bacteria could be shown using buccal swabs. As this method is less invasive and seems to be a robust method for future ruminant experiments. Microbial diversity analysis revealed the highest alpha diversity (Shannon) on almost all samples from animals at alpine pastures, followed by the permanent pasture. Beta diversity analysis showed a clustering of the indoor samples with intensive, and permanent with alpine. Changes according to the age of animals were minor while showing only no or minor significance for the diversity structure. Calves grazing alpine and permanent pastures developed richer, more diverse microbiota compared to indoor or intensive systems. In conclusion, our results support the hypothesis that greater diversity in pasture composition is associated with higher diversity and complexity of microbial communities in calves. In addition, we assume that buccal swab sampling provides a good approximation on rumen fluid microbial community.

Multi-block sPLS-DA Shows That Plasma Metabolomics Most Accurately Classifies Piglets Across Production Chains than fecal metabolomics and metagenomics

F. Correa[1], D. Luise[1], P. Trevisi[1]
[1] University of Bologna, Department of Agro-Food Sciences and Technologies, Viale Fanin 46, 40127 Bologna, Italy

Omics technologies offer powerful approaches to characterise complex biological systems and to uncover biomarkers associated with health, disease, and performance. They also hold considerable promise for describing animal production environments, where pigs are exposed to interacting management- and environment-related factors, including housing conditions, sanitary status, and antimicrobial usage, all of which may influence disease susceptibility. Given the substantial costs associated with omics analyses, determining which omics layers most effectively capture biologically relevant variation driven by management practices is of practical importance. In this study, we applied an integrative multi-omics strategy to investigate biological responses to contrasting management systems in pigs and to compare the discriminative ability of different omics datasets. Forty piglets originating from the same farrowing unit were assigned to two swine production chains (SPC1 and SPC2) that differed in housing conditions and antimicrobial protocols. Animals were monitored from weaning to slaughter. Blood haematology, plasma metabolomics, faecal metabolomics, and faecal shotgun metagenomics were collected two weeks post-weaning (T1), seven weeks post-weaning (T2), two weeks after transfer to growing–finishing facilities (T3), and at slaughter (T4). Growth performance did not differ between production chains at any sampling point ($P > 0.05$), whereas diarrhoea incidence was significantly higher in SPC2 at T1 ($P < 0.05$). Multi-omics datasets were integrated at each time point using DIABLO (Data Integration Analysis for Biomarker discovery using Latent Components). Across time points, faecal microbial functional profiles (KEGG orthologs) accounted for the largest share of variance in the discriminant components (up to 0.45 at T2), suggesting a sustained influence of management conditions on microbial metabolic potential. In contrast, plasma metabolomics consistently achieved the lowest classification error rates and highest AUROC values, outperforming both microbial taxonomic and functional profiles. At the early post-weaning stage, group separation was primarily driven by inflammatory and immune-related haematological markers, along with microbial metabolites derived from amino acid metabolism, particularly in SPC2. At later stages, discrimination was mainly associated with plasma metabolites related to lipid metabolism, xenobiotic processing, and energy pathways, together with faecal metabolites involved in carbohydrate and aromatic compound metabolism. In conclusion, this study demonstrates that plasma metabolomics is the most informative omics layer for discriminating farming conditions and capturing management-driven effects in pigs. Among the evaluated omics layers, the systemic metabolome consistently showed the strongest discriminative performance across time points, indicating a high sensitivity to differences in management practices under field conditions. This was particularly evident during the post-weaning and growing phases, when physiological responses to environmental and nutritional factors are most pronounced. These findings highlight plasma metabolomics as a robust systemic indicator of management effects, reflecting the downstream physiological consequences of farming conditions by directly capturing host metabolic responses it provides a reliable framework for identifying biomarkers of management practices and for linking interventions to animal physiology

Genome-Resolved Profiling of an Expanded Swine Gut Isolate Collection Reveals Functional Signatures of Health and Disease

A. S. M. Z. Rahman[1], F. M. Loojaly[1], S. Walkowiak[1,2], C. Yang[1], H. Derakhshani[1]
[1] University of Manitoba, Animal Science, 12 Dafoe Road, R3T 2N2 Winnipeg, Canada, [2] Canadian Grain Commission, Grain Research Laboratory, 303 Main Street, R3C 3G8 Winnipeg, Canada

High-resolution genome data are critical for resolving the functional roles of swine gut microbes. However, many swine-associated lineages remain uncultured or underrepresented in reference databases, limiting our ability to link microbial functions to host traits. Although culture-independent metagenomics provides valuable community-level insights, it often lacks the taxonomic resolution required to assign functional potential to specific organisms, thereby constraining the translation of microbiome associations into actionable strategies. This limitation is particularly consequential for post-weaning diarrhea (PWD), a major challenge in swine production that results in substantial economic losses and increased antimicrobial use. Understanding the functional capacity of gut microbes and identifying health-associated microbial features is therefore critical for the development of microbiome-based interventions to promote gut health and reduce disease susceptibility. Here, we constructed an integrated genomic resource of the swine gut and fecal microbiota comprising 300 high-quality, non-redundant bacterial isolate genomes recovered from pig gastrointestinal tract. The isolate collection encompasses 33 bacterial families, featuring several previously uncultured representatives of the Lachnospiraceae, Lactobacillaceae, Desulfovibrionaceae, Clostridiaceae, Streptococcaceae and other phylogenetically diverse lineages. Notably, the collection includes 55 putatively novel species not represented in current reference databases. Functional profiling of the isolate genomes revealed extensive diversity among both known and previously uncharacterized metabolic gene clusters, biosynthetic gene clusters (BGCs), and antimicrobial peptides (AMPs). To assess the ecological and clinical relevance of these features, we analyzed their distribution across the microbiota of pigs with and without post-weaning diarrhea. Metagenomic read recruitment from independent swine cohorts against the isolate genome database showed that key functional features, particularly BGCs and AMPs, robustly discriminated between healthy and diarrheic pigs, with significantly reduced abundance in PWD-associated host microbiomes. Several taxa, including Aneurinibacillus, Blautia, Dorea, Prevotella, Paratractidigestivibacter, and Parabacteroides emerged as dominant contributors to health-associated functional traits. Combining high-throughput culturomics with machine learning-based functional inference, this study establishes an expanded swine gut isolate genome resource and identifies microbial functional signatures linked to host health. Our findings highlight the biosynthetic potential of secondary metabolites and antimicrobial peptides as key determinants of gut resilience and provide candidate microbial biomarkers and therapeutic targets for improving resilience to post-weaning diarrhea in sustainable swine production systems.

Characterization of the core porcine microbiota across production phases, animal tissues and genetic lines in an integrated production system

G. De La Fuente Oliver[1], A. Morillo[2], P. Fernandez[3], L. Escudero[3], D. Villalba[1]
[1] Universitat de Lleida- Agrotecnio, Rovira Roure 191, 25198 Lleida, Spain, [2] Tests and Trials S.L.U, Paseo San Juan Bosco 13, 22400 Monzon, Spain, [3] Kerbest, Av. de Juan Carlos I 30, 05004 Avila, Spain

The microbiome constitutes a complex and dynamic ecosystem that plays a central role in digestive efficiency, immune modulation and reproductive performance in pigs' production. While most studies focus on the gut, a holistic, longitudinal characterization across multiple body sites and production phases within a single integrated system is essential to identify critical windows of instability and opportunities for intervention. The aim of this study was to characterize the structure, diversity and stability of porcine microbiota from sows to finishing pigs within an integrated production system. We evaluated the effects of productive phase (gestation, farrowing, weaning, fattening), sample tissue (faeces, vagina, mouth, skin and nasal mucosa), farm of origin and genetics (purebred vs. hybrid) .We hypothesized that (i) tissue type and transition periods are the main determinants of microbial structure, and (ii) farrowing and weaning/feed transitions represent phases of reduced stability and increased variability. High-throughput 16S rRNA gene sequencing was performed in three complementary cohorts:(1) sows (n=453; fecal and vaginal samples collected during insemination, gestation and peri-partum; 47.1 million sequences); (2) piglets (n=270; mouth, feces and skin samples collected from 72 h post-birth through weaning and starter phases; 27.9 million sequences); and (3) wean-to-finish pigs (n=99; mouth, feces and skin; 7.8 million sequences). Alpha diversity indices, beta diversity (PCA, PLS-DA, permanova), taxonomic profiling at phylum and genus level, and determination of the core microbiota were performed using R (v3.6), Excel and JMP programs. Core populations were defined as species present in ≥85% of samples (sows) or ≥90% samples (wean-to-finish). In sows, vaginal microbiota displayed lower alpha diversity and a markedly smaller core (25 species representing 41.7% of sequences) compared to faeces (138 species; 74.5%). The post-partum period was characterized by significantly reduced diversity ($P<0.001$), higher dispersion in beta diversity analyses and pronounced alterations in the Bacillota:Bacteroidota ratio, indicating microbial instability at farrowing. Farm of origin influenced vaginal communities more strongly than fecal ones. In piglets, sample type was the main source of variance. Skin exhibited the highest richness (277 core species) and greater evenness compared with mouth (63) and feces (49). Diversity increased progressively with age, reflecting microbial maturation, but a transient decrease was observed at weaning, particularly in gut and oral samples. Farm of origin significantly shaped community structure (PERMANOVA $P<0.001$), especially in skin. ##In wean-to-finish pigs, feed transitions induced short-term fluctuations in alpha diversity, mainly in feces and skin, followed by stabilization. Genetic background exerted moderate effects: hybrid pigs showed greater variability in fecal and skin microbiota compared to purebreds. Across tissues, core microbiota accounted for 80–92% of total sequences, indicating a relatively stable microbial backbone. As conclusion, farrowing and weaning/feed transitions represent critical windows of microbial instability and increased dispersion. Farm environment and diet are dominant drivers, whereas genetics exerts a moderate, tissue-dependent influence. Systematic monitoring of these transition periods may provide a basis for targeted nutritional, management and sanitary strategies aimed at enhancing health, resilience and production performance.

Variability of vaccine responses in laying hens: assessing the holobiont

A. Racanati[1], T. Tribout[1], L. Brulin[4], A. A. M. Sabuj[1], F. Blanc[1], A. Lecoeur[1], S. Brard-Fudulea[5], N. Bruneau[1], D. Gourichon[2], B. C. D. Cuyabano[1], T. Burlot[3], L. Becot[3], D. Schokker[6], M. Calus[7], M. H. Pinard-Van Der Laan[1], F. Calenge[1]
[1] Université Paris-Saclay, INRAE, AgroParisTech, UMR GABI, Chemin de l'homme mort, 78350 Jouy-en-Josas, France, [2] INRAE, UE PEAT, Val De Loire, 37380 Nouzilly, France, [3] NOVOGEN, rue des Compagnons, 22960 Plédran, France, [4] GD Biotech – Gènes Diffusion, 1 Rue du Professeur Calmette, 59000 Lille, France, [5] SYSAAF, Centre INRAE, Val De Loire, 37380 Nouzilly, France, [6] Animal Breeding and Genomics, Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, Netherlands, [7] Animal Breeding and Genomics, Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, Netherlands

Vaccination is essential for poultry health, yet marked inter-individual variability in vaccine responses challenges disease control and productivity. Both host genetics and gut microbiota are known to modulate immunity, but their relative contributions to vaccine responsiveness in laying hens remain unclear. This study aimed to quantify genetic and microbial influences on humoral and cellular immune responses to vaccines. A total of 552 White Leghorn hens from a single line were raised under controlled conditions to 22 weeks. Birds were genotyped using a 55K SNP array to estimate heritability and perform genome-wide association studies (GWAS). Humoral and cellular immune responses were evaluated following vaccination against newcastle disease virus (NDV), infectious bronchitis virus (IBV), avian encephalomyelitis virus (AEV), and avian pneumovirus (APV), using antibody titers and enzyme-linked immunospot assays. Caecal microbiota was characterized at 22 weeks using 16S rRNA sequencing, and analyses were performed on rarefied amplicon sequence variant (ASV) counts. Marked variability in vaccine responses was observed, with a mean proportion of birds failing to mount detectable antibody responses between 22.7% and 76.5%. Heritability estimates among responders for antibody levels treated as a continuous trait indicated null-moderate genetic influence (0.00–0.39), whereas analysing vaccine response as a binary trait distinguishing responder from non-responders revealed a moderate genetic contribution (0.22–0.40). Genetic and phenotypic correlations showed complex relationships among vaccine traits, including weak positive and negative correlations across vaccines and time points. GWAS identified significant QTLs on chromosomes 1, 4, 5, 8, 11, 15, and 28, with functional annotation highlighting genes such as MKNK1 and TRABD2B, and the non-coding RNA vaultRNA potentially contributing to immune variation. Microbiability estimates for vaccine response traits ranged from 0.10 to 0.25, indicating a contribution of caecal microbial composition for both continuous traits among responders and traits distinguishing responders from non-responders. Preliminary microbiome-wide associations studies (MWAS) revealed ASVs associated with the responder versus non-responder trait across NDV timepoints, while associations for the continuous trait appeared only for cellular immune response among responders. Overall, these findings demonstrate that host genetics and gut microbiota jointly shape vaccine responses in poultry. Moderate heritability supports the feasibility of genetic selection, while microbiability highlights substantial microbial contributions. Integrating genomic and microbiome data provides a framework to understand immune variation and to design breeding strategies combining genetics and microbiota modulation. Ongoing holobiability analyses will further quantify the combined and interactive effects of the host–microbiota system, advancing holistic approaches to improve poultry vaccine responsiveness and resilience.

Microbiota dynamics and core taxa in milk, teat skin, and feces of cows with and without mastitis

I. Tapio[1]
[1] *Natural Resources Institute Finland (Luke), Production systems, Tietotie 4, 31600 Jokioinen, Finland*

Mastitis is one of the most common and economically significant diseases in dairy production. Yet the temporal dynamics of milk, teat skin, and fecal microbiota surrounding mastitis onset remain incompletely understood. We performed a longitudinal study of 21 Nordic Red primiparous cows by weekly sampling of milk, teat skin swabs, and feces during the lactation. Twelve cows remained mastitis-free, whereas nine experienced at least one case of mastitis. Based on the health records, 373 milk and teat swabs, as well as 295 fecal samples were selected for 16S rRNA gene amplicon sequencing (primers 515F/806R). Reads were denoised to amplicon sequence variants (ASV) in Qiime 2 and taxonomically classified with SILVA 138.1. Milk bacterial community of healthy cows was highly diverse, comprising 612 genera across 28 phyla, with Firmicutes, Actinobacteriota, Proteobacteria, and Bacteroidota being most abundant. While relative abundance fluctuated across lactation, alpha diversity remained largely stable. Indicator species analysis revealed 32 ASVs associated with mastitis-free cows and 65 with mastitis-affected cows; healthy cows showed higher relative abundance of Lactiplantibacillus spp., whereas mastitis-associated samples exhibited elevated levels of Staphylococcus, Streptococcus, and Escherichia-Shigella. Bray–Curtis dissimilarities revealed no significant differences in overall community structure between affected and healthy quarters from the same cow (adonis P=0.32), suggesting that udder-level microbiota shifts precede quarter-specific clinical symptoms. Teat skin microbiota was composed of 29 phyla and was dominated by Firmicutes, Actinobacteriota and Bacteroidota, with stable core genera (Lachnospiraceae NK3A20 group, Oscillospiraceae UCG-005, Corynebacterium, Romboutsia and Methanobrevibacter) observed across lactation. Although indicator ASVs distinguished mastitis-free and mastitis-affected cows, overall taxonomic composition remained similar between groups. Fecal microbiota showed high stability across lactation and was dominated by Firmicutes and Bacteroidota. Core microbiome analysis demonstrated shared ASVs between milk, teat skin, and feces, indicating potential microbial exchange between host body sites and environmental reservoirs. The findings underscore that mastitis-associated dysbiosis is detectable in milk shortly before clinical diagnosis, that microbiota shifts occur across the entire udder rather than being confined to the infected quarter, and that overlapping core microbial populations across sample types reflect interconnected microbial ecosystems. Together, these results advance understanding of host-associated microbiome dynamics regarding mastitis occurrence.

Rumen colonization and succession of microbial guilds during lamb development is affected by the presence of the dam

L. Voland[1], P. Dou[1], J. Tournayre[1], A. Ortiz-Chura[1], A. Dehornoy[1], D. Graviou[1], K. Vazeille[2], D. Morgavi[1], M. Popova[1]
[1] INRAE, Université Clermont Auvergne, VetAgro Sup, UMR Herbivores, Route de Theix, 63122 Saint Genès Champanelle, France, [2] INRAE, Unité Expérimentale Herbipôle, Les Razats, 63820 Laqueuille, France

The health and development of ruminants are largely influenced by their microbiota, particularly the rumen microbial community, which is shaped by early-life factors and microbial colonization processes. In many sheep production systems, lambs are separated from the dam shortly after birth and reared with artificial milk to optimize labor and milk production. However, this practice may negatively affect lamb growth and health. In this work, we investigated the effect of maternal presence on the rumen microbial composition and its temporal dynamics in lambs from birth to the end of the growing period. We also assessed a method of identifying microbial groups of ecological and phenotypic significance while reducing dataset complexity, allowing improved classification of the microbiota and tracking microbial changes during early life. The study involved 19 maternal-reared lambs and 13 artificially-reared lambs without adult contact, all weaned at 7 weeks of age. Rumen contents were sampled weekly from birth to 10 weeks and once more at slaughter (17 weeks). Non-negative matrix factorisation was used to analyse the relative abundance of ASVs revealed by metataxonomic analysis, in order to identify bacterial guilds called RuminoSignatures (RS). We found that the rumen bacterial community was structured into distinct RS whose temporal dynamics varied according to rearing system and feeding conditions. Some RS predominated shortly after birth, while others increased later during the suckling period, revealing a clear temporal succession in the establishment of rumen microbial taxonomic guilds during early life. Overall, RS trajectories were influenced by both age and rearing method, suggesting that maternal presence may shape specific patterns in bacterial guild prevalence. As a perspective, we are currently evaluating the prediction of microbial guilds in ewes before lambing and at weaning to gain further insight into potential maternal influences on rumen microbial establishment in lambs. In addition, metagenomic analyses are being conducted to infer functional capacities and link microbial functions to the taxonomic profiles identified.

Associations between rumen and faecal microbiota and inflammatory status in transition dairy cows

J. Jeyanathan[1], S. Heirbaut[1], M. Zhang[1], K. Hertogs[1,2], E. Stevens[3], B. Aernouts[3], L. Vandaele[4], V. Fievez[1]
[1] Laboratory for Animal Nutrition and Animal Product Quality, Animal Sciences and Aquatic Ecology, Coupure Links 653, 9000 Ghent, Belgium, [2] Inagro, Ieperseweg 87, 8800 Rumbeke-Beitem, Belgium, [3] Hooibeekhoeve, Hooibeeksedijk 1, 2440 Geel, Belgium, [4] ILVO, Scheldeweg 68, 9090 Melle, Belgium

The transition period around calving is critical for dairy cows, due to the significant physiological, metabolic, and nutritional challenges. Growing evidence suggests that inflammation can be a major factor in transition cow health. Although a physiological inflammatory response occurs in all cows after parturition, it generally diminishes within the first three weeks postpartum. However, some animals undergo prolonged inflammation, which could negatively impact cows' health, fertility and milk production. Although the role of gut microbes in inflammation is well established in human studies, it has not been sufficiently researched in ruminants, particularly during the transition period. To investigate the relationship between inflammatory status and gastrointestinal microbial composition, 60 multiparous dairy cows from two research farms were monitored during the transition period. Blood samples collected at 21 days postpartum were analyzed for inflammatory biomarkers (serum amyloid A [SAA], haptoglobin [Hp], and albumin: globulin ratio [A: G]) and metabolic biomarkers (insulin, glucose, beta-hydroxybutyrate [BHBA] and non-esterified fatty acids [NEFA]). Rumen and faecal samples collected at 21 days postpartum and faecal samples collected 7 days prepartum were subjected to metataxonomic analysis targeting bacteria, archaea, protozoa, and fungi. Based on inflammatory biomarkers, cows were classified into two clusters: acute phase response plus diseased cows (APR+, n=20) and non- acute phase response (Non-APR, n=34) cows. Dry matter intake was lower in APR+ cows, whereas milk yield did not differ between clusters. All inflammatory biomarkers differed between clusters, while among metabolic indicators, only NEFA concentrations were increased in APR+ cows. Microbial analyses showed that rumen bacterial and protozoal communities differed between inflammation clusters, with archaeal composition showing a tendency toward a difference. In contrast, faecal microbial communities were not affected by inflammatory status either pre- or postpartum. Distance-based redundancy analysis (db-RDA) indicated that the farm was the primary driver of variation in both rumen and faecal microbiota. After accounting for farm effects, blood inflammatory and metabolic variables explained a modest but sometimes significant proportion of microbial variation. The A: G ratio was associated with differences in rumen bacterial and archaeal communities, while SAA was associated with variations in rumen fungal and protozoal composition. Differential abundance analysis revealed several rumen and faecal bacterial and archaeal taxa that varied at the amplicon sequence variant (ASV) and genus levels between clusters, indicating their potential as indicator species of inflammatory status. Accordingly, inflammation at 3 weeks after parturition is associated with shifts in the rumen but not the faecal microbiome. Although farm effects remain the dominant source of variation, the rumen microbial structure show links with some blood inflammatory biomarkers. This highlights the potential interplay between host inflammatory status and rumen microbial composition in transition dairy cows.

The effect of fat type and inclusion level on the rumen microbiome and methane in dairy cows

S. J. Noel[1], P. Lund[1], A. A. Schönherz[1], M. R. Weisbjerg[1], G. Giagnoni[1]
[1] Aarhus University, Department of Animal and Veterinary Sciences, AU Viborg – Research Centre Foulum, DK 8830 Tjele, Denmark

Dietary fat inclusion is a way to reduce enteric methane (CH4) emission in dairy cows. Different fat types contain different proportions of fatty acids (FA), however, the effects of fat types and their levels of inclusion on the rumen microbiome are poorly understood. The aim of this study was to test the effect on rumen microbiota (Bacteria, Archaea, Fungi and Protozoa) when cows were fed either a diet including rapeseed (RS) at 3 different inclusion levels (low=LR, mid=MR and high=HR) or palm kernel oil (PK) at 2 different inclusion levels (low=LP and mid=MP) or no fat (control=CO). The trial was run with 24 multiparous Holstein cows, 4 per treatment in each of 6 periods of 21 days each, with 6 treatments in a 6×6 Latin square design (N=144). Gas production and milk composition was determined. Amplicon sequencing was conducted on rumen samples for four microbial target groups, namely; Bacteria, Archaea, Protozoa and Fungi using specific primer sets. Analysis for each microbial target group included microbial composition, diversity and differential abundance. Dietary supplementation with RS at mid or high dose or PK at both doses was effective at reducing CH4 intensity (CH4/ECM) and yield (CH4/DMI). Low to mid levels of RS had a positive effect on ECM whereas PK had negative effect, particularly in the case of MP. Palm kernel oil had the greatest reduction in CH4 production at the mid dose. However, after accounting for the associated decrease in ECM, the reduction in CH4 intensity (CH4/ECM) was slightly lower than that observed for the high RS treatment (HR, 14% vs MP, 13% reduction). Rumen communities were dominated by (genera >10% reads) Prevotella, UBA2810 (Bacteria), Methanobrevibacter and Methanosphaera (Archaea), Neocallimastix, Piromyces, NY05 and NY09 (Fungi) and Entodinium, Epidinium and Isotricha (Protozoa). RS showed minor effects on the rumen microbial diversity while larger shifts were seen with PK especially in cows fed MP. Rumen Bacteria and Fungi compositions were most affected by PK, whereas the archaeal community showed comparatively smaller changes. Bacterial and archaeal richness was reduced in MP compared to all other diets, fungal richness was reduced in LP compared to all other diets and the protozoal richness was not affected by diet. Compared to the control RUG420 (Acutalibacteraceae) increased with both RS and PK diets but was the only bacterial genus detected differentially abundant across all RS levels, while 14 and 41 additional genera differed in the low and mid PK diets, respectively. For archaeal taxa, 1, 4, 1, and 6 genera were found differentially abundant in MR, HR, LP and MP diets, respectively. Methanarcanum decreased with MR, HR and MP diets, Methanosphaera increased with HR, LP and MP, and Methanobrevibacter increased in HR and MP, compared to CO. The fungal genus Buwchfawromyces dramatically increased (16-27 fold change) with all but the LR diet. Additionally, PK diets had an increase in Neocallimastix and a decrease in NY05 and NY09. RS diets had 1 differentially abundant protozoa genus at the mid (Eudiplodinium) and high (Entodinium) levels, while the PK diets resulted in a decrease in Dasytricha plus 3 additional changes at the mid levels. In conclusion, PK resulted in a greater disruption of the microbiome and the largest drop in CH4 production but was accompanied by a drop in DMI and ECM. Low RS had minimal effects on the rumen microbiome, DMI and ECM but also CH4. Mid and high levels of RS resulted in less changes to the rumen microbiome than PK and reduced CH4 measures linearly, however, feeding high RS did not provide additional ECM yield.

Effects of Heat Stress on gut microbiota in Iberian and crossbred pigs

L. Sarri[1], J. Balcells[1], E. Labussiere[2], A. R. Seradj[1], G. De La Fuente Oliver[1]
[1] Universitat de Lleida-Agrotecnio, Rovira Roure 191, 25198 Lleida, Spain, [2] INRAE, UMR Pegase, 16, le clos, 35590 Saint-Gilles, France

Heat stress (HS) in pigs reduces feed intake, productive performance, and protein and energy metabolism, while increasing water intake to maintain body temperature within physiological ranges. These physiological changes may alter the composition and functionality of the gut microbiota. In addition, elevated temperatures can disrupt gastrointestinal homeostasis, potentially leading to dysbiosis, which is associated with impaired nutrient absorption and immune suppression. The aim of this study was to evaluate the effects of prolonged HS exposure on hindgut microbial composition and predicted functionality in growing pigs, and to assess potential differences between two distinct genotypes. A 2×2 factorial experimental design was used, including 11 commercial crossbred pigs (CO; Pietrain × (Landrace × Large White)) and 11 Iberian pigs. Animals were exposed to either thermoneutral conditions (TN; 23.5°C) or heat stress (HS; 33.5°C) for 28 consecutive days. At the end of the experimental period, pigs were sacrificed and colonic contents were collected, snap-frozen in liquid nitrogen, and stored for further analyses. Microbial community composition was assessed by amplification and sequencing of the V3–V4 regions of the 16S rRNA gene using the Illumina MiSeq platform. Taxonomic assignment was performed using a Bayesian classifier (Wang et al., 2007) trained with the SILVA database version 138 (99% OTUs full-length sequences) (Pruesse et al., 2007). Alpha diversity indices (Shannon, Simpson, richness, and evenness), beta diversity analyses (PCA, PLS-DA, and permutational analyses), and taxonomic profiling at phylum and genus levels were conducted using R (v3.6), Excel, and JMP. Functional potential was predicted using PICRUSt2 (Douglas et al., 2020). No significant differences were observed in alpha diversity between the main factors, although a significant interaction was detected for Pielou's evenness index ($P < 0.05$). Permutational analysis revealed differences between breeds ($P = 0.042$), but not between thermal treatments, suggesting a possible long-term adaptation of hindgut microbiota to HS in both genotypes. Likewise, no differences were observed in the relative abundance of the main bacterial phyla. Functional prediction analysis identified differences between breeds in 21 metabolic pathways, mainly related to energy metabolism (NADPH2 dehydrogenase, sucD, HypD), carbohydrate metabolism (pfkC, dhaB, rbsD, epsF), cell envelope processing (LptD, LptA), and bacterial immunity (csm1, csm2, csm4, csm5). Heat stress only affected the NADPH2 dehydrogenase pathway. As conclusion, prolonged exposure to heat stress appears to have a limited effect on hindgut microbial composition and predicted functionality, possibly due to the ability of microbiota to adapt and recover under these conditions. However, differences between genotypes suggest that host genetics may influence gut microbial composition and metabolic potential, reflecting underlying physiological, metabolic, or behavioral differences. The PIGWEB project has received funding from the European Union's Horizon 2020 research and innovation programme (grant agreement No. 101004770).

Utilization of free amino acids in broiler chickens revisited

W. Siegert[1]
[1] *University of Göttingen, Department of Animal Sciences, Kellnerweg 6, 37077 Göttingen, Germany*

The inclusion of free amino acids (AA) in feed formulation enables precise adjustment of individual dietary AA concentrations to meet animal requirements while simultaneously lowering the crude protein (CP) content. This approach reduces nitrogen (N) intake and excretion without compromising performance. Hence, the environmental impact of animal production is mitigated and the efficiency of animal-derived food production is enhanced by increasing nitrogen utilization efficiency (NUE). The need to include free AA rises as the dietary CP level decreases. Absorption processes in the intestine differ between peptide-bound and free AA. Several studies in various species, including poultry, have shown that free AA are absorbed more rapidly into the systemic circulation than peptide-bound AA. With different absorption rates, AA may be available in an unbalanced pattern for protein synthesis even though dietary AA supply is formulated as balanced. The dietary inclusion of free AA apart from which utilization is impaired seems to be higher than previously assumed. In a recent research project, incremental substitution of peptide-bound with free AA was investigated in very low-CP diets (~16.5% for birds up to 3 weeks of age) that remained adequate in all AA concentrations. This required the use of 19 g free AA/kg of diet. Soy protein isolate served as the source of peptide-bound AA, as it provides protein with minimal amounts of other nutrients. The digestible AA from the soy protein isolate were substituted with all 20 proteinogenic AA in free form, keeping digestible AA concentrations constant. Performance remained unaffected at inclusion levels up to 54 g free AA/kg of diet—considerably higher than current standards in commercial feed formulations. Results of experiments on the utilization of free AA in diets may be confounded by affected feed intake after a change to diets high in free AA. In a complementary experiment, the immediate effects of changing to diets high in free AA were investigated over time using an almost identical feed composition. Feed intake was affected for 3 days after diet change. This impacted on the determined weight gain, gain:feed, and NUE—likely reflecting delayed responses to the previous day's intake. This temporary reduction in feed intake may have been associated with a shift in acid-base balance toward acidity. Reasons for this shift include an acidifying effect of AA degradation and the hydrochloride of l-lysine·HCl, which increased the acid load due to HCl concentrations with rising substitution of peptide-bound by free AA. Whether the altered acid-base balance was a cause, consequence, or unrelated correlate of reduced feed intake remains unknown. Adaptation to high dietary inclusion levels of free AA appeared to occur mainly within the first 3 days after diet change. Indicators of acid-base status in blood, plasma AA concentrations, and the number of altered metabolites detected in untargeted metabolomics analyses all declined or normalized thereafter, while NUE remained unchanged. The unaffected NUE after 3 days of adaptation suggested an equal efficiency of accretion of free or peptide-bound AA. Hence, plasma AA concentrations seem unsuitable as indicators for AA utilization because NUE, being the most reliable key figure, was unaffected. In summary, results of a series of experiments gave no evidence for different utilization of peptide-bound and free AA despite of different absorption processes. While an upper threshold for dietary free AA inclusion was found, it is considerably higher than current commercial practice. Reduced feed intake seemed to be the main cause for reduced performance above this level.

Effects of controlled lactic acid bacteria fermentation on physicochemical properties of rye and wheat grains

S. Salehi[1], M. F. E. Ahmed[1], A. Godglück[1], J. Gickel[2], A. Abd El-Wahab[1], A. Von Felde[1], C. Visscher[1], C. B. Arnold[1]
[1] University of Veterinary Medicine Hannover, Institute for Animal Nutrition, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] University of Veterinary Medicine Hannover, Science for Innovative and Sustainable Poultry Farming (WING), Bünteweg 13, 30559 Hannover, Germany

Cereal grains such as rye (Secale cereale) and wheat (Triticum aestivum) are widely used in animal nutrition. However, the nutritional utilization of certain feedstuffs in poultry may be limited by anti-nutritional factors such as non-starch polysaccharides (NSP) resulting in high digesta viscosity, which can negatively affect nutrient digestibility. Fermentation with lactic acid bacteria (LAB) has been proposed as a promising strategy to modify physicochemical properties of cereal grains and improve their suitability as feed ingredients.The aim of the present study was to evaluate the effects of LAB fermentation on three rye cultivars (A, B, C) and wheat as control. Fermentation was carried out using three LAB strains: Lactiplantibacillus plantarum, Limosilactobacillus fermentum and Pediococcus acidilactici. Dry matter content was set to 62.5%. Eight experimental treatments were applied for each cereal: individual inoculation of each LAB strain, three combinations of two strains, a combination of all three strains, and a non-inoculated control. Every treatment was prepared in three independent replicates twice (a1+2, b1+2 and c1+2). Total LAB counts (CFU/g), pH values and viscosity (mPa*s) were determined before (t0) and after 24 hours (t24) of fermentation. Each parameter was measured in triplicate. Fermentation resulted in a clear increase in total LAB counts in the inoculated samples after 24 h as well as compared with the non-inoculated control, indicating active microbial growth during fermentation (t0 ~ 8.0 log10 CFU/g, t24 ~ 10.0 log10 CFU/g). A consistent decrease in pH values was observed across all fermented samples, reflecting organic acid production by LAB (t0 ~ 6.5, t24 ~ 4.0). In addition, viscosity decreased in all rye cultivars after fermentation (A: t0 ~ 5.6 mPa*s, t24 ~ 4.6 mPa*s; B: t0 ~ 4.4 mPa*s, t24 ~ 2.3 mPa*s; C: t0 ~ 5.5 mPa*s, t24 ~ 2.9 mPa*s). Viscosity values in wheat only changed minimally (t0 ~ 1.7 mPa*s, t24 ~ 1.4 mPa*s). The variables cereal (species and also rye cultivar), bacterial treatment (without inoculation and with the different strains) and cereal*bacterial treatment all significantly influenced absolute pH values, viscosity and LAB counts after 24 hours as well as changes in those parameters from 0-24 hours (ANOVA via linear model, $p < 0.05$). For the cultivars A and C, there was a significant influence of the bacterial strain on change in viscosity for cultivars A, B and C on change in pH values and for cultivars A and B for change in LAB counts from t0 to t24. The pH values and viscosity of non-inoculated control samples changed only slightly after fermentation, highlighting the importance of lactic acid bacteria inoculation in fermentation batches with relatively high dry matter content. These results demonstrate that LAB fermentation significantly alters the physicochemical characteristics of cereal substrates even with high dry matter content. The observed microbial growth, acidification and reduction in viscosity confirm active fermentation and structural modification of the cereal matrix. Such changes may contribute to reducing viscosity-related anti-nutritional effects associated with cereal-based feed ingredients in poultry nutrition making fermentation an interesting technology for sustainable feeding strategies.

Impact of dietary Foeniculum vulgare Mill. on the growth performance of broiler chickens: Insights from a meta-analysis

C. F. Egbu[1], C. J. Smit[1]
[1] University of South Africa, Department of Agriculture and Animal Health, 28 Pioneer Ave, Florida Park, 1709 Roodepoort, South Africa

Background Increasing global food demand due to population surge warrants nutritionists harnessing every available resource as feedstuff to improve the growth performance of poultry. Poultry farming aims to achieve a reduced feed conversion ratio (FCR); however, this goal is hindered by high feed costs (Alhotan, 2021). Khan et al. (2022) have confirmed the safety of fennel (Foeniculum vulgare Mill.) as a phytogenic ingredient in chicken feed. Authors (Ghonime et al., 2025; İpçak et al., 2024) have reported conflicting data on dietary fennel effects on feed intake (FI), body weight gain (BWG), and FCR, which may be due to differences in strains, dosage, and growth phases. Presently, no systematic attempt has been made to evaluate the impact of these factors on the growth performance of broiler chickens fed diets supplemented with fennel using data from previously published studies. Given the above, this meta-analysis aims to provide data on the effect of diets with or without fennel supplementation on FI, BWG, and FCR in broiler chickens. Methods This study was done by a systematic literature search of studies (2012–2025) reporting the effect of dietary fennel on growth performance in broiler chickens using Scopus, Web of Science, and PubMed databases. A total of 104 studies were identified of which 19 fulfilled the inclusion criteria; thereafter, data were extracted and analysed using OpenMEE. A random effects model was used and presented as a standardised mean difference (SMD) with a 95% confidence interval (CI). Sources of heterogeneity (I_2) were explored by subgroup analysis using continent, sex, strain, form, phase, and dosage. Results Results showed that broiler chickens on dietary fennel had reduced FI (SMD = -0.28; $p < 0.001$; $I_2 = 87\%$) and FCR (SMD = -0.46; $p < 0.039$; $I_2 = 96\%$), while increasing BWG (SMD = 0.2, $p < 0.001$; $I_2 = 94\%$). Subgroup analysis showed that dietary fennel significantly reduced FI in Africa and Asia, mixed-sex groups, Ross, finisher phase, extract form, and at dosages >15 g/kg (SMD ranging from -0.208 to -0.697, $p < 0.05$). Moreover, BWG was significantly improved in Europe, Hubbard and Arbour Acre, and with powder form at 11–15 g/kg showing the greatest effect (SMD = 1.021, $p < 0.001$), while extract form reduced BWG (SMD = -0.659, $p < 0.001$). Dietary fennel reduced FCR in Asia and Europe, Hubbard strain, starter phase, powder form, and at dosages of 11–15 g/kg (SMD = -1.371, $p < 0.001$). Discussion The noted decrease in FI and FCR with improved BWG suggests that dietary fennel promotes feed efficiency. The > 87% I^2 observed was partly explained by subgroup analyses, which showed that the efficacy of fennel inclusion varied depending on continent, strain, growth phase, form, and dosage. Notably, powder improved BWG, while extract reduced it, highlighting the importance of processing methods in determining bioavailability and biological activity of fennel's bioactive compounds. The dose-response relationship was evident for FCR, where 11–15 g/kg produced optimal results, suggesting higher dosages may not confer further benefits or could potentially be detrimental. These findings underscore the need for precision inclusion strategies during the starter phase when feed efficiency is most critical for subsequent performance. Conclusion Fennel inclusion in powder form at 11-15 g/kg significantly improves feed efficiency in broiler chickens, although the substantial I^2 across studies emphasises that optimal benefits are contingent upon careful consideration of broiler strain, growth phase, and geographical production context. Postbiotics derived from Saccharomyces cerevisiae are promising alternatives to antibiotic growth promoters to improve sustainability in poultry production. This study evaluated the effects of S. cerevisiae-derived postbiotic on growth performance, jejunal morphometric traits, serum biomarkers, liver metabolome profile and mineral deposition in broiler chickens. A total of 96 one-day-old Arbor Acres chicks were randomly assigned to 2 dietary treatments with 4 replicate cages per treatment and 12 birds per cage: a basal control diet (CON) or CON diet supplemented with postbiotic (XPC, Diamond V, USA, 1.0 kg/MT; POST) for 35 d. Body weight and feed intake were recorded weekly per cage to calculate average daily gain (ADG), average daily feed intake (ADFI) and feed conversion ratio (FCR). At d 35, two birds per cage were slaughtered for jejunal histomorphometry, serum biochemistry, mineral analysis of liver and breast muscle, and untargeted LC–MS-based hepatic metabolomics. Data were analyzed by one-way ANOVA with diet as fixed effect (cage as the experimental unit for performance; bird for morphology, serum and mineral traits), and differential liver metabolites were identified using a combination of Student's t-test and OPLS–DA variable importance in projection scores ($P \leq 0.05$, $VIP \geq 1$). Postbiotic improved early growth and overall feed efficiency. POST birds showed greater BW at d 7 ($P = 0.03$) and d 14 ($P = 0.04$), and over d 1–35 had greater ADG ($P = 0.04$), lower ($P = 0.03$) ADFI and improved ($P = 0.03$) FCR (1.47 vs. 1.52) compared with CON. In the jejunum, POST markedly increased villus height (1,907 vs. 1,454 µm; $P < 0.01$), villus height:crypt depth ratio (8.01 vs. 6.53; $P < 0.01$) and villus surface area (1,092 vs. 812 mm²; $P < 0.01$), indicating enhanced absorptive capacity. Serum total protein and calcium were greater ($P \leq 0.05$) in POST birds, whereas alanine aminotransferase, glucose and uric acid were lower ($P \leq 0.05$), suggesting improved protein and mineral status and altered energy and nitrogen metabolism. Postbiotic also shifted mineral distribution, decreasing ($P \leq 0.05$) hepatic Na, Mg and K and increasing ($P \leq 0.05$) breast muscle Mg, K, P, S and Cu. Untargeted liver metabolomics revealed clear separation between POST and CON groups in both positive and negative ion modes, with numerous differential metabolites and enriched pathways, indicating a substantial impact of the postbiotic on hepatic metabolic networks. In conclusion, S. cerevisiae-derived postbiotic improved broiler growth performance, enhanced intestinal morphology, modulated serum biochemistry, shifted minerals deposition and altered the hepatic metabolome, supporting the use of dietary postbiotic as a functional feed additive for a more sustainable broiler production.

Multigenerational effects of in ovo synbiotic and choline supplementation on gut microbiota diversity and composition in broiler chickens

K. Stadnicka[1], J. Gawor[2], T. Aleksandrzak-Piekarczyk[2], E. Grochowska[1]
[1] University of Nicolaus Copernicus, Health Sciences, Jagiellońska 13-15, 85-067 Bydgoszcz, Poland, [2] Polish Academy of Sciences Institute of Biochemistry and Biophysics, Pawińskiego 5, 02-106 Warszawa, Poland

In ovo delivery of bioactive compounds represents a promising programming strategy to modulate gut microbiota and immunocompetence in the animal. We hypothesized that in ovo injection of synbiotics, with or without choline, exerts cross-generational effects on the structure and composition of the intestinal microbiota in broiler chickens. Fecal samples were collected from young and adult birds across three successive generations (F1–F3) originating from four injection-derived lineages: non-injected control (C), synbiotic single-dose (SYNs), synbiotic repeated-dose (SYNr), and synbiotic with choline single-dose (SYNCHs) and repeated-dose (SYNCHr). Total genomic DNA was extracted using a commercial stool purification kit. The V3–V4 hypervariable region of the 16S rRNA gene was amplified and sequenced on an Illumina NovaSeq 6000 platform (2 × 250 bp). Amplicon sequence variants were resolved via DADA2 within the QIIME2 pipeline and classified against the SILVA 138 reference database. Alpha diversity (Shannon index) was compared using Kruskal–Wallis tests; beta diversity (Bray–Curtis dissimilarity) was assessed by PERMANOVA. Differentially abundant taxa were identified by LEfSe (LDA threshold > 2.0). Shannon alpha diversity increased consistently with age across all generations, reflecting progressive microbiome maturation. Injection-derived effects on alpha diversity were generation-dependent, with significant group differences detected in F2 (young: $p = 0.016$; adult: $p = 0.045$). Beta diversity revealed more pronounced treatment-associated signals. LEfSe identified lineage-specific genus-level biomarkers, including enrichment of fermentation-associated taxa in synbiotic treated lineages. In ovo synbiotic supplementation, in combination with choline, induced cross-generation observed shifts in gut microbiota composition without systematically disrupting global diversity. The findings support the potential of in ovo bioactive interventions as a sustainable strategy for improving gut ecosystem stability and resilience. The research and analysis was funded by National Science Centre grant 2020/37/B/NZ9/00497 and 2019/35/B/NZ9/03186.

Low protein diets in broilers chickens: insight from a holistic evaluation

T. De Rauglaudre[1]
[1] *Adisseo, Innovation & Customer Success, 10 place du Général de Gaulle, 92160 ANTONY, France*

Reducing dietary protein has emerged as a promising strategy to improve nitrogen-use efficiency in broiler production and mitigate the environmental impacts associated with poultry protein production. A comprehensive assessment of this approach was carried out, examining its implications for animal response, nitrogen fluxes, economic outcomes and the environmental impacts of broiler production. Three meta-analyses were conducted to identify robust response patterns from the existing literature. A first meta-analysis based on 106 trials confirmed that it was possible to reduce crude protein content without compromising performance, as long as essential amino acid requirements were met. A second meta-analysis highlighted the metabolic consequences of reduced dietary protein, quantifying the associated increases in body lipid accumulation and energy digestibility. A third meta-analysis quantified the effects of reduced protein on nitrogen flow, particularly nitrogen volatilisation and manure production. These findings were complemented by two in vivo studies designed to differentiate protein-level effects from correlated factors such as soybean meal inclusion and dietary electrolyte balance. Results showed that full replacement of soybean meal is achievable but constrained by the protein level, and that reductions in NH_3 emissions arise from both protein and dietary electrolyte balance reduction. In response to limitations of existing model, a new mechanistic model was developed to estimate nitrogen emissions (NH_3, N_2O, NO_x, N_2) across all stages of manure management, from housing to field application. Compared with the European reference model, this new model yields substantially different emission estimates, resulting in either higher or lower environmental impacts depending on the impact category considered. Life-cycle assessments conducted in North American and European contexts demonstrated that reducing dietary protein effectively lowers acidification and terrestrial eutrophication—two impact categories highly sensitive to NH_3 emissions. However, other environmental impacts, including climate change and energy demand, may increase depending on regional context and ingredient sourcing. Economic analyses of costs and benefits further complement this assessment and will be discussed. Overall, this work supports reduced dietary protein as a relevant strategy to address nitrogen-related challenges in poultry production. Future improvements could arise from combining this approach with complementary strategies, such as lowering dietary phosphorus, precision feeding or increasing the use of low impact raw materials.

Comparative effects of a multi-carbohydrase and single xylanase supplementation on broiler performance and environmental impacts

C. Gras[1], S. Salami[2]
[1] Adisseo France S.A.S., 20 rue Prosper Monnet, 69190 Saint-Fons, France, [2] Adisseo (Nutriad Ltd.), Chester Gates, CH1 6LT Chester, United Kingdom

Exogenous carbohydrases can alleviate the anti-nutritional effects of non-starch polysaccharides in poultry diets, improving nutrient availability and feed efficiency. This allows lowering dietary nutrient density without compromising performance, while reducing environmental impacts. This study evaluated the effects of supplementing nutrient-reduced corn-wheat-soybean meal diets with either a multi-carbohydrase complex (MCC) or a single xylanase (SX) on broiler performance and environmental impacts quantified by life cycle assessment (LCA). A total of 1,480 day-old male Ross 308 broilers were randomly allocated to four dietary treatments with 10 replicate pens per treatment and 37 birds per pen. Dietary treatments included: (1) a positive control (PC) formulated to meet animal requirement; (2) a negative control (NC) formulated with a 3% reduction in apparent metabolisable energy and digestible amino acids relative to PC; (3) the NC supplemented with MCC (50 g/ton of feed); and (4) the NC supplemented with SX (70 g/ton of feed). Performance parameters (feed intake, body weight (BW), BW gain (BWG), feed conversion ratio (FCR), and mortality) were evaluated over a 35-day experimental period. Data were analysed by ANOVA (GLM) with significance declared at $P < 0.05$, and treatment means separated using the Tukey test. A cradle-to-feed mill and farm-gate LCA was conducted using the feed, performance, and default European broiler farm data. Feed ingredient impacts were obtained from GFLI v2.2 (2024), with origins reflecting average Polish and European production and imports. Sixteen environmental footprint (EF) impact categories were assessed in accordance with PEFCR and FAO LEAP (2020) guidance. Results are expressed per 1 kg feed and 1 kg broiler liveweight (LW) as functional units. For the overall trial (0–35 d), feed intake, BW and BWG were similar ($P > 0.05$) among treatments. The NC diet increased FCR compared to PC (1.582 vs. 1.493; $P < 0.05$). The MCC supplementation improved FCR relative to NC (1.502 vs. 1.582; $P < 0.05$) and restored FCR to PC levels (1.502 vs. 1.493; $P > 0.05$). However, the SX diet resulted in an FCR comparable to NC (1.574 vs. 1.582; $P > 0.05$) and failed to restore FCR ($P < 0.05$) to PC levels. Based on 1 kg feed at the feedmill gate, the NC formulations (starter, grower and finisher) reduced all 16 EF impact categories compared to PC. The largest reductions occurred for total climate change (−5% to −7%; -0.06 to -0.08 kg CO2eq/kg feed), freshwater ecotoxicity (−5% to −6%; -5.83 to -7.81 CTUe/kg feed), land use (−3% to −4%; -5.04 to – 6.70 Pt/kg feed), and water use (−8% to −11%; -0.04 to -0.05 m3 depriv./kg feed). For climate change impacts, the primary feed-related hotspots were soybean meal and oil from European imports. Based on 1 kg of broiler LW, the MCC diet reduced 14 of 16 EF impact categories compared to PC, with notable decreases in total climate change (-4 %; -0.09 kg CO2eq/kg LW), climate change-land use and land use change (-10%; -0.09 kg CO2eq/kg LW), land use (-3%; -7.39 Pt/ kg LW), water use (-7%; -0.06 m3 depriv./kg LW) and freshwater ecotoxicity (-4%; -9.33 CTUe/kg LW). However, NC and SX supplementation reduced only 2 of 16 EF impact categories relative to PC (-6% and -5% (-0.05 and -0.04 kg CO2eq/kg LW) for climate change-land use and land use change; -3% and -2% (-0.03 and -0.02 m3 depriv./kg LW) for water use, respectively). Hence, SX supplementation did not reduce the overall EF mainly due to impaired broiler performance. In contrast, MCC supplementation in nutrient-reduced diets mitigated the environmental impacts of broiler production without compromising performance.

Multi-carbohydrase and bacterial 6-phytase co-supplementation improves performance, nutrient digestibility and feed cost efficiency in broilers fed nutrient-reduced corn-soybean meal diets

S. Salami[1], H. Yakout[2]
[1] Adisseo (Nutriad Ltd.), Chester Gates, CH1 6LT Chester, United Kingdom, [2] Adisseo USA Inc., North Point Parkway, 30022 GA Alpharetta, United States

Exogenous carbohydrases and phytase are widely used in broiler diets to improve nutrient availability by degrading non-starch polysaccharides and phytate, thereby supporting dietary nutrient reductions without compromising performance. However, evidence supporting their efficacy when co-supplemented within multi-nutrient matrix reduction strategies remains limited. This study evaluated the effects of multi-carbohydrase and bacterial 6-phytase co-supplementation on performance, nutrient digestibility, and feed cost efficiency in broilers fed corn-soybean meal diets reduced in energy, amino acids (AA), Ca and P. A total of 756 day-old male Cobb 500 chicks were randomly assigned to three dietary treatments with 12 replicate pens of 21 birds each. Treatments included: (1) a positive control (PC; standard diet) formulated to meet animal requirements; (2) a negative control (NC) diet reduced by -150 kcal/kg apparent metabolisable energy (AME), -5% digestible AA and -0.19% Ca and P relative to PC; and (3) an enzyme (ENZ) diet consisting of NC supplemented with 50 g/t feed of a multi-carbohydrase complex (Rovabio® Advance, Adisseo, France) and 1000 FTU/kg feed of bacterial 6-phytase (Rovabio® PhyPlus, Adisseo, France). Feed intake, body weight (BW), BW gain (BWG), feed conversion ratio (FCR) and mortality were measured across starter (0–14 d), grower (14–28 d), and finisher (28–35 d) phases. The European Production Efficiency Factor (EPEF) and feed cost efficiency (feed cost €/kg BWG) were calculated for 0–35 d. Excreta were collected on days 21–24 to determine apparent dry matter (DM), gross energy, protein, starch and fat digestibility, and for the calculation of AME. Data were analysed as a randomised complete block design with pen as the experimental unit, using PROC MIXED in SAS. Significance was declared when $P < 0.05$, and treatment means were compared using the Tukey-Kramer test. Across phases, PC birds showed higher ($P < 0.001$) feed intake, BW, and BWG, and lower ($P < 0.001$) FCR than NC birds. The ENZ diet restored BW and BWG to similar levels ($P > 0.05$) as the PC in all phases. Over 0–35 d, the PC diet increased ($P < 0.001$) feed intake (3.18 vs. 2.57), final BW (2.51 vs. 1.88) and BWG (2.47 vs. 1.84), and lowered ($P < 0.001$) FCR (1.375 vs. 1.513) relative to the NC diet, resulting in higher EPEF (494 vs. 334). The ENZ diet improved ($P < 0.05$) feed intake (3.31 vs. 2.57 kg), final BW (2.47 vs. 1.88 kg), BWG (2.44 vs. 1.84 kg), FCR (1.442 vs. 1.513) and EPEF (484 vs. 334) compared with NC. Similarly, the ENZ diet restored final BW, BWG, and EPEF to levels comparable ($P > 0.05$) to the PC. Performance improvements in ENZ birds were supported by higher digestibility ($P < 0.001$) of DM (+6.2%), protein (+12.2%) and energy (+6.6%), resulting in increased AME (+192 kcal/kg) compared to NC. Apparent digestibility did not differ between ENZ and PC diets ($P > 0.05$), except that ENZ-fed birds exhibited higher ($P < 0.05$) digestibility of DM (+4.2%) and energy (+2.4%). The ENZ diet improved ($P < 0.01$) feed cost efficiency by 3.5% (-0.0126 €/kg BWG) and 2.4% (-0.0085 €/kg BWG) compared to PC and NC diets, respectively. Relative to the PC diet, the ENZ diet could translate to an estimated saving of €31,463 per million birds (2.5 kg target BW). In conclusion, co-supplementation of a multi-carbohydrase complex and bacterial 6-phytase in multi-nutrient-reduced corn-soybean meal diets effectively maintained broiler performance and nutrient digestibility at levels comparable to the standard diet, while significantly reducing feed cost.

Phytogenic dietary inclusion level modulates key performance indicators and meat quality biomarkers in heat-challenged broilers

I. Brouklogiannis[1], E. Iliopoulou[1], E. Misirli[1], A. Kouvatsou[1], G. Kefalas[2], K. C. Mountzouris[1]
[1] Agricultural University of Athens, Animal Science, Iera Odos 75, 11855 Athens, Greece, [2] Nuevo SA, Schimatari, 32009 Viotia, Greece

Heat stress represents one of the most detrimental stressors affecting poultry production worldwide. This study evaluated the dose-dependent effects of a dietary phytogenic blend (PB) on broiler growth performance and meat quality following cyclic heat stress during the finisher phase. In addition to growth performance responses, meat antioxidant status and key molecular biomarkers relevant for antioxidant (Nuclear factor erythroid 2-related factor 2; Nrf2) response were assessed. One day-old, Ross 308 (n=490) broilers were allocated to 5 dietary treatments, with 7 replicates of 14 chickens each, for a 40-d feeding trial. Experimental treatments received corn-soybean meal basal diets with no PB (CON) or supplementation with PB at 500 (PB500), 1000 (PB1000), 1500 (PB1500) and 2000 mg/kg diet (PB2000), respectively. The PB had olive oil polyphenols, carvacrol and thymol among its main bioactive components (nuPhoria®; Nuevo SA, Greece). Birds were reared under thermoneutral conditions for 35 days and then exposed to cyclic heat stress (32 ± 1 °C; RH 55 ± 5%) for 7 h/day during days 36–40. Growth performance was recorded per growth phase and results reported as overall. At day 40, breast meat samples were collected for antioxidant capacity determination, and gene expression analysis. Data were analyzed using ANOVA with means compared by Tukey's honest significant difference test and statistical significance was determined at $P \leq 0.05$. Polynomial contrasts tested the linear and quadratic effects of PB inclusion levels. Results revealed that PB inclusion improved ($P \leq 0.05$) overall FCR, protein efficiency ratio and energy efficiency ratio in PB1000 and PB1500, compared to CON. Moreover, PB supplementation improved breast oxidative stability, as reflected by reduced malondialdehyde ($P < 0.001$) and protein carbonyl concentrations ($P = 0.048$), with the most pronounced responses observed at 1000–1500 mg/kg diet. In addition, the breast total antioxidant capacity increased with PB inclusion ($P < 0.001$), reaching the highest levels at 1500 and 2000 mg/kg, compared to the CON. At the molecular level, PB antioxidant capacity was evidenced via beneficial changes ($P \leq 0.05$) seen for the majority of the Nrf2-pathway genes assessed in the breast. In conclusion, dietary PB improved broiler performance and enhanced breast meat oxidative stability under cyclic heat challenge conditions. The improved breast quality was further supported by beneficial modulation of critical antioxidant genes. Considering collectively the overall performance and meat quality biomarkers, PB inclusion levels at 1000 and 1500 mg /kg diet proved beneficial for heat-challenged broilers.

Effect of black soldier fly larvae oil and feed withdrawal on productive performance in broiler chicken subjected to cyclic heat stress during the final growth period

M. K. Atehortua[1], A. J. Maldonado[1], F. Sevillano[1], A. I. Rey[2], M. A. Ibáñez[3], D. Menoyo[1]
[1] Escuela Técnica Superior de Ingeniería Agronómica, Alimentaria y de Biosistemas, Universidad Politécnica de Madrid, Producción Agraria, Avda. Puerta de Hierro 2, 28040 Madrid, Spain, [2] Facultad de Veterinaria, Universidad Complutense de Madrid, Producción Animal, Avda. Puerta de Hierro s/n, 28040 Madrid, Spain, [3] Escuela Técnica Superior de Ingeniería Agronómica, Alimentaria y de Biosistemas, Universidad Politécnica de Madrid, Economía Agraria, Estadística y Gestión de Empresas, Avda. Puerta de Hierro 2, 28040 Madrid, Spain

Medium-chain fatty acids (MCFAs) present in black soldier fly larvae oil (BSFO) possess antimicrobial, and anti-inflammatory properties, and provide rapidly available energy, which might support the physiological response and intestinal health of poultry under heat stress conditions. In addition, controlled feed withdrawal during peak heat periods has been proposed as a strategy to improve thermoregulation by preventing the postprandial heat increment from coinciding with maximal ambient temperatures. The aim of this study was to evaluate whether the inclusion of BSFO rich in MCFAs, combined with a 6-hour feed withdrawal, could mitigate the negative effects of cyclic heat stress during the final growth period on broiler performance. It is hypothesized that combining a lipid source rich in MCFAs with feed withdrawal during peak heat periods may mitigate thermogenic load and support intestinal health improving productive performance. For this purpose, 540 one-day-old Cobb 500 broilers were randomly allocated to 54 pens and fed the same commercial diets from 1 to 20 days of age. Broilers were then divided into 6 groups (9 replicates per treatment; 10 birds per pen) following a completely randomized design. Two experimental groups were kept under thermoneutral conditions and fed isoenergetic (3,079 kcal/kg) and isoproteic (19% CP) corn–soybean diets supplemented with 5.5% soybean oil (SBO) or BSFO from 22 to 35 days of age. The other four groups were also housed under thermoneutral conditions until day 29, then exposed to cyclic heat stress (temperature-humidity index 80) for 6 hours daily from days 30 to 35. These birds received SBO or BSFO diets, and two of the groups additionally underwent a 6-hour feed withdrawal during the peak heat-stress period. Main effects stress (thermoneutral or cyclic heat stress), fat source (SBO or BSFO), feed withdrawal and their interactions were analysed with orthogonal contrasts using the General Linear Model procedure of SAS. Average daily feed intake (ADFI), average daily gain (ADG), and feed conversion ratio (FCR) were recorded at 29 and 35 days of age. No significant differences in performance parameters were observed between 21 and 29 days of age in broilers fed SBO or BSFO ($P > 0.05$). During the period from 30 to 35 days, heat-stressed birds showed lower ADG ($P < 0.001$) and ADFI ($P = 0.003$), as well as higher FCR ($P = 0.002$), compared to birds maintained under thermoneutral conditions. No significant effects of fat source or feed withdrawal under heat stress were found ($P > 0.05$), and no interactions among the evaluated factors were observed. In conclusion, cyclic heat stress applied during the final growth period negatively affected broiler performance, reducing ADG and ADFI and increasing FCR. Neither the BSFO nor the feed withdrawal improved the productive parameters during heat stress, showing similar results to ad libitum feeding and SBO. This research was supported by grant PID2023-149145OB-I00 funded by MICIU/AEI/10.13039/501100011033 and ERDF/EU.

Effect of Marine mineral complex on skeletal mineral deposition and liver health in aging laying hens

O. A. Demehin[1], M. A. Bouwhuis[1], K. Kozłowski[2], A. Van Vilsteren[3], S. O'connell[1,4]
[1] Celtic sea minerals, Marigot Research Center, Sycamore court, clash road, V92N6C8 Tralee, Ireland, [2] Department of Poultry Science and Apiculture, Faculty of Animal Bioengineering, University of Warmia, 10-718 Olsztyn, Poland, [3] Jadis Additiva, Schie 38,, 3111 PN Schiedam, Netherlands, [4] Center for Applied Biotechnology Research, Munster Technological University, clash road, V92 CX88 Tralee, Ireland

Modern agricultural practices require an extended laying cycle for layers to meet with efficiency and supply demands of a growing population. Through management, genetic and nutritional practices, the laying period can be extended up to 100 weeks. However, during extended lay the birds are faced with the problem of declining bone quality due to deterioration in the absorption, retention and metabolic supply of minerals such as calcium (Ca) and phosphorus (P). This often results in stress, inflammation, increased mortality and consequently reduced flock laying performance and eggshell quality. In this study, we investigated the effect of a marine mineral complex (MMC) in several particle sizes and doses of compared with feed-grade limestone as Ca source on bone quality, bone mineral deposition, and liver health. The study involved feeding 448, forty week old Hy-line brown layers, grouped into 76-77 birds per treatment group, with the following treatments: a) control diet with coarse and fine limestone with 3.8%w/w total Ca in the diet, b) coarse MMC (at 0.25%), partially replacing coarse limestone c) coarse MMC (at 0.5%), d) commercial MMC (0.5%) partially replacing fine limestone, e) fine MMC (0.25%), and fine MMC (0.5%) partially replacing fine limestone. At the end of the trial, bone and liver samples were collected from 22 hens per treatment group for analysis. The data showed that MMC significantly ($P<0.05$) affected mineral deposition in the tibia and toe bones with inclusion of fine particle MMC leading to higher mineral deposition (Ca increase by 3.1% and Sr by 20%). Keel fracture (reduced by 23%) and curvature scores (reduced by 14%) were numerically lower in MMC treatment group, but differences were not significant ($p>0.05$). Fatty liver scores were significantly ($P<0.001$) reduced by MMC versus limestone control (1.35 v 2.32, respectively) with an effect of dose and MMC particle size detected. High dose and large particle size MMC inclusion provided the biggest reduction in fatty liver scores. Overall, inclusion of MMC in layer diets are shown to improve bone mineral deposition and liver health, making it an interesting product to use in layers and especially in the case of extended lay.

Assessing Selenium Source Bioavailability via Excretion Patterns in Broiler Feces

S. Poulain[1], E. Chevaux[2], L. Vigier[2], Y. Le Treut[2], A. Sacy[2]
[1] Aveyron Labo, Bel Air, 195 rue des Artisans, 12000 Rodez, France, [2] Lallemand SAS, 19 rue des briquetiers, 31702 Blagnac, France

Selenium (Se) is an essential micronutrient involved in antioxidant defense and metabolic functions, yet its homeostasis requires tight regulation to avoid toxicity. In poultry, urinary and fecal routes merge in the cloaca, making fecal Se excretion a potential indicator of dietary Se utilization. This study aimed to evaluate whether fecal Se output can serve as a practical biomarker of Se source bioavailability in broilers. Four trials were conducted using ROSS 308 broilers fed iso-selenium diets (0.5 ppm total Se) containing either inorganic sodium selenite (SS) or selenium sources, including Se-enriched yeast (S. cerevisiae R397, SC R397). Birds were reared under standard conditions, and intestinal fecal samples were collected at day 14 (Trials 1 to 4) and day 32 (Trial 1). Selenium concentration in feces was determined after lyophilization, and excretion ratios (Se feces/Se intake) were calculated to assess retention efficiency. Results consistently showed that organic Se sources, particularly Se-enriched yeast, were less excreted than mineral forms. Despite increased intake levels, organic Se did not proportionally raise fecal Se output, suggesting higher tissue retention. Among all tested sources, SC R397 exhibited the lowest excretion ratio and the highest Se deposition in tibia (1,937 µg/kg FM), confirming superior bioavailability compared to SS (1,557 µg/kg FM). Conversely, sodium selenite displayed the highest fecal Se concentrations (up to 1,660 µg/kg DM) and ratios exceeding 46%, while SC R397 remained below 40%. These findings align with previous reports (Barbé et al., 2017; Leukert et al., 2026) highlighting the efficiency of yeast-based Se in improving Se status and reducing waste. In conclusion, fecal Se analysis offers a simple, non-invasive approach to compare Se sources in poultry nutrition. Lower fecal excretion reflects better absorption and retention, making this parameter a valuable tool for assessing bioavailability. Further research should integrate statistical modeling and explore correlations with performance and oxidative stress markers to strengthen its predictive value.

Embryonic stage-dependent effect of in ovo synbiotic administration at day 12 vs. day 18-implications for immunocompetence conditioning

K. Stadnicka[1,2], C. Randazzo[4], K. Guinan[3], K. Skowron[1], K. Grudlewska-Buda[1], J. T. O'Sullivan[3], J. Bogucka[5]
[1] Nicolaus Copernicus University, Institute of Advanced Sciences, Gagarina 11, 87-100 Toruń, Poland, [2] Nicolaus Copernicus University, Health Sciences, Jagiellońska 13-15, 85-067 Bydgoszcz, Poland, [3] Bioatlantis Ltd., Clash Industrial Estate, V92 RWV5 Tralee, Ireland, [4] University of Catania, Via Santa Sofia, 95123 Catania, Italy, [5] Nicolaus Copernicus University, Institute of Veterinary Medicine, Szosa Bydgoska 13, 87100 Toruń, Poland

In ovo administration of microbial bioactives has the potential to prime the developing immune system, enhance mucosal barrier integrity, and stimulate gastrointestinal tract function prior to hatch — effects with downstream consequences for performance, disease resilience, and food safety. The embryonic stage at the time of intervention is a critical determinant of these outcomes, yet comparative data on ED12 versus ED18 administration remain limited. This study aimed to evaluate the developmental stage-dependent effects of in ovo synbiotic injection administered at embryonic day (ED) 12 versus ED18 on post-hatch broiler growth, serological responses to commercial vaccination, and jejunal histomorphometric parameters in broiler chickens. Fertilized Ross 308 broiler eggs from a 45-week-old flock were incubated and allocated to experimental treatment groups receiving in ovo injection at ED12 (manual injection into the air chamber; 200 µl total volume: 2 µl 1% prebiotic extract + 188 µl physiological saline + 10 µl Lactobacillus rhamnosus H25 at 1×10^4 CFU/egg) or ED18 (50 µl total volume: 25 µl 1% prebiotic solution + 2.5 µl probiotic suspension at 1×10^3 CFU/egg + 22.5 µl live attenuated IBD vaccine), alongside a non-treated negative control group. Birds were reared under standardised commercial conditions. In ovo synbiotic injection at ED12 (group B: SYN-12ED) produced higher body weight gain, becoming most pronounced during the terminal phase of the rearing period. Serological analyses demonstrated the elevated post-vaccination antibody titres in synbiotic-treated groups relative to controls, suggesting enhanced B-cell-mediated humoral activation facilitated by synbiotic-induced immune conditioning. The findings demonstrate that the embryonic time point of synbiotic delivery critically determines the direction and magnitude of post-hatch outcomes. This study validates in ovo administration of microbial bioactives and natural immunomodulators as an evidence-based tool for early-life immunocompetence conditioning, supporting the One Health imperative for resilient production systems. The research was supported by the collaborative Ovobiom project grant number 2019/35/B/NZ9/03186, National Science Centre in Poland.

Lipid structure and energy utilization in high-performance broiler diets: impacts on performance, carcass traits and oxidative status

R. Schemmer[1], C. Heidemann[2], H. Rashid[2], R. Puntigam[3]
[1] BEWITAL agri GmbH & Co. KG, Industriestraße 10, 46354 Südlohn, Germany, [2] University of Bonn, Institute of Animal Science, Endenicher Allee 15, 53115 Bonn, Germany, [3] South Westphalia University of Applied Sciences, Lübecker Ring 2, 59494 Soest, Germany

Dietary lipids are essential components of energy-dense broiler diets and play a central role in nutrient digestibility, metabolic energy supply and carcass composition. Fatty acid chain length and saturation influence digestion kinetics, absorption pathways and post-absorptive metabolism. However, the extent to which structurally different lipid sources affect nutrient partitioning under modern high-performance conditions remains unclear. Therefore the present study was conducted to evaluate the effect of different fats differing in fatty acid profile and physical structure on growth performance, carcass characteristics and physiological parameters in broiler chicken. A total of 198 one-day-old male Ross 308 broilers were allocated to three dietary treatments (6 replicates; 11 birds per pen). Following a common starter phase (d1–10; 208 g/kg CP, 79 g/kg CL, 12,0 MJ AMEN/kg), birds received isoenergetic grower- (d11–23; 216 g/kg CP, 72 g/kg CL) and finisher diets (d25–35; 210 g/kg CP, 75 g/kg CL) containing either soybean oil (feed group 1, FG 1), a spray-cooled palm oil-based fat powder enriched with lecithin (FG 2; BEWI®-SPRAY 99L), or a mixture of short- and medium-chain fatty acids incorporated in a rapeseed oil-based matrix (FG 3; BEWI®-FATRIX SynerG+). Lipid inclusion ranged from 3.4 to 3.8 %. Performance parameters were recorded until d35. Carcass traits were determined post-slaughter. Plasma thiobarbituric acid-reactive substances (TBARS), ferric reducing ability of plasma (FRAP) and advanced oxidation protein products (AOPP) were analyzed to assess oxidative status. Data were evaluated using one-way ANOVA with Tukey-Kramer adjustment ($p \leq 0.05$). Growth performance was high across all treatments. Final body weight averaged 3,040 g and feed conversion ratio 1.34, with no significant differences among groups ($p > 0.05$). In contrast, carcass parameters were affected by lipid source. Dressing percentage was highest in birds from FG 3 ($p \leq 0.05$). Both alternative treatments with spray-cooled fat powder increased absolute breast meat yield compared with soybean oil (675 g (FG 1) vs. 746 g and 747 g (FG 1 and FG 2, respectively), and lecithin inclusion improved relative breast meat proportion ($p \leq 0.05$). No treatment effects were observed for TBARS, FRAP or AOPP ($p > 0.05$), indicating that substitution of soybean oil did not induce measurable systemic oxidative stress. Although the literature describes increased digestibility of short- and medium-chain fatty acids compared to long-chain fatty acids, this study found no significant differences in performance parameters. The absence suggests comparable metabolizable energy utilization across treatments when diets are formulated isoenergetically. However, differences in carcass yield indicate that lipid structure may influence nutrient partitioning and muscle deposition independently of overall growth rate. Lecithin supplementation may have supported emulsification and intestinal lipid utilization. In conclusion, structurally distinct lipid sources such as spray-cooled fat powders can replace soybean oil in high-energy broiler diets without impairing performance or oxidative stability, while influencing carcass composition. These findings underline the importance of lipid structure in poultry nutrition and support strategic fat source selection as a tool to optimize nutrient efficiency and product value.

Enhancing broiler chickens' performance through synergistic citrus extract prebiotic and probiotic supplementation

S. Cisse[1,2], A. Mansour[3], C. Maltret[1,2], M. E. A. Benarbia[1,2]
[1] Joint lab ANR FeedInTech (FIT: SONAS/Nor-Feed), 42 rue George MOREL, 49070 Beaucouzé, France, [2] Nor-Feed SAS, R&I, 3 rue Amédéo Avogadro, 49070 Beaucouzé, France, [3] Sofabel SARL, Route De Ain, 14200 Sougueur, Algeria

In recent years, probiotics have gained increasing attention for their potential to beneficially modulate the gut microbiota and improve intestinal function, highlighting their relevance in the prevention and management of gastrointestinal and metabolic disorders. However, their efficacy may be limited by microbial competition, variability in gut ecology, and various stresses related to livestock farming. Synergistic interactions between a targeted probiotic strain and a complementary prebiotic substrate may enhance intestinal health more effectively than the probiotic alone, leading to better animal performance. Therefore, this study aimed to assess the effects of a symbiotic combination of a probiotic and a citrus extract prebiotic on broiler chickens' performance, compared to the probiotic alone. In an experimental station in Algeria, 540 broiler chickens (Arbor Acres, Aviagen) were randomly divided into 3 groups: a control group (CTL group) fed with a standard diet;a probiotic group (PRO Group) supplemented with the recommended dose by the producer of a commercial probiotic (200 ppm), added to water, and fed with the standard diet;a symbiotic group (SYM Group) fed with a standard diet supplemented with 80% of the recommended dose of a citrus extract prebiotic (Nor-Spice AB®, Nor-Feed SAS, 200 ppm) and 50% of the recommended dose of the same probiotic used in the PRO group (100 ppm).Supplementation occurs from day 1 to day 46. Chickens were put under a thermic stress at 30°C for 4 hours from day 26 to day 30. Growth performance (weight, feed intake, and mortality) of each group were weekly recorded. The Feed Conversion Ratio (FCR) and the average daily gain (ADG) were also calculated. Results showed that chickens from the SYM group have a higher weight (2647.97) than chickens from the PRO group (2608.57) and the CTL group (2504.79, $p < 0.05$, ANOVA). The ADG was also significantly higher in the SYM group (68.08 g/day) compared to the pro group (66.86 g/day) and the CTL group (63.31 g/day, $p < 0.05$, ANOVA). Regarding feed intake, broiler chickens from PRO group had a higher overall feed intake (5,214 g/chicken) compared to the SYM group (5,171 g/chicken) and the CTL group (5,001 g/chicken). As a consequence, the FCR from the SYM group was lower (2.11) than the FCR from CTL (2.20) and PRO groups (2.18, $p < 0.05$, ANOVA). No difference was observed between broiler chickens' mortality from the 3 groups ($p > 0.05$, ANOVA). These results show that the combined administration of citrus extract and probiotics exerts a greater positive effect on broiler growth performance than the probiotic alone. Such a symbiotic strategy represents a promising nutritional alternative to antibiotic growth promoters for sustaining growth performance in poultry production systems.

Evaluation of protected sodium butyrate supplementation to optimize gut health biomarkers in broiler chickens

A. Kihal[1], A. Y. Alhady[1], A. Radwan[1], M. Puyalto[1], J. J. Mallo[1]
[1] Norel Animal Nutrition, Technical department, Calle Jesus Aprendiz, 19, 28007 Madrid, Spain

Butyrate is recognized to be a potent modulator of gastrointestinal health, exerting its effects by enhancing intestinal epithelial integrity, supporting the immune system, and promoting a beneficial shift in the commensal microbiota. This study aimed to evaluate the effects of a protected sodium salt of butyric acid on gut health biomarkers in broilers. A total of 300 one-day-old broiler chicks were randomly assigned to 2 dietary treatments with 10 replicate pens per treatment and 15 birds per pen. The treatments included a control group fed a standard diet (CTR) and a treatment group fed the CTR diet supplemented with 1 kg/t of sodium butyrate protected by sodium salts of palm fatty acid distillates (GR, Gustor N'RGY, 70% sodium butyrate, Norel Animal Nutrition). Chicks were fed pelleted diets for 35 days. At 35 days, blood samples were collected for immunoglobulin (IgY and IgA), cytokines (TNFα and IL10), and antioxidant [Total Antioxidant Capacity (TAC), superoxide dismutase (SOD) and glutathione (GSH)] analysis. Duodenal and ileal tissues were sampled and analyzed for histology (villi height and crypt depth), and mRNA expression of tight junction proteins (OCL, MUC-2, and ZO-1). Cecal content was collected at 35 days and analyzed for bacterial count of Coliform and Clostridium. Data were analyzed using one-way ANOVA in RStudio. Results of blood immunoglobulin levels were the highest in GR compared to CTR for IgY (424 vs. 328 ng/ml, $P < 0.05$) and were similar for IgA (530 vs. 474 ng/ml, $P > 0.05$). Cytokine concentrations showed the lowest TNFα concentration in GR compared to CTR (351 vs. 503 Pg/mL, $P < 0.05$), and similar IL10 concentrations between treatments (503 vs. 439 Pg/mL, $P > 0.05$). Blood antioxidant analysis showed the highest values in GR compared to CTR for TAC (5.64 vs. 4.54 ng/ml, $P < 0.05$) and GSH (150 vs. 114 ng/ml, $P < 0.05$), but no difference for SOD (134 vs. 132 U/ml, $P > 0.05$). Duodenal villi height and the ratio of villi height to crypt depth were the highest in GR compared to CTR (1072 vs. 1037 µm and 6.46 vs. 6.05, $P < 0.05$, respectively). Crypt depth at the duodenum level wasn't affected by treatment. At the ileal level, villi height was also higher in GR compared to CTR (485 vs. 472 µm, $P < 0.05$). However, crypt depth and the ratio of villi height to crypt depth were not different between treatments ($P > 0.05$). The GR treatment also improved tight junction expression for OCL (2.54 vs. 1.00), ZO-1 (1.87 vs. 1.00), and MUC-2 (2.01 vs. 1.00) compared to the CTR ($P < 0.05$). For microbial count analysis, lower Coliform and Clostridial counts were observed in GR compared to CTR (46% and 65% lower, $P < 0.05$, respectively). In summary, protected sodium butyrate was effective in improving gut health biomarkers, indicating better intestinal homeostasis. This enhanced resilience is critical in modern broiler production, providing the physiological foundation necessary to maintain high performance and efficiency.

Effects of Dietary Energy Levels During the Growing and Early-Laying Periods on Late-Laying Performance, Egg Quality, and Organ Characteristics in Laying Hens

J. Hong[1], H. Kim[1], Y. Kim[1], E. C. Hong[1], C. Lim[1], H. J. Kim[1], M. Yu[1], H. K. Kim[1], D. Lee[1]
[1] National Institute of Animal Science, Rural Development Administration, Poultry Research Center, Department of Animal Resources Development, 321-11, Daegwallyeongmaru-gil, Daegwallyeong-myeon, 25342 Pyeongchang, South Korea

Achieving a 100-week laying cycle in commercial layers necessitates nutritional approaches that preserve productivity and metabolic health in aging hens. Accordingly, this study investigated the impact of lowering dietary metabolizable energy (ME) levels during the growing and early laying periods on hepatic condition and productive performance during the late laying period. A total of 360 Hy-Line Brown pullets (3 weeks of age; initial body weight 205.8 g; uniformity 76.6%) were assigned to four diets differing in ME density [high (H), control (CON), low (L), and very low (VL)]. The control (CON) diet was formulated according to the breeder manual recommendations, and the other treatments were adjusted relative to CON as follows: H, CON +100; L, CON −100; and VL, CON −200 kcal/kg. Diets were fed from 3 to 18 weeks of age (growing period) and from onset of lay to 36 weeks (early laying period), after which all birds received the same commercial layer diet. Late-laying performance (46–60 weeks of age), egg quality, and organ characteristics were evaluated. At 60 weeks of age, selected hens were euthanized for measurements of abdominal fat, liver traits (weight, fat content, malondialdehyde (MDA)), and ovarian characteristics. Data were analyzed by one-way ANOVA using the GLM procedure of SAS, with means separated by Duncan's test ($P < 0.05$). Late-laying hen-day egg production, egg weight, egg mass, feed intake, feed conversion ratio, and standard egg quality traits (shell strength and thickness, yolk color, albumen height, Haugh units) did not differ among treatments. Abdominal fat and oviduct weight were also unaffected. In contrast, VL hens showed lower liver weight than H hens, and hepatic fat content decreased significantly from H to L and VL. Liver MDA concentration declined progressively with decreasing dietary ME and was lowest in VL hens. Moreover, L and VL hens showed higher weights of the largest and second-largest preovulatory follicles (F1, F2), and VL hens had more small yellow follicles (5–10 mm) but fewer large yellow follicles (>10 mm) than H and CON. These findings indicate that reducing dietary energy density during the growing and early laying periods can mitigate hepatic fat accumulation and oxidative stress in late-laying hens without compromising productivity, thereby potentially improving metabolic robustness for extended laying cycles. However, the slight numerical increase in feed conversion ratio observed in lower-energy diets warrants further investigation to determine its biological relevance and whether these early nutritional effects persist through 100 weeks of age.

Climate protection and food security: antagonists or synergists in grassland-based production?

F. Leiber[1]
[1] *FiBL, Research Institute of Organic Agriculture, Livestock Sciences, Ackerstrasse 113, 5070 Frick, Switzerland*

The call for mitigation of enteric methane has a tendency to shift cattle production systems towards intensification, because higher concentrate-to-forage ratios may reduce emissions per kg of milk or meat. Furthermore, precision livestock feeding (PLF), aiming at maximising nutrient efficiency also requires tailored diets, with considerable amounts of concentrated components offered as mixtures which avoid selective behaviour of the cows; thus PLF solutions are often barn-based and intensive. Against these practises, pasture- and grassland-based production systems are facing challenges regarding justification of higher product-related methane emissions, apparently low resource efficiency and high land-requirements. However, with a feed-food competition perspective, land-use and edible food efficiency can comprise a clear advantage for grassland-based over intensive systems. Especially in regions and systems, which possess or require larger shares of grassland (permanent pastures, or, in organic systems, crop-rotation grass-clover leys), their utilisation can provide a significant contribution to animal sourced proteins outside the feed-food competition. Furthermore, grassland landscapes bring along several relevant ecosystem services, such as biodversity, carbon stocks and animal welfare aspects. Crucial questions resulting are, (1) if carbon footprints of grassland-based vs. intensive cattle production systems can be fairly compared, and on which level of system boundaries this should be done, (2) which measures of methane mitigation are practicable for grassland-based systems, and (3) how can costs and benefits of different targets be balanced in the optional actions. This lecture will provide an overview of quantifications to compare different production systems and raise the question, how different targets such as low carbon footprint vs. food security can be prioritzed, balanced or joined. Not the least, various emission mitigation approaches in grassland-based systems will be discussed, in order to reconcile multiple targets of sustainable livestock agriculture.

Enhancing MIR-based methane prediction through systematic integration of cow- and farm-level information

C. Matzhold[1], A. Köck[1], S. J. Burn[2], K. Linke[1], C. Schmid[3], M. Mayerhofer[1], C. Egger-Danner[1]
[1] ZuchtData, Dresdner Str. 89, 1200 Vienna, Austria, [2] University of Natural Resources and Life Sciences, Vienna (BOKU University), Department of Agricultural Sciences, Institute of Livestock Sciences, Gregor-Mendel-Str. 33, 1180 Vienna, Austria, [3] LKV Austria, Dresdner Str. 89, 1200 Vienna, Austria

The quantification of methane emissions is essential for sustainable dairy production, yet direct measurements remain costly and difficult to scale. Mid-infrared (MIR) milk spectra provide a practical and widely available data source in Austria. This study evaluated whether MIR-based methane prediction can be improved through structured data integration and whether increasing information depth requires more complex modelling approaches. The dataset comprised 12 Austrian dairy farms with 444 cows and 574 repeated observations (cow × period). Methane emissions were defined as 6-week mean CH_4 production (g/day), aligned with a representative MIR sampling week. The value of contextual information was assessed through a hierarchical data integration strategy. Starting from a MIR-only baseline, additional data blocks were sequentially incorporated: routinely available cow-level variables from dairy herd improvement (DHI) records (e.g., parity, milk yield), non-routinely recorded cow-level traits requiring additional measurements (e.g., body weight, feed intake), herd-level indicators summarizing long-term performance (e.g., longevity, disease incidence, annual herd milk yield), and farm management characteristics (e.g., pasture access, diet composition). At each integration stage, four modelling approaches were evaluated — Partial Least Squares (PLS), Random Forest, XGBoost, and Support Vector Machines — enabling systematic assessment of whether increasing information depth necessitates more complex models. Model performance was assessed under two complementary validation settings reflecting distinct deployment objectives. Within-farm predictive performance was quantified using animal-grouped cross-validation, preserving intra-animal dependencies and evaluating prediction for new animals within previously observed farms. Structural transportability was assessed using leave-one-farm-out validation, where each farm was excluded during training and used exclusively for testing to evaluate generalization across heterogeneous production systems. Results from the within-farm validation framework showed that prediction accuracy improved consistently with increasing information depth. Using the full information set, PLS achieved the best performance (RMSE = 48.12 g/day, r = 0.73, R^2 = 0.54), closely followed by XGBoost (RMSE = 49.00 g/day, r = 0.72, R^2 = 0.52). These results indicate that linear modelling is sufficient to capture most of the additional predictive signal introduced by structured data integration. Under leave-one-farm-out validation, overall performance decreased, reflecting substantial between-farm heterogeneity. PLS again performed best but with clearly reduced accuracy (RMSE = 56.65 g/day, r = 0.61, R^2 = 0.39), indicating limited structural transferability across farms. More flexible machine learning approaches did not provide consistent improvements under this setting. In conclusion, structured data integration is the primary driver of improved MIR-based methane prediction, whereas model complexity remains of secondary importance in this data regime. However, cross-farm generalization remains a key limitation and requires further methodological and data-related research.

Methane emission and feeding behavior of dairy cows grazing versus indoor feeding with silage

D. W. Olijhoek[1], N. P. Hansen[1], M. R. Weisbjerg[1], M. Maigaard[1], P. Lund[1], M. Larsen[1]
[1] AU Viborg – Research Centre Foulum, Aarhus University, Dept. of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark

Grazing cattle may have lower methane emission than cattle fed grass-clover as silage indoors. This study aimed to quantify enteric methane emission and eating and rumination time of Danish Holstein dairy cows grazing perennial ryegrass and white clover pasture compared to dairy cows fed grass-clover silage indoors. The experiment covered 2 weeks of adaptation and 9 experimental weeks (May 6th to July 7th, 2024). Three treatments were allocated to 45 lactating dairy cows (15 cows/treatment) in a continuous design: 1) indoor feeding with a spring growth (first cut) grass-clover silage (GCS), 2) grazing during day and night (DAY+NIGHT), and 3) grazing during the day (ca. 8 h) with indoor feeding of grass-clover silage during the night (DAY+GCS). Methane emission was measured with the GreenFeed system (C-Lock Inc., USA) using 2 units indoors and 2 units placed in huts on pasture. Feeding behavior was measured with RumiWatch (ITIN+HOCH GmbH, Switzerland) over 6 days repeated over 3 weeks for a subset of cows and only for the GCS (6 cows) and the DAY+NIGHT treatments (6 cows). Concentrate was provided in GreenFeed (up to 2.4 kg dry matter/d; DM) and in the milking parlor (2.7 kg DM/d). The grazing system was strip grazing with rotations over paddocks. Pre- and post-grazing herbage mass per paddock was measured with Grasshopper (True North Technologies, Ireland). The pre-grazing herbage mass was on average 1259 kg DM/ha, and the pre- and post-grazing sward heights were on average 99 and 68 mm, respectively. Total dry matter intake (DMI) was the sum of DMI of concentrate, grass-clover silage and/or pasture. Pasture DMI was calculated using energy requirements for maintenance, milk production, gestation, growth, mobilization, and deposition, and energy intakes with concentrate and silage. Preliminary data show that DAY+GCS had the highest total DMI (20.9 kg/d) and energy-corrected milk (ECM) yield (31.7 kg/d), while DAY+NIGHT had the lowest total DMI (19.5 kg/d) and ECM yield (28.8 kg/d) with GCS being intermediate in total DMI (19.9 kg/d; P=0.01) and ECM yield (29.9 kg/d; P<0.001). A significant interaction between treatment and week (P<0.001) was observed for both variables. Weekly GreenFeed visits per cow were on average 26, 15, and 23 visits/week for GCS, DAY+NIGHT and DAY+GCS treatments, respectively. Methane emission was lower for DAY+NIGHT (311 g/d and 11.2 g/kg ECM) compared to GCS (449 g/d and 15.1 g/kg ECM) with DAY+GCS being lower (409 g/d and 13.0 g/kg ECM; P<0.001 for both) than GCS. Compared to GCS, methane (g/kg ECM) was 25.8 and 14.2% lower for the DAY+NIGHT and DAY+GCS treatments, respectively. No significant interaction between treatment and week was observed for both methane variables (P>0.05). For DAY+NIGHT, total eating time (620 min/d) and per unit DMI (29.9 min/kg DMI) were higher than for GCS (446 min/d and 20.7 min/kg DMI; P<0.001), whereas total rumination time and per unit of DMI were lower for DAY+NIGHT (450 min/d and 21.8 min/kg DMI) than GCS (543 min/d and 25.3 min/kg DMI; P=0.001 and 0.02, respectively). Both eating time variables showed a significant interaction between treatment and week (P=0.03 for both), whereas this was not found for both rumination time variables (P>0.05). In conclusion, cows grazing during both day and night had a lower methane emission compared to cows fed with spring growth grass-clover silage indoors, which coincided with a longer eating time and shorter rumination time when grazing. Cows grazing during the day and fed with grass-clover silage indoors during the night had methane emission intermediate to the other treatments, while having highest total DMI and ECM yield.

Comparison of two approaches for quantifying methane emissions at housing or individual animal level

K. Orquera-Arguero[1], M. Zähner[1], F. Dohme-Meier[2], G. Lazzari[2], S. Schrade[1]
[1] Agroscope, Ruminant Nutrition and Emissions, Tänikon 1, 8356 Ettenhausen, Switzerland, [2] Agroscope, Ruminant Nutrition and Emissions, Tioleyre 4, 1725 Posieux, Switzerland

Enteric fermentation in ruminants contributes substantially to of agricultural methane (CH_4) emissions, underscoring the urgent need for accurate quantification of mitigation strategies and to improve greenhouse gas inventory reporting. Increasing demand for precise CH_4 measurements has led to the development of several techniques at individual animal level (e.g. respiration chambers, tracer gas bolus methods, GreenFeed) and at housing level (e.g. tracer-ratio method). This study assessed the accuracy of two approaches for quantifying CH4 emissions from dairy cows. In the first approach using the tracer-ratio method (TR), CH_4 emissions are measured at housing level, which includes animal-based and housing-based emission sources. The tracer gas sulphur hexafluoride was continuously released through a dosing system with critical capillaries positioned adjacent to the aisles. Composite air samples were collected via a PTFE tubing system with critical capillaries. Sulphur hexafluoride concentrations were analysed by gas chromatography and CH_4 concentrations by cavity ring-down spectroscopy. The second approach, the GreenFeed system (C-Lock Inc., Rapid City, SD, USA) quantifies individual enteric CH_4 emissions. Cows were attracted to the GreenFeed units using bait feed. The study involved 20 lactating dairy cows (Brown Swiss and Holstein; average milk yield 33.8 kg/day; body weight 698 kg) kept in a naturally ventilated housing with cubicles and solid floors. The experiment was conducted in early summer 2023 and comprised six sampling weeks (6–7 days each), separated by 3-day intervals, for a total duration of 29 complete days. Cows were fed a partial mixed ration supplemented with concentrate according to milk yield and stage of lactation. All collected raw data from both approaches were consolidated into CH_4 emissions hourly averages (g/h per cow). Original hourly emissions were converted to 4-h rolling means to smooth short-term events and highlight longer-term trends. Data were analysed using R software. The differences in frequency of GreenFeed visits between cows and days of the experiment were assessed using a Kruskal–Wallis test. The differences between both methods were analysed using a T-test and Pearson correlations. Cows visited the GreenFeed unit with a mean frequency of 3.9 ± 1.2 visits/day per cow. Differences between cows' visits were observed ($p < 0.001$). No differences ($p > 0.05$) in visit frequency were found across the days of the experiment. The CH4 emissions per cow were higher when using the TR method (555 ± 114 g CH_4/day) compared with the GreenFeed system (441 ± 50 g CH_4/day, $p < 0.001$). A moderate positive correlation ($r = 0.35$, $p < 0.001$) was observed between the approaches. The two different approaches used to measure the CH4 emissions from a naturally ventilated dairy housing system with the TR method at the housing level and the GreenFeed system at individual level provided consistent realistic values of CH_4 emissions under practical conditions. The higher values obtained using the TR approach may reflect CH4 sources not fully captured by GreenFeed, including hindgut fermentation as well as non-enteric sources such as manure-derived emissions and environmental CH4 . In contrast, GreenFeed enables the assessment of variability between individual animals.

Diurnal profiles of methane emission in response to feed intake patterns of cattle: Implications for GreenFeed measurement sampling schemes

H. J. Van Lingen[1], U. Arshad[2], M. Niu[2], J. L. Ellis[1]
[1] University of Guelph, Animal Biosciences, 50 Stone Road East, N1G 2W1 Guelph, Canada, [2] ETH Zurich, Department of Environmental Systems Science, Universitätstrasse 2, 8092 Zurich, Switzerland

Gas sampling frequency and timing relative to diurnal CH4 emission and feed intake patterns are critical (Hammond et al., 2016), particularly in experiments using voluntary GreenFeed visits (De Mol et al., 2024). Respiration chamber data analysis showed that accurate quantification of CH4 production (g/d) required sampling at ≤2-h intervals for twice-daily restricted feeding (Van Lingen et al., 2023), whereas sampling frequency and timing did not affect estimates for twice-daily ad libitum feeding. For grazing cattle in particular, feed intake patterns may not be recorded, which makes it difficult to adjust sampling frequency and timing. However, dynamic model simulations could help evaluate diurnal CH4 emissions patterns in response to observed or simulated feed intake rates. The aim was to assess the accuracy of various sampling schemes for estimating CH4 production of dairy cattle that was dynamically simulated for different feed intake patterns. We developed a dynamic model that included differential equations for nutrient degradation, volatile fatty acid production, and methanogenesis in the rumen, based on Van Lingen et al. (2019). Model inputs included two simulated within-day feed intake patterns applicable to grazing cattle and twelve patterns from published studies to simulate diurnal CH4 emission profiles. These studies included 2 to 4 feed deliveries per day. For each simulated diurnal profile, sampling schemes ranging from twice daily to twice per hour were applied to evaluate the accuracy of CH4 production estimates. Simulated diurnal CH4 emission peaks followed the 2 to 4 feed deliveries per day with a delay of approximately 1.0 to 1.5 h, relatively closely aligning with previous work (Van Lingen et al., 2019). Sampling from these simulated diurnal CH4 emissions using intervals ≤ 2h resulted in CH4 productions that did not differ from the areas under the curve across the feed intake patterns. However, samplings that used intervals ≥ 3h or applied only 2 or 3 unequally spaced samplings per day resulted in CH4 productions that differed from the simulated areas under the curve. Preliminary simulations suggested 2-hourly sampling provides optimal CH4 production accuracy across within-day feed intake patterns applicable to grazing cattle and published patterns with 2 to 4 feed deliveries per day. Projecting threshold of annual non-fossil methane emissions at which the atmospheric methane burden equals methane removal

Ž. Pečnik[1], J. Verbič[1]
[1] Agricultural Institute of Slovenia, Department of Animal Science, Hacquetova ulica 17, 1000 Ljubljana, Slovenia

Recently, we developed a novel method to calculate the balance of cumulative non-fossil methane emissions (BME) over consecutive or non-consecutive livestock production periods. This method enables assessment of whether a (sub)sector or (sub)population (e.g. a dairy region) achieves methane burden or methane removal, by comparing periods and considering methane's atmospheric behaviour in real time. However, among available climate metrics, there is currently no method to project the threshold of current annual methane emissions (AME) required for a sector or population to achieve zero BME at either the population or product level in the current year. As a result, we lack information on how many emissions a production can release without creating additional burden over production periods. Here, we derive and demonstrate equations to project the AME threshold. Below the calculated value, methane is removed, resulting in atmospheric cooling; above it, the methane burden increases, causing atmospheric warming relative to the current temperature. First, we set equations for cumulative methane emissions (CME) in years t and t – 1, taking into account AME and the atmospheric removal of methane over twelve-year periods. The probability that historical methane remains in the atmosphere in real time was calculated taking into account the methane lifetime and the difference in years between the past and the real-time year. Second, for burden equalling removal, we assumed that BMEt, the difference between CME in year t and, in this case, t – 1, equals zero. Third, in the equation BMEt = CMEt – CMEt–1, this means that CMEt equals CMEt–1. Fourth, this assumption enables the use of CMEt–1 instead of CMEt in projecting AMEt. Finally, we derive AMEt threshold from the CMEt equation, where we replace CMEt with CMEt–1. This novel methodology determines the maximum annual methane emissions that may be achieved so that, in the current year, the methane burden does not exceed methane removal, relative to past emission trends and accounting for methane's atmospheric behaviour. Thresholds for future years can be calculated by shifting the periods and considering possible variability in AME. In practice, the developed method can be applied at the population or product level. Furthermore, as with BME, recalculations to carbon dioxide equivalents or carbon dioxide warming equivalents are unnecessary, making the results easier to interpret for non-climatologists. The method aligns with the sustainable development goals and enables the development of tools that animal scientists, regional development institutions, advisory services, breeding and milk recording organisations, or farmers can use to assess the efficiency of methane mitigation measures or short- and long-term production efficiencies at any global livestock population or product level.

Variation in N and P excretion in manure from dairy farms

C. F. Børsting[1], A. L. F. Hellwing[1], M. J. Brask[1], P. Kai[2], H. Martinussen[3], A. M. Kjeldsen[3]
[1] Aarhus University, Dep. Anim. a. Vet. Sci., Blichers Alle 20, 8830 Tjele, Denmark, [2] Aarhus University, Dep. Bio. a. Chem. Engineering, Gustav Wieds Vej 10 C, 8000 Aarhus, Denmark, [3] SEGES Innovation, Animal Innovation, Agro Food Park 15, 8200 Aarhus, Denmark

In Denmark norm values for N and P excretions ex-storage from livestock are based on mean values obtained from around 70% of all Danish dairy cows. The norm values are used in the field nutrient management plans, that farmers must submit to the authorities. The excretion ex-storage is a mass balance based on mean values for feed intake and composition as well as for milk yield and composition from these farms. Furthermore, constants from literature are used for N and P retention in the body and fetuses, N and P from bedding and N emission from barns and storages. The aim of the study was to examine the variation between farms in the excretion of N and P ex-storage, and to examine if the variation can be explained by individual farm data applied in correction equations provided by authorities. The study was based on data from 1,100 farms with Holstein and crossbred dairy breeds. Data were cured to delete data outside biological relevance. The farms were divided into five percentile groups of equal size based on the level of excretion of N and P ex-animal, respectively. Within each percentile group the mean ex-animal value was calculated as well as mean dry matter intake (DMI), milk yield, and crude protein and P concentration in the feed. For each of the five groups three different emission factors were applied. Within each group it was assumed that 60% had emission compatible with the standard emission for barns with solid floor and automatic scraper at 10.4% of urinary N, and 20% had emission which was either 1.1% higher or lower. Standard amounts of N and P from bedding were added. The emission from outdoor slurry storage was estimated at a constant 3,4% of urine-N ex-barn. The group with lowest N ex-animal excreted on average 140 kg N/cow/y, whereas for the highest group the excretion was 181 kg. Compared to the mean value this was 14% lower and 12% higher, respectively. DMI was 7% lower and 7% higher, respectively, for these two groups, whereas yield of energy corrected milk (ECM) was 5% lower and 5% higher, respectively. Crude protein in DM was 4% lower and 3% higher than the mean. Hence, there was a high variation in N excretion, and DMI was the major driver of N excretion. The group with lowest P ex-animal excreted on average 20.6 kg P/cow/y, whereas for the highest group the excretion was 31.6 kg. Compared to the mean value this was 21% lower and 21% higher, respectively. DMI was 5% lower and 4% higher, respectively, whereas yield of ECM was 5% lower and 3% higher, respectively. The content of P in DM was 11% lower and 11% higher, respectively. Hence, there was a larger variation in P excretion between farms compared to N excretion, and dietary P content was the major driver. The excretion of N ex-storage was estimated at 153 kg/cow/y with a CV of 8.5%, when combining variation in N ex-animal with variation in losses of N from barns. Excretion of P ex-storage was estimated at 26.2 kg/cow/y with a CV of 14.4%. In nutrient planning, farmers are allowed to correct the standard excretions by use of their own data for DMI, crude protein and P in feed, milk yield and protein content in milk in correction equations provided by authorities. When such corrections were used for the highest and lowest groups, the corrected values were at the same level as actually registered for these groups, both for N and P. In conclusion, there is a large variation in N and P excretion between dairy farms, but by using correction equations based on valid data from the individual farm, it seems possible to account for most of the variation.

Feeding strategies to reduce dietary crude protein levels and ammonia emissions on dairy farms

M. Moleman[1], A. M. Smid[1], P. Galama[1], T. Wind[1], M. De Haan[1], M. J. Paulo[1], S. K. Schnabel[1]
[1] Wageningen University and Research, Wageningen Livestock Research, De Elst 1, 6708 WD Wageningen, Netherlands

Ammonia emissions pose a significant environmental and societal challenge in The Netherlands, particularly in the dairy sector, which faces increasing pressure to reduce its contribution. At the same time, national policy is shifting toward results-based policy, emphasizing on-farm environmental targets rather than uniform regulations. Within this context, reducing dietary crude protein (CP) is suggested as a practical and measurable strategy to lower on-farm ammonia emissions. To explore this strategy, the 'Koe & Eiwit' (Cow and Protein) project was conducted from 2022 to 2025. The project involved 150 dairy farms and aimed to reduce CP levels in the diet to 155 g/kg dry matter (DM). On-farm strategies and challenges for lowering CP were examined using data calculated with the Dutch dairy model ANCA (Annual Nutrient Cycling Assessment), covering 2020–2025. ANCA calculates farm-level environmental performance, including CP levels, ammonia emissions and greenhouse gas emissions. Yearly changes in CP were analyzed using a linear mixed-effects model, incorporating annual variation in feed composition, while controlling for farm characteristics and interactions between project period, soil type, and production intensity. Preliminary results indicate an average reduction of 8 g/kg DM in CP from 2020 to 2025, corresponding to an 8% decrease in ammonia emissions. Key drivers included lower CP levels in grass silage (due to fertilization adjustments and mowing timing), increased maize feeding, and reduced CP levels in concentrates. Reductions were achievable across farms, although peat soils and grass-based systems posed greater challenges. No significant effects were observed on milk production, feed costs, or other environmental indicators. The results highlight feeding strategies for lowering CP and identify farm characteristics that may require tailored targets and support. They provide guidance for policymakers and farmers to achieve environmental goals while maintaining production and animal health and safeguarding vulnerable natural habitats.

Long-term effects of reduced dietary protein supply in lactating dairy cows

T. Michou[1], M. R. Weisbjerg[1], M. Larsen[1], S. E. Räisänen[1]
[1] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark

Current feeding practices in dairy systems tend to overfeed protein in relation to the predicted milk production response. However, few studies have addressed the long-term effects of providing protein at levels currently considered below requirements. This experiment aimed to evaluate the effects of diets formulated around 5% below current protein recommendations provided by the Nordic Feed Evaluation System (NorFor) with varying levels of metabolizable protein (MP) and rumen protein balance (RPB) on lactational performance over the long term. A total of 72 mid-lactation Danish Holstein cows, 36 multiparous and 36 primiparous [averaging (mean± SD) 119 ± 57.6 and 138 ± 65.2 days-in-milk and 41.2 ± 5.4 kg/d and 32.0± 3.1 kg/d milk yield, respectively], were included in a 15-week complete randomized block design experiment preceded by a 2-week covariate period. During the covariate period, all cows ate the ration fulfilling protein recommendations according to NorFor (MP: 15.5 g/MJ, RPB: 12 g/kg DM). A total of 9 dietary treatments in a 3 × 3 factorial arrangement with 3 levels of MP (15.5, 14.5, and 13.5 g/MJ) and 3 levels of RPB (12, 4, and -4 g/kg DM) were formulated by varying maize gluten, protected soybean meal (SoyPass), sunflower meal, lupin pulses, and urea. The diets were fed as TMR and offered ad libitum. Intake was recorded daily using automated feed bins (RIC; Insentec BV) with each cow randomly assigned to one bin throughout the study. Cows were milked twice daily and daily milk yield (MY) was recorded. Milk samples were collected weekly from 2 milkings. Dry matter intake (DMI), energy-corrected milk yield (ECM), and milk protein yield were averaged by week and analysed using the nlme function in R with a model including covariate week and fixed effects of parity, MP level, RPB level, experimental week, and interactions among MP, RPB and week. Experimental week within cow was used as a repeated term with an autoregressive residual correlation structure. The interaction between MP, RPB and experimental week were not significant for any of the tested variables. Overall, DMI did not differ among MP or RPB levels and averaged 21.7 ± 0.26 kg/d across parity groups. However, there was an interaction between RPB and experimental week (P = 0.03), it being lower for the lowest RPB level in the first experimental weeks, recovering to a similar level across the RPB levels towards the end of the experiment. When taking into consideration the duration of the trial, a lower RPB may have limited microbial protein synthesis and ruminal fermentation during the first weeks of the experiment, and therefore limited DMI, whereas in later experimental weeks the rumen may have had time to adapt to the lower levels of RPB and recovered DMI to a similar level across the RPB levels. Energy-corrected milk yield was affected by MP overall (P = 0.01), but the response was neither linear nor quadratic. Adjusted means suggested lower ECM (33.1 ± 0.79 kg/d) at the lowest MP level (13.5 g/MJ), whereas the intermediate and highest levels (14.5 and 15.5 g/MJ) did not differ (35.0 vs 34.7 ± 0.79 kg/d; overall MP effect, P = 0.01). Rumen protein balance did not affect ECM. Milk protein yield decreased in a linear manner (P = 0.01) with both decreasing MP and RPB from 1.20 to 1.13 kg/d for MP and from 1.21 to 1.14 kg/d for the RPB levels, respectively. In conclusion, these preliminary findings indicate that a moderate reduction of dietary protein supply is possible in dairy cows' diets, without compromising overall production and feed intake. Further, the distinguishing between metabolizable protein and rumen protein balance still remain important for sustaining the overall production of the animals.

Quantitative meta-analysis on the effects of manipulating rumen degradable protein balance by changing protein degradability on fat and protein corrected milk in Holstein dairy cows

E. Parand[1], H. Van Laar[1]
[1] Wageningen Livestock Research, Animal Nutrition, De Elst 1, 6708 WD Wageningen, Netherlands

Inefficiency of nitrogen (N) utilization in dairy cattle production results primarily from N losses in urine and feces. These losses are partly attributed to an imbalance between rumen-available N and fermentable energy, which limits microbial capture of ammonia in the rumen. RDPB, calculated according to the DVE/OEB system (Van Duinkerken et al., 2011), represents the balance between microbial protein synthesis potential from rumen degradable protein and that supported by fermentable energy. A positive rumen degradable protein balance (RDPB) indicates potential N loss from the rumen, while a negative RDPB suggests microbial protein synthesis may be impaired due to an N shortage. We performed a meta-analysis to quantify the effect of changing RDPB, through changes in protein degradability, on fat and protein corrected milk (FPCM). A literature search covered PubMed, Google Scholar, ScienceDirect, Web of Science, and CABI. Inclusion required clear descriptions of animal characteristics (milk yield and composition, dry matter intake, body weight) and diet composition. To isolate the effect of RDPB, we retained studies where intestinal digestible protein (DVE) was kept relatively constant while RDPB varied due to changes in rumen degradable protein supply from protein-rich feedstuffs. The final dataset comprised 206 observations from 56 studies. Milk yield was standardized to FPCM using: FPCM (kg/d) = milk (kg/d) * (0.337 + 0.116 * fat% + 0.060 * protein%). Mean body weight, DMI, and FPCM were 638 kg, 23.2 kg/d, and 33.3 kg/d. Statistical analysis used exponential mixed models in SAS (GLIMMIX and NLMIX), with study as a random effect: FPCM = a + b * (1 – exp(-c * RDPB)). Predictors were RDPB (g/kg DM) and RDPB intake (RDPBI). Models were evaluated using mean square prediction error (MSPE), RMSPE, and concordance correlation coefficients (CCC). Both the RDPB and RDPBI models performed well (R2 = 0.88; CCC = 0.93). The FPCM response to RDPB was curvilinear (a = 33.01, b = 1.376, c = 0.0350; $P < 0.05$). Model fit was good (RMSPE = 6.82; AIC = 1164.9). Increasing RDPB from -20 to 0 g/kg DM increased FPCM by 1.4 kg/d, nearly double the 0.69 kg/d increase from 0 to +20 g/kg DM. The response flattened at approximately 20 to 25 g RDPB/kg DM. In conclusion, RDPB levels significantly influence FPCM via a nonlinear relationship. Maintaining a non-negative RDPB is important for rumen function and production, while increasing RDPB far beyond zero offers diminishing returns for milk output and may increase environmental N losses. Impact of diet optimisation on diet carbon footprint intensity and productive performance of lactating dairy cows

R. Schmith[1], R. Tonucci[2], M. M. Campos[2], J. P. Matiello[2], M. A. C. Danes[1], J. P. P. Rodrigues[2], A. Rytz[3], C. Powell[4], J. B. Daniel[5], A. B. P. Fontoura[6], M. E. Van Amburgh[6], R. Rauch[3]

[1] Universidade Federal de Lavras, Prof Edmir Sá Santos, 37203202 Lavras, Brazil, [2] Empresa Brasileira de Pesquisa Agropecuária, Embrapa Gado de Leite, Eugênio do Nascimento, 3603830 Juiz de Fora, Brazil, [3] Nestlé Institute of Agricultural Sciences, Nestlé Research, Route du Jorat, 1000 Lausanne, Switzerland, [4] Trouw Nutrition, McLean Rd, N0B 2J0 Puslinch, Canada, [5] Trouw Nutrition, R&D, Stationsstraat, 3800 AG Amersfoort, Netherlands, [6] Cornell University, Thurston Ave, 14853 Ithaca, United States

Milk carbon footprint intensity (MCFI) is influenced by emissions associated with dietary ingredients. We hypothesized that diet optimization can improve MCFI by reducing diet carbon footprint intensity (DCFI, kg CO2e/kg fat and protein corrected milk (FPCM)) where DCFI is based on FPCM and ingredient intake and emission factors. Ingredient and cow data were used by 2 models to optimize diets relative to a control diet formulated to reflect commercial conditions (CON): Trouw Nutrition Response research model (OT1) and Cornell Net Carbohydrate and Protein System v6.5.5 (CNCPS, OT2). A prior Brazil study evaluated commercially available ingredients not currently used by enrolled commercial farms (dried distillers grain with solubles, urea, rumen protected methionine, rumen protected lysine); these were optional in the current study optimisations, partly replacing other ingredients. The study was a randomized complete block design in Brazil (28 d adaptation and covariate, 56 d experimental). Forty-five Holstein cows (20% primiparous, 80% multiparous; 36.0 ± 7.5 kg/d milk yield (MY); 133 ± 57 days in milk (DIM)) were enrolled, paired by parity, MY, DIM and body weight, and randomly assigned to treatment. Data analysis used a mixed model with treatment, week and their interaction as fixed effects and block as a random effect. Least squares means were compared using Tukey's test. Significance and trends were declared at $P \leq 0.05$ and $0.05 < P \leq 0.10$, respectively. Based on covariate data (including observed DMI of 27.4 kg/d) and subsequent diet optimisations, predicted MY was 35.7 and 54.2 kg/d, whereas predicted DCFI was 1.03 and 0.64 for OT1 and OT2, respectively. Dry matter intake was lower in OT1 vs. CON and OT2 (25.6; 26.3; 26.6 kg/d) but did not differ in CON vs. OT2. Milk yield was lower in OT1 vs. CON and OT2 (35.3; 36.2; 36.4 kg/d) and FPCM responded similarly (31.5; 33.5; 33.3 kg/d). Milk protein content was higher in OT2 vs. CON and OT1 (3.63%, 3.51%; 3.45%) and CON vs. OT1 tended to differ. Milk fat content was higher in CON vs. OT1 and OT2 (3.36%; 3.10%; 3.14%). The DCFI differed in OT1 (-11.3%) and OT2 (-21.8%) vs. CON (1.18; 1.04; 1.33 kg CO2e/kg FPCM) and differed in OT1 vs. OT2. Milk urea nitrogen was lower in OT1 (-11.2%) and OT2 (-25.7%) vs. CON. Nitrogen utilization efficiency (NUE) was higher in OT1 (+4.5%) and OT2 (+16.9%) vs. CON, supported by different dietary crude protein levels (18.0%; 16.9%; 16.2% of dry matter for CON, OT1 and OT2). Feed efficiency (FPCM–based) was lower in OT1 vs. CON and OT2 (1.23; 1.28; 1.26) and tended to differ in CON vs. OT2. Relative to model predictions, observed MY was 1% and 33% lower, while DCFI was 15% and 63% higher for OT1 and OT2, respectively, the latter partly explained by 8% higher DCFI for CON in experimental vs. covariate phases. Differences in predicted vs. observed outcomes merit further research. Diet optimization had variable effects on productivity. For both OT1 and OT2, we confirmed the hypothesis that diet optimization can improve DCFI, while NUE also improved. Ongoing research is evaluating economics and enteric methane and manure emissions to confirm effects on MCFI.

Grazing, feeding, manure and air management for dealing with environmental impacts of intensive dairy farming

A. Kuipers[1], P. Galama[1]
[1] Wageningen University & Research, De Elst 1, 6708WD Wageningen, Netherlands

Intensive dairy farming is increasingly challenged to reduce environmental emissions while maintaining productivity and economic viability. This contribution focuses on practical farm-level strategies and emerging technologies that can support this transition. A first pathway concerns grazing and feeding management. In the Netherlands, sector agreements have aimed to stimulate grazing and reduce crude protein content in dairy cow rations. However, implementation of more grazing remains challenging, particularly for the increasing number of herds using automatic milking systems. Lowering dietary crude protein has proven effective in reducing nitrogen losses and ammonia emissions in a field project set-up, but further progress requires improved farm-specific ration formulation and monitoring; expansion of this activity of lowering crude protein to the whole dairy farm sector is in progress. A second pathway is the transition toward target-oriented environmental management, in which farmers can combine practices and technologies to meet farm-specific emission goals. This approach requires reliable on-farm sensors for monitoring emission outflows; the current state of development of such tools will be discussed. A third pathway involves innovations in housing, manure and air management. Systems such as the cow toilet and Lely Sphere illustrate the movement from experimental concepts to practical application. In addition, our work addresses the combined removal of ammonia and methane from barn air. We currently evaluate new options such as the Methane Eradication Photochemical System (MEPS), developed at Copenhagen University, which has shown reductions of more than 90% for NH3 and about 50% for CH4 under experimental conditions. In parallel, cooperation with the University of Washington explores methanotroph bacteria for methane digestion at low concentrations (90% CH4 reduction at 500 ppm; CH4 concentrations in dairy barns vary from 5 to 100 ppm). The potential valorization of the N captured from manure and air in housing facilities, to be used as fertilizer, and the bacteria digested methane to protein, envisioned to become useful as animal feed, are essential for the economic result of these new technologies. Wageningen University & Research supports and plans implementation through demonstration and system redesign at two locations: an emission-free, labour-efficient dairy housing facility at Dairy Campus, and a lower-input dairy system with precision grazing, precision feeding, and freewalk housing with compost bedding at Agro-Innovation Centre De Marke. These examples show that reducing environmental impacts in intensive dairy farming will depend on integrated, farm-specific combinations of management, monitoring, gas emission capture and nutrient valorization.

Farm level analysis of on-farm monitoring of methane from dairy cows and relationship to farm characteristics and farm level climate accounts

K. Horsted[1], L. Sembach[2], G. Giagnomi[3], P. Lund[3], T. M. Villumsen[4], H. Schneider[5], A. M. Kjeldsen[5], L. Mogensen[1]
[1] Aarhus University, Agroecology, Blichers Alle, DK-8830 Tjele, Denmark, [2] Arla Foods Amba, Sønderhøj, DK-8260 Viby J, Denmark, [3] Aarhus University, Animal and Veterinary Sciences, Blichers Alle, DK-8830 Tjele, Denmark, [4] Aarhus University, Center for Quantitative Genetics and Genomics, C. F. Møllers Alle, DK-8800 Aarhus, Denmark, [5] SEGES Innovation P/S, Agro Food park, DK-8200 Aarhus N, Denmark

The aim of the present study was to analyze methane measurements obtained from on-farm monitoring of dairy cows in Denmark using the Sniffer-method in AMS systems during milking to identify farm characteristics associated with variation in average methane emissions between farms. Furthermore, on-farm methane measurements were compared with methane emissions per cow as calculated in the Arla farm-level climate accounting tool. The analysis was based on data from 24 dairy farms, each contributing between 1 and 4 years of observations from the period 2021–2024. The dataset included cows of the Holstein, Danish Red, and Jersey breeds. For the analysis, methane data were aggregated as annual farm-level averages, and the following variables were included: measured CH_4 concentration (ppm) in expired breath, calculated kg CH_4/cow/day, and calculated kg CH_4/kg ECM. These annual methane averages were further stratified into two groups: first-parity cows, and cows in second or higher parity. Each farm was visited once by a technician, who conducted interviews to collect information on farm characteristics. Key variables hypothesised to influence methane emissions included: The proportion of roughage in the ration (% of DM), the composition of roughage (proportion of grass silage and grazed grass), the strategy for concentrate allocation (e.g., individually allocated vs. group-based), and the amount of concentrate provided per cow. Using routinely recorded farm performance data, several key performance indicators (KPIs) were calculated, including milk yield per cow per year, culling rate, average age of cows in the herd, cow mortality, incidence of hoof and limb disorders, metabolic disorders and mastitis, as well as live weight. The analysis examined whether variation in these KPIs could explain variation in methane emissions among farms. On-farm methane measurements were compared with methane emissions per cow estimated in the climate accounting tool from Arla. The hypothesis was that the ranking of farms in terms of methane emission per kg of milk would be similar whether methane was directly measured on-farm or estimated through the climate account. Measured enteric methane emissions per cow per day were increased with increased milk yield per cow per day. Whereas g CH4 per kg ECM declined with increased milk yield across all three breeds. This was the case both when presented per breed and across all three breeds.

Carbon farming potential of Mediterranean cow–calf systems under different cultivation intensities

M. F. Lunesu[1], S. Sechi[1], F. Correddu[1], S. Carta[1], S. P. G. Rassu[1], G. Pulina[1], G. Battacone[1], A. Nudda[1]
[1] University of Sassari, Agraria, Viale Italia 39, 07100 Sassari, Italy

This study aimed to estimate the net carbon footprint (Net-CFP) of Mediterranean cow-calf systems and to assess how cultivation intensity affects their carbon farming potential. Eighteen beef farms adopting a cow-calf grazing system, with an open productive cycle, were considered. Farms were selected in relation to the cultivation rate (CR) and classified as: high (high-CR; > 15% of cultivated lands) and low (low-CR; <15% of cultivated lands). Data were collected by interviewing farmers, in a cradle to farm gate approach, and according to ISO14040:2006 and 14044:2006 standards. The average of five producing years was chosen as the temporal boundary. Emission intensity was reported as kilogram of CO2 equivalent (CO2e) per kg of live weight (LW) sold from yearling beef, per kg of total LW (TLW) sold from end-career cows, bulls, and yearling beef, and per hectare (ha) of land. Soil carbon sequestration was estimated by considering the above- and below-ground biomass residues, and the organic carbon from manure deposition. Carbon sequestration from Meriagos, forests, and Mediterranean scrubland was also considered. Gross CFP was lower in low-CR farms than in high-CR farms (19.80 vs. 26.75 kg CO_2e/kg LW sold). Enteric methane was the main contributor, accounting for 68.3% and 74.2% of total GHG emissions in high and low-CR farms, respectively. When carbon sequestration was included in the model, Net-CFP was lowest ($P<0.01$) in low-CR farms. In conclusion, lower cultivation intensity reduced the CFP of cow-calf system, generating higher carbon credits that could fully offset the emissions of the fattening phase. These results highlight the carbon farming potential of extensive Mediterranean beef system, where practices that increase soil carbon sequestration can enhance sustainability and support EU climate policies. However, this potential is based on farm level assessments and does not automatically translate into certified carbon credits. Therefore, further work is needed to assess eligibility and practical implementation within formal carbon crediting frameworks. Acknowledgements The authors acknowledge the University of Sassari for the financial support (Mobilità Giovani Ricercatori, annualità 2024-2025; D.R. rep. n. 4422/2025, prot. n. 148562 del 23/12/2025).

Seasonal variation in enteric methane emissions and production efficiency metrics in a higher-output Irish pasture based dairy system including concentrates with differing levels of crude protein.

F. Monaghan[1], K. M. Mccarthy[1], K. M. Pierce[2], Z. C. Mckay[2], Y. Kavanagh[2], N. Dooley[2], F. J. Mulligan[1]
[1] UCD, School of Veterinary Medicine, UCD, Dublin 4, Belfield, D04 W656 Dublin, Ireland, [2] UCD, School of Agriculture and Food Science, UCD, Lyons Farm, Celbridge, Naas, Co. Kildare, W23ENY2 Dublin, Ireland

Quantifying seasonal variations in enteric methane (CH4) and its relationship with production metrics allows for the development of more accurate, system-specific conversion factors for pasture-based dairy systems. Accurate CH4 conversion factors are essential for correct national greenhouse gas inventories, yet current Irish estimates rely largely on predictive Tier 2 models rather than direct measurement . This approach poorly captures the variation due to season, diet, grazing conditions or cow types, applicable to Irish pasture-based systems. Furthermore, Irish farmers are required to restrict concentrate crude protein (CP) to a maximum CP of 14% during the main grazing season . The effects of concentrate CP concentration, and the associated response in enteric CH4 production in grazing dairy cows, are not established. Therefore, the objectives of the study were to 1) directly measure enteric CH4 across the grazing season and 2) quantify the effect of concentrate CP content on enteric CH4 production in a higher output grazing system. Fifty spring-calving Holstein-Friesian dairy cows were blocked by parity and days in milk (DIM). Within blocks, primiparous cows were balanced by body weight (BW) and pre-experimental milk solids (MS) , while multiparous cows were balanced by their previous 305-day MS and milk yield. Cows were randomly allocated to one of two dietary treatments: a 12% (C12) or 14% (C14) CP concentrate formulated with barley, oats, and beans. The concentrate supplementation (CS) rate was adjusted based on DIM, decreasing from 8 kg/d in early lactation to 3 kg/d in late lactation. The herd grazed a 17.35-ha farmlet as a single group, receiving their allocated concentrates individually during twice-daily milking. Daily pasture allowances ranged from 14 to 17 kg dry matter (DM) per cow, adjusted for stage of lactation and CS levels. The 17-week study (April 28–August 22) was preceded by a 3-week acclimatization period. Enteric CH4 emissions were measured continuously using three GreenFeed units (GEM). Pasture intake was estimated via the n-alkane marker method during weeks 6 (Period 1), 12 (Period 2), and 19 (Period 3). Data was analysed using repeated measures ANOVA (MIXED procedure). A probability of $P \leq 0.05$ was selected as the level of significance, and statistical tendencies were reported when $0.05 < P \leq 0.10$. Neither milk yield nor MS production was affected by concentrate CP concentration. Daily milk yield was 32.6 kg/d and 33.2 kg/d for cows offered C12 or C14 respectively. Pasture dry matter intake (DMI) was unaffected by treatment ($P = 0.722$), though it did vary between period ($P < 0.001$). Mean pasture DMI per cow was 15.1 kg DM, 17.8 kg DM and 17.6 kg DM in period 1, 2 and 3 respectively. Mean enteric CH4 production was lower ($P = 0.05$) for cows offered C12 (323 g/d) than C14 (343 g/d). CH4 expressed per kg of milk, MS, DMI or BW was not affected by treatment. However, both enteric CH4 emissions and intensity metrics increased from period 1 to period 3 ($P < 0.05$). Absolute CH4 production rose from Period 1 to Period 3, a trend mirrored by CH4 yield (CH4 /kg DMI) and CH4 intensity (CH4/kg MS). These results show that enteric CH4 in higher-output grazing systems varies seasonally and highlight the need for season-specific conversion factors.

Environmental impact of pasture turnout strategies in dairy cows grazing timothy–meadow fescue pasture

G. Mantovani[1], M. Vadronova[1], M. Ramin[1], P. Fant[1]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Skogsmarksgränd, 901 83 Umeå, Sweden

Grazing animals affect pastoral systems by removing nutrients during grazing and redistributing them through excreta. In grazing systems, urinary N deposition can exceed plant N uptake, leading to nitrate leaching, ammonia volatilization, and nitrous oxide emissions that contribute to atmospheric pollution. Moreover, data on enteric methane (CH4) emissions from grazing systems are often inconsistent and vary with experimental conditions. This study investigated the impact of early-season part-time grazing on urinary N and urea excretion and CH4 emissions in dairy cows in northern Sweden. The experiment followed a randomized block design with 40 lactating Nordic Red cows. During a 14-day covariate period, cows were housed indoors and fed a TMR ad libitum containing grass silage and concentrate (60:40 forage-to-concentrate ratio on a DM basis). During the subsequent 28-day treatment period, cows within blocks were randomly assigned to 1 of 4 treatments: indoor feeding only (CON), 12 h grazing with ad libitum indoor feeding (G1), 12 h grazing with restricted indoor feeding (80% of DM intake during the covariate period; G2), and 12 h grazing with ad libitum indoor feeding and a 50:50 forage-to-concentrate ratio in the TMR (G3). The pasture was sown with 10% white clover, 40% timothy, 40% meadow fescue, and 10% Kentucky bluegrass, and herbage allowance exceeded 20 kg DM/cow per day. Spot urine samples were collected once daily for 3 consecutive days at the end of each period and pooled within cow and period. Urinary creatinine was used to adjust urea and N concentrations for urine dilution. These data were used to estimate excretion of urinary N (UNe) and urinary urea (UUNe). Enteric CH4 and CO2 emissions were measured using two indoor GreenFeed (GF) units (C-Lock Inc., Rapid City, SD), with no GF available on pasture, and data from the final 14 days of each period were used for analysis. Records with <20 GF visits per cow during the measurement period were excluded. Data were analyzed using analysis of covariance (ANCOVA) in SAS, including treatment and block as fixed effects and baseline value as a covariate. When treatment effects were significant, the following contrasts were specified: CON vs. G1 and G2; CON vs. G3; and G1 and G2 vs. G3. Because cows in G2 did not reach the intended restriction level, they were considered ad libitum and therefore analyzed together with G1. Treatment did not affect urinary urea or N concentration, UNe or UUNe ($P \geq 0.14$). Mean UNe values were 261 ± 19, 212 ± 16, 246 ± 17, and 256 ± 16 g N/d for CON, G1, G2, and G3, respectively. Daily CH4 emissions were lower ($P < 0.01$) in G1 and G2 than in CON (368 ± 11 and 375 ± 11 vs. 415 ± 12 g/d, respectively), whereas daily CO2 emissions did not differ among treatments. Methane intensity did not differ among treatments and averaged 11.4 ± 0.4 g/kg ECM. Several limitations should be considered. Grazing cows had access to GF only during daytime indoor periods, with no GF available on pasture, with no measurements during the 12 h night grazing period, limiting the ability to capture diurnal variation in CH4 emissions related to feeding patterns. In addition, urinary volume was estimated from pooled spot urine samples, which may have introduced uncertainty in the estimates. Within the conditions of this study, early-season part-time grazing did not affect urinary urea or N excretion. Although daily CH4 emissions were lower in grazing cows receiving the same daytime diet as indoor-fed cows, CH4 intensity was similar between indoor-fed cows and part-time grazing cows.

Forage type and lipid-rich concentrates as practical levers to mitigate enteric methane in fattened lambs: links to rumen fermentation and methanogenic microbiota

J. Łodyga[1], B. Borys[2], E. Wawrzyniak[1], W. Warguła[1], M. Szott[1], S. Olorunlowu[1], A. Cieślak[1]
[1] Poznan University of Life Sciences, Department of Animal Nutrition, Wołynska 33, 60-637 Poznan, Poland,
[2] National Research Institute of Animal Production, Experimental Station Kołuda Wielka, Parkowa 1, 88-160 Janikowo, Poland

Enteric methane (CH_4) from ruminants remains a key contributor to the environmental footprint of livestock systems. Practical mitigation strategies that can be implemented at the farm level, through feeding and forage management, are therefore urgently needed. This study evaluated how forage type (grass vs. red clover) and a lipid-rich concentrate influence rumen fermentation, microbial ecology, and CH_4 production in fattened lambs, providing evidence for an applicable dietary approach to reduce emission pressure. The experiment was conducted over two consecutive years (2022 and 2023) and involved a total of 48 ram lambs (24 lambs per year), fattened to a body weight of approximately 35 kg (± 3 kg). Animals were assigned to four dietary treatments based on concentrate offered at 3% of body weight and forage provided ad libitum: (1) control: standard cereal-based concentrate (>50%) with rapeseed + soybean meal (>40%) plus grass; (2) "OL" concentrate containing 35% oily components (15% rapeseed cake, 15% DDGS, 5% linseed) plus grass; (3) standard concentrate plus red clover; (4) OL concentrate plus red clover. Rumen fluid was collected post mortem from all 48 lambs to determine pH, volatile fatty acid (VFA) profiles, ammonia concentration, and the abundance of bacteria, protozoa, and methanogens. Methane production (g CH_4/day) was measured at the final stage of fattening using respiration chambers equipped with infrared gas detection (Servomex 4000 Series, UK). Measurements were performed on a subset of animals representing 4 groups × 2 lambs × 2 experimental repetitions. In total, 16 lambs were evaluated, with 8 animals measured in each year. Dietary inclusion of oily components modified the rumen microbial profile, as reflected by a lower protozoal count (10.3 × 10^5/mL vs 18.2 × 10^5/mL in the control) and a shift in fermentation toward greater propionate production (16.8 vs 13.0 mM/L). These changes were accompanied by a reduction in methane emission. The greatest mitigation effect was observed in lambs receiving the red clover-based diet combined with the OL concentrate, where methane emission was reduced by 20.5%, from 19.6 g CH_4/day in the control group to 15.6 g CH_4/day. Our findings indicate that combining legume forage (red clover) with a lipid-enriched concentrate can deliver meaningful (by ~20%) CH_4 mitigation in intensive lamb fattening, likely through coordinated effects on rumen fermentation pathways and microbial communities involved in methanogenesis.

Evaluation of dibromomethane as an anti-methanogenic feed additive for dairy cows in a dose-response study

M. Thorsteinsson[1], A. L. F. Hellwing[1], P. Lund[1], M. R. Weisbjerg[1]
[1] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Alle 20, 8800 Tjele, Denmark

Bromoform, a trihalomethane, has been identified in numerous studies as an effective methane-mitigating feed additive, with most studies focusing on bromoform derived from the red seaweed Asparagopsis spp. However, large-scale cultivation or harvesting and subsequent post-harvest processing of Asparagopsis spp. presents practical challenges. Moreover, concerns regarding animal and consumer health have been raised, as bromoform is classified as a possible human carcinogen. Studies using Asparagopsis spp. have also reported elevated bromine concentrations in milk. Dibromomethane (DBM), a dihalomethane, has likewise demonstrated anti-methanogenic effects in vitro. In theory, the use of DBM as a methane-mitigating feed additive may result in lower bromine transfer to milk compared with the trihalomethane. Therefore, this study investigated the effects of increasing doses of DBM in the feed ration of dairy cows on enteric gas emissions, dry matter intake (DMI), and energy-corrected milk (ECM) yield. It was hypothesized that increasing levels of DBM would result in greater inhibition of ruminal methanogenesis without affecting DMI or milk yield. The experiment was conducted as a 4 × 4 Latin square using four multi-cannulated Danish Holstein dairy cows. According to a balanced Williams design, the cows received either a control ration without additive (CONTROL) or the same ration supplemented with 7 (LOW), 14 (MEDIUM), or 21 mg DBM/kg DM (HIGH). Each period lasted 21 d and consisted of 14 d of adaptation, followed by 3 d of digesta sampling and 4 d of gas exchange measurements using respiration chambers. The rumen was visually inspected for signs of damage, such as papillae atrophy or ulcers, prior to the experiment and on d 17 of each period by rumen evacuation. Milk yield and feed intake were recorded daily, DMI was determined from d 14 to 21, and milk solids were analysed from d 18 to 21. All parameters were statistically analysed using a mixed procedure of R. The addition of DBM had no effect on DMI (kg/d; linear effect: $P = 0.24$), whereas ECM yield (kg/d) tended to decrease linearly with increasing DBM dose ($P = 0.09$). Daily methane emission (g CH_4/d), yield (g CH_4/kg DMI), and intensity (g CH_4/kg ECM) decreased with increasing DBM dose ($P < 0.01$, $P = 0.02$, and $P = 0.03$, respectively). In contrast, daily hydrogen emission (g H_2/d), yield (g H_2/kg DMI), and intensity (g H_2/kg ECM) increased with increasing DBM dose ($P < 0.01$ for all parameters). No indications of rumen damages were observed (visual inspections) during rumen evacuations. Methane yield and intensity were reduced by 16% and 15%, respectively, from CONTROL to HIGH, whereas similar doses of bromoform in seaweed studies have resulted in 25–30% reductions in dairy cows. Hence, the efficacy of DBM appears to be lower than that of bromoform at the same halomethane inclusion level (mg/kg DM). In the rumen, both bromoform and DBM are rapidly metabolized. However, because bromoform is converted to DBM as an intermediate, methanogenesis is inhibited for a longer duration following bromoform supplementation than with DBM alone, which may explain its greater methane-mitigating potential. In conclusion, increasing DBM dose resulted in a linear inhibition of rumen methanogenesis; however, a tendency for a linear decrease in ECM yield was also observed, while DMI was unaffected.

Grape stem inclusion in the diet of fattening young bulls reduced methane emissions

D. Villalba[1], I. Casasús[2], M. Joy[2], S. Lobón[2], M. Blanco[2]
[1] Universitat de Lleida, Av. Rovira Roure 191, 25198 Lleida, Spain, [2] CITA - IA2, Av. Montañana 930, 50059 Zaragoza, Spain

To promote circularity, grape (Vitis vinifera) stems, a fibrous agro industrial by product, can be included in fattening cattle diets at low doses (up to 6%) without deleterious effects on performance. The polyphenols present in grape have antioxidant and anti-inflammatory effects, and besides they could reduce the methane emissions modifying rumen fermentation. Young bulls (162 days old; 173 kg BW, n=24) were fed iso-energetic (13.2 MJ/kg DM) and iso-proteic (11.2% CP) concentrates plus barley straw ad libitum for 17 weeks. Concentrates contained different proportions of grape stem and barley straw in inverse ratios: 0% stem (6% straw), 3% stem (3% straw) and 6% stem (0% straw). Young bulls were weighed weekly to monitor body weight (BW) and calculate average daily gain (ADG). Concentrate intake per animal was registered with two ALPRO feeding stations (ALPRO Herd Management 7.0, DeLaval) to estimate dry matter intake (DMI). Methane concentrations were recorded with two wall-mounted Guardian NG NDIR methane monitors (Edinburgh Instruments, Livingston, UK) sampling air continuously from the concentrate feed bins via a fixed inlet tube. Average weekly methane emissions were derived by converting the sniffer-measured CH_4:CO_2 concentration ratio into daily CH_4 output using an estimated daily CO_2 production from animal heat production (based on BW and ADG). Methane emissions were analysed using a mixed-effects model (PROC MIXED, SAS), including grape stem inclusion level, week and their interaction as fixed effects, with the animal as a repeated subject (ARH(1) covariance structure), Kenward–Roger adjustment for degrees of freedom, and Tukey-corrected pairwise comparisons of least squares means. Compared with the control diet (0% grape stem), both grape-stem inclusion levels (3% and 6%) reduced daily methane production by approximately 10% (146, 131 and 131 g/d for 0%, 3% and 6% respectively; $P < 0.05$). When methane emissions were expressed per unit of DMI, only the 6% inclusion level remained lower than the control, whereas the 3% level was intermediate (19.4, 18.0 and 17.5 g/kg DMI, respectively ($P=0.03$). In contrast, expressing methane relative to BW reduced the magnitude of treatment differences and no significant contrasts with the control were detected (0.364, 0.339 and 0.340 g/d kg BW; $P>0.05$), suggesting that part of the reduction in absolute emissions was associated with differences in intake and animal growth rather than a uniform shift in methane yield. This lack of significance is likely due to the limited sample size and the variability in methane measurements. The inclusion of grape stems in high-concentrate diets for fattening young bulls reduced methane emissions. However, the magnitude and statistical significance of the reduction depended on how methane production was expressed. Further studies with larger sample sizes and more precise methane measurements are needed to confirm these effects.

Impact of sainfoin (Onobrychis viciifolia) inclusion in beef fattening diets on methane emissions

D. Villalba[1], E. Molina[1], I. Casasús[2], M. Joy[2], M. Blanco[2]
[1] Universitat de Lleida, Av. Rovira Roure 191, 25198 LLeida, Spain, [2] CITA - IA2, Av. Montañana 930, 50059 Zaragoza, Spain

Improving feed self-sufficiency in beef production is essential to reduce economic vulnerability and the environmental footprint associated with imported protein sources such as soybean meal. Sainfoin (Onobrychis viciifolia, SF), a tannin-rich legume adapted to local conditions, may enhance nitrogen (N) utilization while reducing enteric methane (CH_4) production. We hypothesized that increasing dietary sainfoin inclusion would modify CH_4 emissions depending on its NDF content and starch-to-NDF ratio of the diets. Forty Montbéliarde calves (117 days; 188 kg initial BW) were allocated to four diets in a 2 × 2 factorial design over 28 weeks, differing in forage type (barley straw vs. sainfoin hay) and concentrate formulation (control vs. sainfoin concentrate). The sainfoin concentrate was formulated by including 15% pelleted sainfoin, mainly replacing fibrous by-products and part of the cereal–protein fraction of the control concentrate (notably wheat bran, soybean meal, rapeseed meal and barley), while maintaining a similar cereal base based on corn grain. Treatments were: C+straw (control concentrate + straw, 0% SF in the total diet), CSF+straw (sainfoin concentrate + straw, 12% SF in the diet), C+SFhay (control concentrate + sainfoin hay, 20% SF in the diet), and CSF+SFhay (sainfoin concentrate + sainfoin hay, 33% SF in the diet). Individual intake and BW were recorded daily automatically and were used to calculate feed efficiency (growth:feed). Methane concentrations were recorded with a wall-mounted Guardian NG NDIR methane monitor (Edinburgh Instruments, Livingston, UK) sampling air continuously from the concentrate feed bin via a fixed inlet tube. Average weekly methane emissions were derived by converting the sniffer-measured CH_4:CO_2 concentration ratio into daily CH_4 output using an estimated daily CO_2 production from animal heat production (based on BW and ADG). Each treatment was recorded during one month. Methane emissions were estimated using mixed linear models (lmer, R), including animal as random effect and second-order polynomial BW adjustment. Methane production increased as dietary starch:NDF ratio decreased. Absolute CH_4 emissions were highest in CSF+SFhay (80.9 g/d) and lowest in CSF+straw (65.8 g/d). The increase of emissions observed exceeded the expected increase according to starch:NDF ratio in CSF+SFhay and C+straw (1.9 and 2.2 respectively), suggesting a stronger-than-expected NDF effect from sainfoin. On the other hand, CSF+Straw had equal methane emissions than C+Straw despite a higher NDF content. The random effect obtained from the model had a low negative correlation with individual efficiency ($r=-0.31$, $p<0.05$). In conclusion, a high inclusion of sainfoin (33%) increased enteric CH_4 emissions due to the greater dietary NDF associated with higher forage intake, whereas at a medium inclusion level (20%) this increase was partially counteracted by the greater intake of sainfoin-derived tannins. Based on the analysed tannin concentration of sainfoin hay (3.96 g equivalents condensate tanins/kg DM) and measured feed intake, estimated tannin intake increased from 0.0 to 3.2, 4.0 and 10.0 g/d in the 12%, 20% and 33% sainfoin diets, respectively. Therefore, when maximizing circularity is the main objective, the combined inclusion of sainfoin in pellet and hay form is recommended, whereas a moderate inclusion through pellets with straw may be preferable when prioritizing absolute CH_4 mitigation.

Optimizing fattening duration in Hanwoo steers: Impacts on growth performance, enteric methane emissions, feed efficiency, and rumen microbial communities

J. I. Berdos[1], K. S. Dhia[1], M. Miguel[1], M. N. Aprilliza Am[1], S. Begum[1], Y. P. Naing[1], A. R. Son[1], K. S. Baik[1], K. C. Nam[1], S. H. Kim[1], S. S. Lee[1]

[1] Sunchon National University, Department of Animal Science and Technology, 255, Jungang-ro, 57922 Suncheon-Si, South Korea

Methane (CH4) from ruminant enteric fermentation contributes significantly to anthropogenic greenhouse gases, particularly Hanwoo beef production in Korea, relying on prolonged fattening (>30 months) for marbling, amplifying emissions. This study evaluated the impact of fattening duration on growth performance, greenhouse-gas (GHG) emissions, and rumen microbial communities in Hanwoo steers. Forty-eight Hanwoo steers were assigned to six groups (n=8 per group) by starting age (10 or 13 months) and slaughter age (26, 28, or 30 months): 10/26 , 10/28, 10/30, 13/26, 13/28, and 13/30. Steers were monitored for body weight (BW), dry matter intake (DMI), GHG emissions (CH4 and CO2), and rumen fermentation profiles. Gas measurements were meaured using the GreenFeed system (C-Lock Inc., Rapid City, SD, USA) over three consecutive days at slaughter age, following an 8 spot-sampling protocol to cover a 24-h feeding cycle: 0900, 1500, 2100 h (day 1); 0300, 1200, 1800 h (day 2); and 0000, 0600 h (day 3). At slaughter age, body weight was measured, and rumen fluid was collected using an oral stomach tube connected to a vacuum pump. Collected samples were used to analyze the fermentation and rumen microbiota profiles. Microbial composition was characterized by 16S rRNA amplicon sequencing of the V3-V4 (bacteria) and V5-V6 (archaea) regions. Data were analyzed using a two-way fixed-effects model implemented in SAS (PROC MIXED). The model included two categorical fixed effects: starting age (10 or 13 months) and slaughter age (26, 28, or 30 months), along with their interaction. Statistical significance was declared at $P \leq 0.05$. No significant differences were observed in rumen fermentation parameters across groups ($P > 0.05$). The slaughter age showed a tendency to influence final body weight (PSlaughter age = 0.0532) across groups, with the highest BW recorded in the 10/30 group (835.00 ± 30.00 kg). Additionally, the 13/28 group exhibited greater feed efficiency, with the lowest feed conversion ratio (FCR = 11.16 ± 0.81) and a negative residual feed intake (RFI = -1.91 ± 0.30) compared to other groups. Total CH4 and CO2 emissions revealed significant interactions between starting and slaughter ages ($P < 0.05$). The 13/28 group had the lowest total CH4 emissions (70.60 ± 8.07 kg CH4 /head) and CO2 (3942.70 ± 443.55 kg CO2/head) compared to other groups ($P< 0.05$). Additionally, the 13/28 group exhibited the lowest daily CH4 production (g/d) and CH4 yield (g/kg DMI) than other groups ($P < 0.05$). Microbial analysis identified Bacteroidota and Bacillota as dominant bacterial phyla and Methanobacteriota as the primary archaeal phylum. Ruminococcus bromii ($r = 0.80$, $P = 0.055$) and Methanobrevibacter olleyae ($r = 0.94$, $P = 0.017$) showed strong positive correlations with propionate concentrations, suggesting a mechanistic link between microbial composition and reduced methanogenesis. Overall findings suggest that a moderately shortened fattening period (starting at 13 months, slaughter at 28 months) improved feed efficiency and significantly reduced GHG emissions, while maintaining stable rumen microbial ecosystems, offering a practical strategy for more sustainable Hanwoo beef production.

Isotope patterns in fiber fractions of grass samples with high variability in nitrogen content

T. M. Liegsalz[1], T. Hofmiller[1], J. Kurek[1], C. Ostendorf[1], R. Schäufele[1], G. P. Bienert[1], S. Muetzel[2], S. Colombini[3], F. Giudice[3], L. Rapetti[3], J. Steinhoff-Wagner[1]

[1] Technical University of Munich, School of Life Science, Alte Akademie 8, 85354 Freising, Germany, [2] AgResearch, Private Bag 11008, 4442 Palmerston North, New Zealand, [3] Università degli Studi di Milano, Via Festa del Perdono 7, Milano 20122, Italy

Determining the feed value of dairy-intended feed or predicting ruminal gas production currently necessitates animal-based experiments or at least fistulated ruminants as rumen fluid donors for in vitro incubations. However, considering the 3R strategy (Directive 2010/63/EU), non-invasive modeling approaches might be a promising alternative. However, modeling pathways of microbial fermentation require the absence of differences in the fiber fractions of feed. Therefore, in this study, isotope patterns of varying grassland samples were determined across various crude protein (CP) concentrations. Samples (n = 42) were taken from a long-term field study of permanent grassland at the Technical University of Munich that highly differ due to the long-term fertilization strategy. After gentle drying (60 °C), dry matter (DM), CP (by Kjeldahl N-determination), crude ash (CA), crude fat (CL), and fibre components (neutral detergent fibre (aNDFom), acid detergent fibre (ADFom), and acid detergent lignin (ADLom)) were analysed according to VDLUFA (2023). Additionally, carbon and nitrogen concentrations, as well as $\delta_{13}C$ and $\delta_{15}N$, were measured in the original samples, and their fiber fractions, whereby samples were prepared by boiling in the corresponding neutral or acid solution, and drying them according to the determination of aNDFom, ADFom, and ADLom (VDLUFA, 2023), although ashing was skipped. Carbon, nitrogen, $\delta_{13}C$ and $\delta_{15}N$ were determined by combusting samples in an elemental analyzer coupled to a continuous-flow IRMS. Depending on CP concentration, samples were categorized into high (n = 15, 15.2-18.1% DM), medium (n = 14, 12.23-14.7% DM) and low (n = 13, 8.8-12.1% DM) CP samples, which were used for statistical analyses using a general linear model comparing the CP groups and a mixed model with fiber fractions (original sample, aNDF, ADF, ADL fraction) and CP group as fixed factors. Samples with lower fiber components showed increased CP concentrations ($p < 0.05$), while CA was similar between groups ($p > 0.05$). In the lowest CP group highest C/N ratio was observed and highest CP group had lower $\delta_{13}C$ than the lowest CP group ($p < 0.001$), whereas total carbon and $\delta_{15}N$ were similar across groups. Additionally, all parameters differed significantly between the fiber fractions ($p < 0.001$). I.e., $\delta_{13}C$ was highest in aNDF and lowest in ADL, while $\delta_{15}N$ in ADF was significantly below the remaining fractions. The within-fraction heterogeneity suggests that modeling rumen processes could be more complicated than expected and likely benefits from separate analysis of isotope pattern in the individual feed fractions. The project is supported by funds of the Federal Ministry of Agriculture, Food and Regional Identity (BMLEH) based on a decision of the Parliament of the Federal Republic of Germany via the Federal Office for Agriculture and Food (BLE), grant number 2825ERA02U and as part of the CSA Green ERA-Hub has received funding from the European Union's research and innovation Programme Horizon Europa under grant agreement No 101056828.

Use of essential oils on enteric methane emissions and ruminal microbiota of finishing feedlot Nellore cattle

M. Dalafini[1], M. Marques[1], E. Furlan Junior[1], C. Franzon[1], J. Michelini[1], F. Oristanio[3], E. Magnani[1], R. De Freitas[2], L. Drouet[3], R. Dari[4], T. Da Silva[1], R. H. Branco[1]

Reducing enteric methane (CH_4) emissions from ruminants is a global priority to improve the environmental sustainability of livestock production. Nutritional strategies capable of mitigating methanogenesis without compromising animal productivity are particularly important in tropical beef systems, where information on effective mitigation approaches remains limited. Essential oils (EOs) have emerged as promising natural rumen modulators due to their antimicrobial properties and their capacity to alter microbial fermentation pathways involved in hydrogen metabolism. This study evaluated the effects of dietary supplementation with a plant-derived additive containing carvacrol and capsaicin (ValoPro-E) on enteric methane emissions and rumen microbial community structure in finishing Nellore feedlot cattle under tropical production conditions. Forty-eight Nellore young bulls (initial body weight = 333.6 ± 4.1 kg) were allocated in a completely randomized design with two treatments (n = 24): control (basal diet + mineral premix) and EO supplementation (basal diet + mineral premix + 3 g/animal/day of additive) over a 119 day period. Diets were formulated to meet the requirements for an average daily gain (ADG) of 1.5kg/day, with a forage-to-concentrate ratio of 12:88. Animals were housed in collective pens equipped with automated bunks and scales (Intergado®), allowing individual monitoring of feed intake and body weight. Enteric CH_4 emissions were measured in a subset of animals (n = 12 per treatment) using the sulfur hexafluoride (SF□) tracer technique with continuous 24-h sampling over five consecutive days. Rumen samples (100g) were collected immediately postmortem and placed in insulated boxes at 4° C. The rumen microbiota was characterized by 16S rRNA gene sequencing, and differentially abundant taxa were identified using LEfSe analysis. Dry matter intake and average daily gain were not affect by EO supplementation (9.20 vs 8.99 kg/day and 1.15 vs 1.16 kg/day, respective). EO supplementation significantly reduced CH_4 emissions compared with the control group (174.6 vs. 193.1 g/day; P = 0.0023), representing a 9.5% reduction in enteric methane production and . Microbial community analysis showed that the rumen microbiota was dominated by the bacterial phyla Bacteroidota and Firmicutes in both treatments; however, EO supplementation promoted distinct shifts in microbial composition. Specifically, the abundance of Peptostreptococcus and Anaerobacterium increased with EO supplementation, whereas several carbohydrate-fermenting bacteria and potential hydrogen-producing taxa were more abundant in the control group. These microbial shifts indicate a modification of ruminal fermentation pathways that may reduce the availability of metabolic hydrogen for methanogenesis. Overall, EO supplementation effectively reduced enteric methane emissions and was associated with significant alterations in rumen microbial community structure. These findings suggest that targeted modulation of rumen microbiota represents a promising nutritional strategy for methane mitigation in tropical beef cattle production systems. This study was supported by FAPESP (grants 2017/50339-5, 2021/11922-2) and CNPq.

Effects of condensed tannin extract supplementation on performance, carcass traits, and methane emissions of feedlot cattle fed diets with different protein profiles

R. V. Ribeiro[1], O. L. Rigobello[1], W. R. Meireles[1], I. A. Dornellas[1], I. M. C. Tarôco[1], M. M. Silva[1], I. M. Ferreira[1], J. D. Messana[1,2], R. A. Reis[1]

[1] São Paulo State University, School of Agricultural and Veterinary Sciences, Animal Science, Prof. Paulo Donato Castelane Castellane, 14884900 Jaboticabal, Brazil, [2] Brazil University, Animal Science, Estrada projetada F1, S/N Fazenda Santa Rita, 15600000 Fernandópolis, Brazil

Ruminal protein degradability influences overall diet digestibility, nitrogen excretion patterns, and animal performance. Excess rumen degradable protein (RDP) increases nitrogen excretion, whereas insufficient supply limits ruminal digestion; therefore, a minimum level is required to optimize digestive and metabolic efficiency while maximizing animal performance. Condensed tannin extract (CTE) has the potential to modulate ruminal protein degradability, increasing metabolizable protein supply without impairing ruminal microbial efficiency. In this context, the aim of this study was to evaluate the supplementation of CTE in feedlot containing two protein sources differing in rumen degradable protein (RDP) content on dry matter intake (DMI), animal performance, carcass traits, and methane emissions, hypothesizing an increase in performance along with a reduction in methane emissions. Ninety-six Nellore bulls (375 ± 18 kg of initial body weight) were blocked by initial body weight and assigned within blocks to 24 collective pens (n = 6 pens per treatment). The experimental design used was randomized blocks in a 2 × 2 factorial arrangement where, factor 1: dry distillers grains plus solubles (DDGS) or peanut meal; factor 2: with or without inclusion of CTE from quebracho (Schinopsis sp.). The treatments evaluated were: T1: DDGS (~50% RDP); T2: DDGS + CTE (0.08% of dry matter [DM]); T3: Peanut meal (~65% RDP); T4: Peanut meal + CTE (0.08% of DM). The performance trial lasted 105 days. At the end of this period, 48 bulls were randomly selected within blocks (n = 12 per treatment), individually housed, and evaluated for methane emissions using the SF□ tracer technique over a 25-day period. Data were analyzed using a mixed-effects model, with block and experimental unit included as random effects, and protein source, tannin supplementation, and their interaction included as fixed effects. Differences were considered statistically significant at $P \leq 0.05$. No differences were observed among treatments for DMI ($P \geq 0.079$). Bulls receiving condensed tannins (T2 and T4) showed greater average daily gain (ADG) than non-supplemented treatments (T1 and T3) (1.74 and 1.65 vs. 1.61 and 1.61 kg/d; P = 0.015), resulting in higher final body weight (557 and 549 vs. 543 and 544 kg; P = 0.018) and trend to improve feed efficiency (0.170 and 0.164 vs. 0.157 and 0.164 kg; P = 0.063), regardless of protein source. A significant protein source × tannin interaction was observed for hot carcass weight (HCW; P = 0.050), dressing percentage (DP; P = 0.005), and carcass daily gain (CDG; P = 0.043). Tannin supplementation increased HCW (317.97 vs. 330.04 kg; P = 0.033), DP (57.82 vs. 58.91%; P = 0.024), and CDG (1.24 vs. 1.36 kg/d; P = 0.025) in DDGS-based diets, whereas no improvement was observed when peanut meal was used (322.01 vs. 319.04 kg; 58.17 vs. 57.28%; 1.28 vs. 1.25 kg/d; $P \geq 0.578$). No treatment effects were observed for methane emission parameters ($P \geq 0.161$). Therefore, CTE supplementation enhanced overall performance, with greater benefits on carcass traits when lower RDP diets were fed. The improvements associated with tannin supplementation are likely linked to modifications in ruminal fermentation patterns and the dynamics of nitrogen and energy metabolism.

Does a combination between protein reduction and yeast probiotic in the diet of dairy cow impact feed efficiency, nitrogen use, digestibility and rumen microbial protein synthesis?

N. Salah[1], B. Gestes[1], P. Ly[1], K. Hadjeba[1], J. Schulthes[1], J. Duclos[1], E. Pinloche[1], M. Mayer[1]
[1] Phileo by Lesaffre, R&D, Marquette-lez-Lille, France,, 59520 Lille, France

Reducing dietary crude protein (CP) in dairy cows can lower nitrogen (N) excretion and improve N use efficiency (NUE) but may impair ruminal fermentation and productivity. This study evaluated whether reducing protein level alone or in combination with yeast probiotic Saccharomyces cerevisiae CNCM I-4407 (Actisaf® Sc 47) could mitigate these effects. In this study, we evaluated N utilization, feed efficiency (FE), digestibility and rumen microbial protein (RMP) synthesis. Six multiparous Holstein cows (92.5 ± 2.6 DIM; 38.7 ± 5.9 kg milk/d) were assigned to a 3 × 3 Latin square design with three 23-d adaptation periods and 5-d sampling periods, separated by 15-d transition periods. Treatments were: control (CTR; 16.5 % CP in DM), low-CP (LCP; 14.5 % CP in DM), and LCP + Actisaf Sc 47 (5 g/d; LCPActisaf). During the 5 days of sampling, milk samples (100 ml) were individually collected and analyzed for fat and protein to calculate energy corrected milk (ECM) and FE. For NUE, RMP, and digestibility, six spot samples of urine (100 ml) and feces (500 g) were collected at the same time interval over a 24-h cycle. At the end of each sampling period, all the urine samples were mixed, and 30 ml were analyzed for creatinine, N and purine derivatives (PD) to estimate total urine output, NUE and RMP. Offered diets and feces were analyzed for acid insoluble ash (AIA), dry matter, neutral detergent fiber and N to estimate digestibility. Urine output was calculated as the ratio between the creatinine coefficient of 29 mg/kg BW/day and creatinine concentration in urine. RMP was estimated as the ratio of absorbed PD multiplied by the purine protein content (437.5 mg CP/mmol) and divided by the ratio of purine N to total N in mixed rumen microbes (0.116), multiplied by microbial purine digestibility (0.83). FE was calculated as the ratio of ECM to DMI. NUE was calculated as the ratio of N in milk to N intake. Data were analyzed using a generalized linear mixed model including treatment, period and their interaction as fixed effects and cow as a random effect. Cows in the CTR group had numerically greater FE when compared with cows in the LCP group (1.46 vs 1.39; $p = 0.1$) but were similar ($p = 0.39$) to cows in the LCPActisaf group (1.51). Cows in the LCPActisaf group had greater FE when compared with cows in the LCP group ($p = 0.02$). Compared with CTR, N intake was reduced by both LCP and LCPActisaf (−12.95% and −17.44%, respectively; $p = 0.003$). Compared with CTR, fecal N (FN) was not impacted by LCP (233 vs 211.29 g/d; $p > 0.1$), but was decreased by LCPActisaf (182.9 g/d; $p = 0.04$); LCPActisaf tended to decrease FN compared with LCP ($p = 0.1$). Compared with CTR, LCP did not impact urinary N (UN) (264.4 vs 218.3 g/d for CTR and LCP, respectively), however, LCPActisaf tended to decrease UN (211 g/d; $p = 0.1$). NUE tended to increase with LCP and was improved with LCPActisaf (28.3 vs 31.3 vs 35.1 for CTR, LCP and LCPActisaf, respectively; $p = 0.007$). Cows in the LCPActisaf group tended to have greater protein digestibility when compared with LCP (67.9 vs 63.49; $p = 0.1$) but were similar to CTR (67.90 vs 64.25; $p = 0.32$). Despite a greater RMP synthesis in LCPActisaf, no difference was observed between the three treatments (1957 vs 1874 vs 1748 for LCPActisaf, LCP and CTR groups, respectively; $p = 0.95$). In conclusion, reducing dietary CP combined with Actisaf Sc 47 supplementation maintains milk production, enhances FE and NUE, and reduces N excretion, offering a promising strategy for more sustainable dairy production systems.

Testing coated calcium peroxide for methane mitigation in dual-flow fermenters

A. Hall[1], S. Mills[2], V. O'Flaherty[1]
[1] University of Galway, University Road, H91 TK33 Galway, Ireland, [2] GlasPort Rumentech, University of Galway, Unit 1, Galway Business Park, H91 TK33 Galway, Ireland

There is a growing body of research investigating the use of oxidising compounds, such as calcium peroxide (CaO_2), as potential strategies for methane mitigation in agricultural systems. Methane produced during enteric fermentation in ruminants represents a significant source of greenhouse gas emissions from livestock production. Previous studies have demonstrated that CaO_2 can effectively suppress methane production both in vitro and in vivo in beef cattle without negatively affecting animal health or performance. However, when administered in powder form, CaO_2 reacts rapidly with moisture to produce oxygen (O_2), typically within a matter of hours. This rapid reaction results in only short-term effects, limiting its practical application under grazing conditions. Developing a coated formulation of CaO_2 could therefore provide a controlled, slow-release mechanism, extending its activity in the rumen and improving its suitability as a methane-mitigating feed additive for pasture-based farming systems. The aim of this research was to develop and evaluate a coating strategy capable of slowing the release of CaO_2 within the rumen environment. Initial closed-system batch experiments assessed the performance of a gelatine-coated CaO_2 formulation. These preliminary trials demonstrated a significant reduction in methane production when gelatine-coated CaO_2 was used compared with uncoated CaO_2 ($p < 0.001$), indicating that the coating may enhance the efficacy of the treatment by modifying its release dynamics. Following these encouraging results, a subsequent in vitro experiment was conducted using dual-flow continuous culture fermenters in order to evaluate the coated formulation under more representative rumen simulation conditions. The experimental design consisted of a 14-day acclimation period followed by a 7-day sampling phase. Fermenters were fed daily with a diet consisting of a 1:1 ratio of grass silage and coarse ration at a rate of 10 g dry matter per day. Treatments were applied in triplicate, with three fermenters receiving uncoated CaO_2 and three receiving the gelatine-coated CaO_2 formulation. Following administration of the treatments, oxidative reduction potential (ORP) increased to above +100 mV across all fermenters, reflecting the oxidative effect of CaO_2. However, differences were observed in the rate at which ORP subsequently declined. In fermenters receiving the gelatine-coated treatment, the decrease in ORP occurred more gradually than in those receiving uncoated CaO_2. This pattern suggests that the coating slowed the release of CaO_2, resulting in a more sustained oxidative effect within the system. Overall, these results indicate that coating CaO_2 with gelatine can successfully modify its release profile in continuous dual-flow fermenters, allowing for a slower decline in ORP compared with the uncoated powder form. This supports the potential of coated CaO_2 formulations as a methane mitigation strategy for ruminant production systems. Further in vitro work is required to optimise the coating composition and release characteristics. Future research will also include small-scale animal trials to evaluate the treatment in vivo, with particular attention to methane emissions, nutrient digestibility, and potential impacts on the rumen microbial community.

Nitrogen balance and nitrogen use efficiency in extensive Charolais beef cattle systems facing nitrate water pollution risk

R. Ibidhi[1], M. Ubertosi[2], A. Cavillon[2], A. Tanda[2], P. Rolland-Muquet[2], Y. Moulin[3]
[1] Université de Bourgogne Europe, Institut Agro Dijon, INRAE, UMR Agroécologie, D2A2E, 26, bd Docteur Petitjean - BP 87999, 21079 Dijon Cedex, France, [2] Institut Agro Dijon, 26, bd Docteur Petitjean - BP 87999, 21079 Dijon Cedex, France, [3] Chambre d'agriculture de Saône-et-Loire, 59 rue du 19 mars 1962, CS 70610 71010 Mâcon Cedex, France

Nitrogen (N) management is a key challenge for improving the environmental performance of livestock farming systems, particularly in areas vulnerable to nitrate pollution. This study assesses N balance and nitrogen use efficiency (NUE) at the farm scale in Charolais beef cattle systems located in the Charolais-Brionnais region (Saône-et-Loire, France). In 2020, during the seventh revision of nitrate vulnerable zones, 128 municipalities in western Saône-et-Loire were proposed for classification following high nitrate concentrations in surface and groundwater. This decision raised concerns among stakeholders, as the region is dominated by extensive grassland-based livestock systems with low stocking densities (around 1.2 livestock units per hectare) and a high proportion of permanent grasslands, which theoretically limit nitrate leaching risks. Within this context, N flows were quantified in five representative Charolais beef farms. N inputs included mineral fertilizers, purchased feed, animals, and atmospheric N fixation from grasslands, while outputs corresponded mainly to animal products and crop exports. NUE was calculated as the ratio between useful N outputs and total N inputs. Results showed relatively low N inputs typical of extensive grassland systems, ranging from 11 to 79 kg N/ha per year, while N outputs ranged from 6 to 18 kg N/ ha per year across farms. Consequently, N surpluses remained moderate, with farm N balances ranging from approximately 5 to 61 kg N/ ha per year, depending on farm structure and production objectives. Nitrogen use efficiency (NUE) varied considerably among farms, reflecting differences in management practices, herd composition, and input use. In particular, specialized cow-calf systems that showed lower N surpluses than mixed cow-calf and finishing systems. Overall, the results highlight opportunities to improve N management while maintaining the extensive nature of these production systems. The findings contribute to a better understanding of N dynamics in herbivore-based livestock farms and provide scientific evidence to inform regional discussions on nitrate vulnerability classification and the adaptation of N management policies to grassland-dominated livestock systems.

The environmental impact of dairy cattle farming using Life Cycle Assessment: a meta-analysis

V. Thymis[1], D. Kantas[1], A. Foskolos[1]
[1] University of Thessaly, Animal Science, Campus Gaiopolis, 41500 Larisa, Greece

Multiple Life Cycle Assessments (LCA) have been implemented to estimate the environmental footprint of cattle milk. The aim of this study was to collect available LCA studies, streamline their data (harmonise functional units, allocation methods, impact category units, milk yield, herd size and grazing period) and run a meta-analysis to evaluate the environmental impact of milk production at the farm level. A total of 274 studies with 2928 observations were used. A statistical analysis was performed between six parameters (Continent, Climate, State of LCA, Farm system, Number of animals and Milk yield) and five environmental categories (Global Warming Potential – GWP, Acidification Potential – AP, Eutrophication Potential – EP, Non-renewable Energy – NRE and Land Use – LU). The dataset covered dairy LCA studies across the world allowing the presentation of global mean values for the impact categories examined. The mean contribution of dairy farming in the intensity of greenhouse gas emissions was 1.27 ± 1.32 kg CO2eq. kg Fat and Protein Corrected Milk (FPCM)$_{-1}$. In terms of acidification and eutrophication dairy farming contributed 10.60 ± 5.88 g SO2eq. kg FPCM$_{-1}$ and 5.16 ± 2.53 g PO4$_{3-}$eq. kg FPCM$_{-1}$, respectively. Additionally, it used non-renewable sources at a rate of 2.90 ± 1.05 MJ kg FPCM$_{-1}$ and, on average, occupied a land of 1.49 ± 1.69 m$_2$ kg FPCM$_{-1}$ for its production. The LOW milk yield category demonstrated 83 % higher GWP and 138 % higher LU compared with the VERY HIGH category (1.87 kg CO2eq. kg FPCM$_{-1}$ and 2.86 m$_2$ kg FPCM$_{-1}$, for GWP and LU, respectively). In contrast, HIGH and VERY HIGH categories had a significantly higher AP compared with lower yielding categories. Farms with more than 1,001 animals showed the lowest GWP, 27 % lower compared with smallest farms (0.99 vs 1.26 kg CO2eq. kg FPCM$_{-1}$ for more than 1,0001 animals vs less than 50 animals), while farms with 201 to 1,000 heads had an intermediate value. It is noteworthy that farms with a herd size larger than 1,000 heads had overall the lowest values in four out of five impact categories analyzed when compared with other farms. Overall, the current study found that high milk yields, a herd size of over 1,000 animals, temperate and colder climates were linked to low GWP and LU values. Although, except for large herds, the other categories had apparent environmental drawbacks, especially in the AP and EP impacts. In contrast, farms located in regions with developed dairy farming had lower environmental footprints. This study, taking into account a broader environmental scope, demonstrated that the largest farms displayed the lowest emissions per kg of Fat- and Protein- corrected Milk. Results showed that assessing environmental performance based only on GWP without taking into consideration more impact categories could be misleading.

Modeling carbon cycle from dairy cows, barn, and storage

M. Brask[1], S. Lashkari[1], F. R. Dalby[2], C. F. Børsting[1]
[1] Aarhus University, Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark, [2] Aarhus University, Biological and Chemical Engineering, Inge Lehmans Gade 10, 8000 Aarhus, Denmark

Inventory calculations for emissions from animals and manure are often based on low-Tier emission models; however, nutrient excretion and emissions depend on animal, diet, barn and manure storage characteristics. Carbon from feed ends up in milk, weight gain, feces, urine and gases (CH4 and CO2). These gases originate from rumen fermentation and respiration from the animal, and from manure fermentation and surface respiration in the barn and storage. The aim of the present study was to model carbon cycling at cow, barn and storage level based on dry matter intake (DMI), diet composition, nutrient digestibilities, performance level and farm management. The data were modelled for a dairy farm with 280 cows [11 tons milk/cow/y and 23 kg DMI/cow/d], representing milk yield and feed intake of a typical Danish dairy farm. Slurry emissions were modelled based on 28 d removal interval from a barn with a ring-channel slurry storage under a slatted floor. Slurry was stored in an outside storage with a natural crust (mean retention time 2.8 months). Enteric methane was estimated based on DMI and diet composition (Hellwing et al., 2016). Nutrient composition of feces was calculated based on feed composition and digestibilities of key nutrients. Methane emission from slurry was estimated with the anaerobic biodegradation model (ABM), which was based on hydrolysis of organic matter (OM) to volatile fatty acid (VFA) and then VFA conversion to CH4 and CO2. Two diets with 60% forage (80:20 or 20:80% of grass-clover to corn silage, GS and CS, respectively) were modelled. Carbon intake (kg/d) was 9.3 in GS and 9.2 in CS. Carbon excretion (% of intake) for GS and CS diets was similar in milk (22), CO2 (41), and feces (31). Carbon (% of intake) in enteric CH4 was higher in GS (3.4) than in CS (3.2). Carbon (% of intake) in urine compounds was higher in GS (1.3) than CS (1.0). Carbon excreted in slurry (feces+urine+2% of DMI feed spill) was the same in GS and CS (3.2 kg/d). At barn level, carbon (% of carbon excreted in slurry) in CH4 was higher in CS (3.4) than in GS (3.1), while CO2 was higher in GS (10.7) than in CS (10.1). At storage level, carbon (% of carbon excreted in slurry) in CH4 was higher in CS (2.3) than in GS (1.9), and the CO2 was the same across diets (4.6). Earlier studies found that diets resulting in lower enteric CH4 emissions may result in higher emissions from slurry. This can potentially be explained with lower digestibility of nutrients, resulting in more degradable OM in the slurry, or a different chemical composition of manure excreted, e.g. a higher share of undigested starch, degradable fibers or fat. When evaluating dietary mitigation strategies like fat supplementation, downstream emissions should be included in decision making. In conclusion, the current model shows that it is possible to combine models for nutrient digestion and enteric emissions from animals with degradation in barn and manure storage by including details on nutrient composition and carbon flows, offering a broader perspective on emissions from dairy farms than enteric fermentation alone.

Temperature-driven seasonal variation of soil CO_2 and N_2O emissions under rotational and continuous grazing in a Mediterranean grassland

D. Sarkar[1], G. Bernabucci[1], C. Rossi[1], G. Grossi[1], C. Evangelista[1], R. Primi[1], N. Lacetera[1], A. Vitali[1]
[1] University of Tuscia, Department of Agriculture and Forest Sciences, via San Camillo De Lellis, Snc, 01100 Viterbo, Italy

Accurate greenhouse gas (GHG) inventories for Mediterranean pastoral systems are often confounded by the synergistic effects of seasonal thermal stress and grazing-induced changes to soil microclimates. This study was conducted at the experimental farm, the University of Tuscia (Viterbo, Central Italy). It sought to decouple the influence of grazing regimes; Continuous (CG) and Rotational (RG) using 18 Sopravvissana sheep per system at a stocking rate of 100 sheep ha□¹ (2 h grazing day⁻¹), with contrasting stocking densities (100 sheep ha□¹ in CG vs. 600 sheep ha□¹ in RG), on soil CO2 and N2O emissions across seasonal transitions from spring to summer. We quantified soil CO2 and N2O fluxes at high temporal resolution using automated chambers coupled with laser absorption spectrometers (LI-7810 and LI-7820, LI-COR Biosciences). To capture peak diurnal variability, flux measurements were strategically stratified into morning (08:00–11:00) and afternoon (15:00–18:00) windows over two consecutive days, ensuring representativeness of the mediterranean microclimate. This synchronized, high-frequency monitoring allowed for the detection of gas concentration shifts across ryegrass–clover (spring trial) and teff (summer trial) phenological stages. Soil temperature and moisture were recorded using a Soil Hydra probe installed at 5 cm depth. We utilized generalized linear models (GLMs) and segmented regression to identify environmental breakpoints and management-driven substrate legacies. Soil temperature emerged as the main predictor for both gases ($p < 0.001$). While pre-grazing CO2 fluxes were uniform, post-grazing RG showed significantly higher emissions (8.34 ± 0.22 vs. 7.36 ± 0.19 µmol m^{-2} s^{-1}) compared to CG in spring, suggesting that pulsed grazing under rotational management accelerates root exudation and microbial respiration during regrowth phase. N2O emissions did not differ significantly between grazing systems in spring trial. Conversely, the pre-summer stage revealed a "legacy effect" in CG, which exhibited significantly higher CO2 (15.17 ± 4.49 vs 10.01 ± 2.61 µmol m^{-2} s^{-1}) and N2O (0.12 ± 0.09 vs 0.05 ± 0.03 nmol m^{-2} s^{-1}) emissions than RG ($p < 0.05$). This indicates that sustained grazing pressure may accumulate labile substrates that become highly reactive during early summer warming. Segmented regression identified a critical temperature threshold at approximately 28°C to 30°C. Beyond this point, N2O flux sensitivity increased non-linearly, signaling a potential shift in microbial nitrogen transformation kinetics. Our findings demonstrate that grazing impacts are not static but are highly modulated by seasonal thermal dynamics. The temperature threshold points for N2O suggest that Mediterranean systems may face disproportionate emission spikes under climate warming scenarios. These findings underscore the necessity of seasonally adapted management frameworks. Specifically, strategical timing rotational rest periods to coincide with critical thermal transitions can significantly mitigate the carbon and nitrogen footprints of Mediterranean pastoral systems.

Mitigating emissions from manure: The effectiveness of biochar under real dairy farm conditions

K. Kaikiti[1], K. Philippou[1], A. Phokas[1], P. Pissaridou[1], C. Hadjimichael[1], J. Rhodosthenous[1], A. Rossis[1], A. Houvarta[1], D. Sparaggis[2], M. Omirou[1]

[1] Agricultural Research Institute, Agrobiotechnology, P.O.Box 22016, 1516 Lefkosia, Cyprus, [2] Agricultural Research Institute, Animal Production, P.O.Box 22016, 1516 Lefkosia, Cyprus

Livestock housing is a significant source of ammonia (NH3) and non-CO2 greenhouse gas emissions due to volatilization from freshly excreted manure. Mitigation strategies applied directly at the emission source may reduce these losses. This study evaluated the effectiveness of biochar as a manure amendment for reducing gaseous emissions under real dairy barn conditions. The experiment was conducted during winter 2025 at the Agricultural Research Institute (ARI) experimental dairy farm in Cyprus using lactating Holstein cows housed in a free-stall barn. All cows received the same diet under standard farm feeding conditions, consisting of 15–17 kg of concentrated feed pellets (19% crude protein) via automatic feeders and 9–10 kg dry matter (DM) of hay and silage per cow/day.Two comparable groups of 12 cows were maintained in separate barn sections, where one group received bamboo biochar (Phyllostachys aurea) application (2.5% w/w, dry matter basis) directly to freshly excreted manure, while the other served as an untreated control. Fresh manure was collected daily from different parts of each barn, pooled and transferred into replicated chambers (six per treatment) for real-time gas emission measurements. No manure removal or cleaning was performed in the barn during the experimental period, while only the manure in the chambers was replaced every 24 h with newly collected material over a 10-day monitoring period. Gas fluxes (NH3, CO2, CH4, and N2O) were measured using automated non-steady-state chambers coupled with a cavity ring-down spectroscopy analyzer, providing high-frequency measurements (about 16 measurements per chamber per day) and enabling detection of short-term emission dynamics.The results showed that biochar application substantially reduced cumulative NH3 emissions by 58%, decreasing losses from approximately 8.2 to 1.5 g m-2. Temporal analysis revealed that mitigation occurred through a gradual flattening of NH3 emission trajectories rather than immediate suppression. Methane emissions exhibited a moderate cumulative reduction (approximately 49%), although no treatment effect was observed at the daily scale. In contrast, cumulative CO2 emissions were higher under biochar treatment, while N2O emissions remained very low and unaffected.Although measurements were conducted in chamber systems, manure was sourced directly from treated and untreated barns and renewed daily in the chambers, ensuring that emission patterns reflect practical barn conditions during the immediate post-excretion phase.

Effect of ventilation regimes on carbon and nitrogen dynamics in composted bedded packs for Mediterranean dairy cattle production

X. Díaz De Otálora[1], B. Fajardo[1], C. Cano[2], T. Monreal[1], A. Villagrá[2], F. Estellés[1]
[1] Universitat Politècnica de València, Institute of Animal Science and Technology, Camino de Vera s/n, 46022 Valencia, Spain, [2] Valencian Institute for Agricultural Research, Centre for Animal Research and Technology, Polígono de la Esperanza, 100, 12400 Segorbe, Spain

Composted bedded packs in dairy systems are strongly influenced by environmental conditions. In warm Mediterranean climates, mechanical ventilation may play a key role in bedding nutrient dynamics, particularly nitrogen (N) and carbon (C). This study evaluated the effect of different ventilation regimes on physicochemical properties and N and C availability in a commercial dairy farm in eastern Spain. The trial was conducted from January to March 2025 on a commercial farm in Valencia (Spain). Three ventilation strategies were compared: (i) no mechanical ventilation, (ii) temperature-controlled ventilation, and (iii) continuous ventilation at full capacity during a fixed daily time slot. Eight weekly samplings were performed in four pens, collecting composite samples at the surface and 15–20 cm depth. Across all treatments, deep bed temperatures remained low (16 °C), well below the optimal range for active composting (45–55 °C). N concentrations were high (3%) and C levels moderate (38%), resulting in low C:N ratios (13:1), far from the optimal 25:1–30:1 range. These conditions likely limited microbial activity, reducing C stabilisation and altering C:N dynamics. High pH values (>9) and the absence of an effective thermophilic phase may have further constrained microbial N immobilisation, maintaining N in more reactive forms. The lack of active composting could be associated with altered N losses and reduced C stabilisation, with potential implications for greenhouse gas emissions. Overall, the evaluated ventilation regimes and management practices during the January–March observation period did not achieve conditions suitable for active composting, thereby influencing C and N dynamics. While these results are specific to the study period, they suggest that optimising ventilation and bed management strategies may be necessary in Mediterranean dairy systems, although further research is required to confirm their representativeness across the full annual cycle.

Interaction between protein source and condensed tannin extract on nitrogen metabolism in feedlot cattle

R. V. Ribeiro[1], P. S. Marchiori[1], I. A. Dornellas[1], M. A. D. O. Castro[1], A. M. Kirchhoff[1], J. V. D. P. Germano[1], P. A. A. Fredes[1], I. M. Ferreira[1], J. D. Messana[1,2], R. A. Reis[1]

[1] São Paulo State University, chool of Agricultural and Veterinary Sciences, Animal Science, Prof. Paulo Donato Castelane Castellane, 14884900 Jaboticabal, Brazil, [2] Brazil University, Animal Science, Estrada projetada F1, Fazenda Santa Rita, 15600000 Fernandópolis, Brazil

Improving nitrogen use efficiency (NUE) in feedlot systems remains a challenge, particularly when high rumen degradable protein (RDP) diets increase ruminal ammonia production and urinary nitrogen losses. Protein sources differing in rumen degradability may interact with condensed tannin extract (CTE), altering NUE. Thus, this study evaluated the effects of CTE supplementation in diets containing two protein sources differing in RDP content on nitrogen intake, excretion, retention, and NUE in feedlot cattle. Eight ruminally cannulated Nellore steers (408 ± 41 kg body weight [BW]) were individually housed and allocated to a replicated 4 × 4 Latin square design, containing four periods of 21 d and a 5-d washout interval. Treatments were structured in a 2 × 2 factorial arrangement, consisting of two protein sources (dry distillers grains plus solubles (DDGS) or peanut meal) and with or without CTE from quebracho (Schinopsis sp.). Diets contained 27% roughage and 73% concentrate, were isonitrogenous (14% CP) and isoenergetic (1.33 Mcal/kg NEg) and differed in RDP content (50% for DDGS-based diets and 64% for peanut meal-based diets). The treatments evaluated were: T1: DDGS; T2: DDGS + CTE (0.08% of dry matter [DM]); T3: Peanut meal; T4: Peanut meal + CTE (0.08% of DM). The trial lasted 105 days. Animals were fed ad libitum, and dry matter intake (DMI) was recorded daily as the difference between feed offered and refusals collected the following day. On days 17, 18, and 19 of each experimental period, samples of the diet and orts were collected, and spot samples of feces and urine were collected twice daily; all samples were pooled to form a composite sample for each steer. Creatinine was used to estimate total urinary volume, and acid detergent insoluble ash was used as an internal marker to estimate fecal output. Nitrogen balance was calculated as nitrogen intake minus nitrogen excretion in feces and urine, and NUE was calculated as nitrogen balance divided by nitrogen intake. Additionally, urinary urea excretion was quantified. Data were analyzed using a mixed-effects model, including Latin square, animal nested within Latin square, and experimental period as random effects, and protein source, tannin supplementation, and their interaction as fixed effects. Effects were considered significant at $P \leq 0.05$. No differences were observed among treatments for DMI or nitrogen intake ($P \geq 0.122$). However, a main effect of protein source was observed for urinary nitrogen excretion, which was lower in steers fed DDGS compared with peanut meal (82.01 vs. 91.69 g/d; $P = 0.002$). Additionally, CTE supplementation reduced urinary nitrogen excretion (83.01 vs. 90.69 g/d; $P = 0.010$). Accordingly, steers fed DDGS excreted less urinary urea than those fed peanut meal (107.10 vs. 129.17 g/d; $P < 0.001$). In addition, CTE supplementation reduced urinary urea excretion compared with the treatments without CTE (112.18 vs. 124.08 g/d; $P = 0.022$). In contrast, fecal nitrogen excretion was not affected by either protein source or CTE supplementation ($P \geq 0.274$). Nitrogen retention and NUE did not differ among treatments ($P \geq 0.227$). In this context, beyond reducing urinary nitrogen losses, CTE supplementation may lower hepatic urea synthesis, thereby decreasing the energetic cost of nitrogen metabolism and potentially improving animal performance and environmental outcomes.

Low crude protein diet balanced for metabolizable methionine positively impacts performance, metabolic status and N emissions in high-yielding dairy cows

A. Vigh[1], M. Müller[1], V. V. Thierer[2], J. Guyader[1]
[1] Evonik Operations GmbH, Rodenbacher Chaussee 4, 63457 Hanau, Germany, [2] Viehweidhof, Zur Viehweid 1, 87775 Hausen, Germany

Protein efficiency is important to the economic and environmental sustainability of modern dairy production. Feeding high-protein diets to dairy cows leads to excess nitrogen (N) excretion that contributes to the farm environmental footprint. In addition, over-feeding expensive protein sources is economically unprofitable and does not benefit production performance. Reducing dietary crude protein (CP) is a viable environmental and economic strategy, but most often requires essential amino acids supplementation to prevent performance losses. Such feeding strategy is increasingly applied after the peak of lactation, because of a general reluctance to reduce the dietary protein level in early lactation stage. Therefore, this study aimed to investigate the effects of reducing dietary CP in combination with rumen protected methionine (RP-Met) supplementation on performance, metabolic status and urinary N excretion of early lactating dairy cows. The study was conducted on a commercial dairy farm in South Germany over 12 weeks of trial period. A total of 52 peripartum Holstein cows (18 primiparous and 34 second-lactation) were divided in two experimental groups, fed either a high-CP (16.9% DM; CON) or a low-CP (15.8%; RPM) diet supplemented with 15 g/day/cow of RP-Met (Mepron®, 85% DL-methionine, Evonik Industries, Germany). Individual milk yield (MY) was recorded daily and milk composition was analyzed every two weeks. Backfat thickness was measured biweekly by ultrasound (EasiScan, IMV-Imaging) at a caudal distance of about 10 cm from Tuber ischiadicus towards Tuber coxae. Blood samples were taken from the caudal vein (2 weeks prepartum and 0, 7, 14 and 50 days in milk) and analyzed for β-hydroxybutyrate (BHB) and urea-N content. Urinary N excretion was quantified during the last trial week, using creatinine concentration as an indicator of urine volume. Dry matter intake (DMI) was registered daily at group level. Statistical effects were analyzed based on a linear model using treatment and period (week) and their interaction as fixed effects. Least square means were compared using Tukey's test. Significance was declared when $P \leq 0.05$ and tendency with $0.05 < P \leq 0.10$. Dry matter intake was not affected by the reduction of dietary CP (24.4 and 24.6 for RMP and CON, respectively). Milk yield tended (P=0.054) to increase in the RPM group (43.8 and 40.5 kg/d for RPM and CON, respectively), while milk fat and protein content were not affected. Blood and milk urea-N were significantly lower in the RPM group after 14 and 50 days, indicating a more efficient N utilization. Urinary N excretion was significantly reduced (P=0.021) with RPM when compared to CON (164 and 218 g/d, respectively). BHB levels for both, CON and RPM, were within the physiological range at any time. Nevertheless, the backfat thickness curve of RPM indicated less fat mobilization than in CON. Contrary to CON, RPM already gained weight from about 50 DIM. In conclusion, the reduction of dietary CP combined with RP-Met supplementation proves to be a practical solution for improving N efficiency and metabolic status in dairy cows. In addition, N losses to the environment are reduced without compromising milk production performances.

Multifunctional utilisation of dual-purpose cropping for pasture, forage & grain

M. Hetta[1], L. Post[1], G. Carlsson[3], G. Bergkvist[6], E. Ekholm[5], V. Picasso[6], S. Delin[4], D. Parsons[2]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Skogsmarksgränd, 90426 Umeå, Sweden, [2] Swedish University of Agricultural Sciences, Department of Crop Production Ecology, Skogsmarksgränd, 90426 Umeå, Sweden, [3] Swedish University of Agricultural Sciences, Department of Biosystems and Technology, Alnarp, 234 22 Alnarp, Sweden, [4] Swedish University of Agricultural Sciences, Department of Soil and Environment, Skara, 75007 Uppsala, Sweden, [5] Lantmännen, Agriculture Division, Stockholm, 104 25 Stockholm, Sweden, [6] Swedish University of Agricultural Sciences, Department of Crop Production Ecology, Ultuna, 75007 Uppsala, Sweden

The European livestock sector is increasingly concentrated in specific regions with limited integration between animal and crop production. High livestock densities generate substantial local environmental impacts and increase the risk of nutrient leakage. In contrast, arable regions with limited livestock production often experience shortages of nutrients and depend heavily on mineral fertilizers. Improved integration of crop and livestock production could provide both economic and environmental benefits by strengthening circular nutrient flows and resource efficiency in agricultural systems (Wilkins, 2008). Increasing climate variability also requires robust and flexible feed production systems, as livestock depend on reliable access to feed and pasture regardless of yearly growing conditions. Diversification of crop rotations has been shown to increase agricultural resilience to adverse weather and climatic variability (Bowles et al., 2020). One strategy to enhance diversification and crop–livestock integration is the use of dual-purpose crops, where crops are cultivated for more than one purpose, typically forage and grain, allowing flexible use for grazing, silage, or grain depending on seasonal conditions. We hypothesize that combinations of spring and winter annual crops, grown either as primary or undersown crops and harvested for pasture, forage, and grain, can increase feed availability and reducing production risks for dairy and beef producers and minimizing environmental impacts. Dual-purpose cropping systems are well established in semi-arid regions such as Australia and North America (Bell et al., 2015) but remain poorly evaluated in temperate high-latitude environments. Within the Mulcropa project (2024–2027), field experiments have been established at four locations in Sweden representing contrasting temperate climatic conditions at high latitudes. Regionally adapted combinations of spring and winter annual crops are evaluated within crop rotations designed to maximize the growing season while maintaining plant cover and improving nutrient retention. The systems include two-year winter rye, grazed in the first year and harvested for grain in the second year, and maize combined with undersown crops to improve feed production and nutrient cycling. The objective is to evaluate the potential of these crop combinations to simultaneously produce forage and grain while improving resilience and nutrient use efficiency in crop–livestock systems. Agronomic performance, biomass production, feed value, and estimated livestock production potential are presented under varying climatic and growing conditions. The results from the first cycle of the evaluation of the agronomic performance tells that the combinations with main and undersown crops produces equal or better compared to the when crops grown alone in sequence in a rotation. The U.S. beef industry has a long history of improving productivity and environmental performance; however, persistent scientific gaps and increasing demands for credible, scalable sustainability solutions underscore the need for a coordinated national research agenda. This work synthesizes current scientific knowledge and expert input to define a unified research roadmap aligned with the U.S. Roundtable for Sustainable Beef's environmental indicator goals. The roadmap identifies six critical research areas—grazing management plans, feedyard optimization, technology innovation, advanced modeling, genetic improvement, and producer practicality— and 22 key research questions that collectively represent the most influential levers for measurable, scalable improvement. Key opportunities include strengthening the accuracy, consistency, and scalability of measurement approaches for emissions, soil carbon, water use, and ecosystem services; validating emerging technologies such as methane-mitigating additives, remote sensing tools, and virtual fencing; refining mechanistic and ecosystem-level models to better inform decision-making; and expanding phenotyping to enhance genetic selection for efficiency and environmental outcomes. A cross-cutting emphasis on producer adoption and economic feasibility underscores the need for research that is practical, regionally relevant, and capable of driving sustained implementation across diverse production systems. By outlining clear research priorities and high-impact opportunities, this work provides a strategic foundation to guide investment, enhance data credibility, support producer-level decision-making, and accelerate continuous improvement throughout the beef value chain. Keywords: sustainable beef, grazing management, greenhouse gas emissions, water resources, land stewardship, environmental modeling, genetics, producer adoption

Optimal deployment of genetic innovation is essential to increasing the productivity and sustainability of global cattle production systems

M. A. Cleveland[1], E. Lai[1]
[1] Genus - ABS Global, 1525 River Rd., 53532 De Forest, United States

Genetic improvement programs for beef and dairy cattle are necessary but not sufficient for ensuring increasingly sustainable food supply chains around the world. While global population growth is expected to slow by 2050, the demand for animal proteins continues to increase and livestock production remains a core part of regional strategies to meet human nutritional needs, improve livelihoods and ensure food security. Genetic improvement has been, and continues to be, key to widespread gains in the efficiency, productivity and sustainability of cattle production systems. Selective breeding is only the first step, however, and better use of existing herd-level tools, combined with further innovation in genetic management, will be needed to strategically allocate genetic resources and sustainably meet the need for more high-quality protein. Innovative approaches can take any number of forms but may include key enabling technologies such as advanced reproductive management, enhanced phenotype recording, and targeted selection or precision breeding, strategies that are designed to optimize on-farm performance resulting from livestock genetic improvement programs. Implementation of genetic innovation at herd level leads to better outcomes for individual producers, while benefits are aggregated across farms and represent a holistic solution for improving systemwide efficiency and productivity. Enabled genetic improvement has delivered better health, more productivity, enhanced profitability and reduction of environmental impact, which all contribute to more sustainable beef and dairy production systems. Opportunities to accelerate this progress with climate smart interventions are now emerging. Ultimately, the optimal solution will be highly dependent on the production situation, but genetic innovation has the unique advantage of being deployable and scalable across production systems, markets and countries, which will be critical to meeting the challenge of profitably increasing animal protein availability while minimizing environmental impact.

Synergistic modulation of ruminal kinetics and metabolic efficiency by Lithothamnium calcareum and oregano extract: A holistic framework for sustainable bovine production

J. Pena[1], G. Mañas[1], X. Rodriguez[2]
[1] Devenish Nutrition, 96 Duncrue St, BT39AR Belfast, United Kingdom, [2] ZellFeed, Luis Calvo 35 -Bis, 15100 La Coruña, Spain

The global dairy sector faces an urgent mandate to synchronize intensive production with rigorous environmental stewardship. In this regard, rumen function and animal health have a key role to play. In dairy herds, SmartMag (SM) acts as a superior ruminal buffer compared to traditional sodium bicarbonate; data indicates that SM effectively stabilizes ruminal pH, leading to increases in energy-corrected milk (ECM). This stabilization fosters a robust environment for rumen microbiota, enhancing fibre digestibility and specifically increasing milk yield (kg/d) during peak lactation keeping production persistency. Concurrently, oregano extract (OE) serves as a potent metabolic modifier and its supplementation in dairy cows has demonstrated an increase in production and therefore improving feed conversion ratios. This response is attributed to OE's ability to promote rumen papillae development, increasing papillae length which optimizes nutrient absorption and systemic nitrogen (N) utilization. Beyond performance, this holistic approach provides critical environmental mitigation. Several studies have revealed that OE can reduce enteric methane production by up to 22% by selectively suppressing the absolute abundance of methanogenic archaea without compromising beneficial bacterial populations. Furthermore, OE enhances systemic resilience, significantly increasing serum immunoglobulin (IgA and IgM) concentrations, thereby reducing the metabolic cost of inflammation. This study evaluates a novel nutritional framework integrating Lithothamnium calcareum (SmartMag) and Oregano Extract (PhytaBoost) to optimize ruminal kinetics and metabolic partition. Utilizing a longitudinal, paired-sample statistical design across seven diverse commercial dairy operations (n=7) in Spain, we quantified the impact of this synergistic intervention on bio-economic efficiency. Statistical analysis via Paired-Samples T-test revealed a highly significant elevation in ECM, which rose from a control mean of 38.16 kg/d to a trial mean of 41.29 kg/d ($\Delta = +3.13$ kg/d; $p=0.002$), signifying superior metabolic conversion of dietary inputs. This gain was supported by a significant improvement in feed efficiency, increasing from 1.51 to 1.65 ($\Delta = +0.14$; $p = 0.013$), and a notable rise in milk protein from 3.34 to 3.47 ($\Delta = +0.13\%$; $p=0.016$). The latter indicates a profound optimization of N use efficiency; by capturing more dietary nitrogen into milk solids, the framework mitigates precursors for ammonia (NH3) emissions. Furthermore, a trend in milk fat was observed, increasing from 3.67% to 3.81% ($\Delta = +0.14\%$; $p = 0.074$), while methane intensity trended downward, suggesting a bioactive-driven shift toward propionogenesis over methanogenesis. Economically, the intervention yielded a significant rise in Income Over Feed Cost, increasing from a control mean of €13.44/cow/d to €14.82/cow/d (Δ = +€1.38/cow/d; $p = 0.011$). These findings demonstrate that the SmartMag-PhytaBoost framework provides a scalable, scientifically validated mechanism for sustainable intensification, aligning farm-level profitability with global net-zero and nitrogen mitigation targets. Moreover, our findings suggest that the combination of LC and OE provides a robust nutritional framework to adapt bovine systems to climate stressors, meeting global demands through enhanced feed-to-protein conversion.

Environmental, economic, and technical performance of goat farming systems compared to cattle and sheep systems: A systematic review and meta-analysis across climatic regions

J. J. Minviel[1], S. Souissi[1]
[1] INRAE, UMR Herbivores, Route de Thiex, 63122 Saint-Genés-Champanelle, France

Livestock production systems face multiple challenges, including low productivity, a growing demand for animal-source foods, and a progressive scarcity of production resources, all of which are further exacerbated by climate change. In this context, goat farming is often considered a particularly relevant option to address these challenges. Scoping literature reviews highlight several advantages associated with goats, which are frequently described as better adapted to heat stress, forage scarcity, and degraded rangelands. However, empirical studies on the potential zootechnical, economic, and environmental advantages of goats relative to other livestock species have yielded mixed results. Moreover, studies examining the potential advantages of goats over other livestock species are often exploratory and largely rely on qualitative assessments. This study aims to provide a quantitative synthesis of the available scientific evidence to robustly assess whether goat farming systems have effective advantages over cattle and sheep systems. A systematic literature review and a meta-analysis were conducted, covering approximately 600 publications from 50 countries over the period 1980-2025. The analysis relies on key indicators describing the zootechnical, socio-economic, and environmental performance of the different livestock systems. The review highlights consistent differences in system performance across livestock species and climatic regions. Goat systems demonstrated superior feed efficiency compared to cattle and sheep in both subtropical (DMI_milk: −39.8% and −45.9%, respectively) and temperate climates (−68.9% and −55.5%), while relying less on grass-based resources across both regions (Grass%: −38.2% to −20.9% vs. cattle; −19.9% to −16.3% vs. sheep). In temperate climates, goat systems emitted less greenhouse gases per liter of milk than cattle (−10.7%) and sheep systems (−50.5%). At the system level, goat systems consistently showed lower GHG emissions than cattle in subtropical (−60.0%) and temperate climates (−62.3%), with more moderate differences relative to sheep (−11.2% and −13.8%, respectively). Regarding economic performance, goat systems showed higher productivity per hectare than cattle and sheep in subtropical regions (+100% and +45.9%), whereas in temperate climates productivity was lower than cattle (−15.9%) but substantially higher than sheep (+81.5%). Production costs per hectare were lower for goat systems than cattle in both climatic regions (subtropical: −20.6%; temperate: −18.2%), and lower than sheep in subtropical contexts (−50.1%), while being markedly higher in temperate settings (+100%). Overall, these results confirm that goat systems offer competitive environmental and economic advantages, particularly under resource-limited or subtropical conditions, although performance remains strongly dependent on climatic region and production context.

Sustainable ruminant livestock transformation through the Global Farm Platform: The hub-and-spoke network

J. Rivero[1], M. Lee[2]
[1] Rothamsted Research, Norh Wyke, EX20 2SB Okehampton, United Kingdom, [2] Harper Adams University, Edgmond, TF10 8NB Newport, United Kingdom

Ruminant livestock systems provide high-quality nutrition and essential socio-economic services but face mounting challenges from climate change, biodiversity loss, soil degradation, and resource scarcity amid rising global food demand. The Global Farm Platform (GFP), launched in 2014 and honoured by the FAO for excellence in sustainable livestock transformation, offers a proven solution through its hub-and-spoke network. Research farms function as "hubs", living laboratories developing innovations, while commercial farms and smallholders act as "spokes" adapting and scaling solutions in diverse contexts via bidirectional knowledge exchange.This presentation introduces the August Special Issue of Animal Frontiers that showcases ten papers from GFP hubs across five continents. The hub-and-spoke approach rejects one-size-fits-all approaches, instead fostering context-specific, multi-actor innovations that enhance productivity, resilience, and public goods while empowering farmers as co-innovators.Key scientific enablers include adaptive genomics, demonstrating how native breeds such as Vechur cattle harbour adaptive alleles and haplotypes for heat tolerance, disease resistance, energy efficiency, and rumen stability. Using the G→P→E→SI framework and haplotype introgression, these genetic resources support low-input, climate-resilient, low-emission circular systems.Long-term agroecosystem research provides robust evidence: the Pioneer Farm (USA) hybrid hub-and-spoke platform undertakes edge-of-field monitoring and farmer partnerships to resolve soil health and nutrient loss dynamics under real-world conditions. Digital innovation further accelerates progress: practical implementation of FAIR data principles is applied at Harper Adams Future Farm (UK), while advanced digital tools and intensified grazing management for rangelands and native grasslands are utilised in Scotland and Uruguay.Regional applications highlight tangible outcomes: in Africa, the hub-and-spoke model mobilises native forage biodiversity to simultaneously boost productivity, restore soils, regenerate ecosystems, and support smallholder livelihoods. At Silent Valley Farm, India, integrated dairy systems with automated heat-stress mitigation (ASWASA), carbon farming, and native breed conservation deliver "Clean, Green and Ethical" production while strengthening community resilience. In Uruguay, INIA researchers show that long-rotation integrated crop-livestock systems achieve the best sustainability balance, with the highest gross margin, lowest emissions and synthetic N per US$ of margin, and soil erosion well below tolerance limits (compared to continuous cropping). Finally, the UWA Future Farm in Australia demonstrates a holistic multidisciplinary sheep-crop system integrating novel indigenous shrubs, conservation cropping, and community initiatives for Mediterranean environments.Collectively, the papers illustrate that the GFP hub-and-spoke network generates foundational science, translates it into context-specific innovations, and scales solutions effectively. This approach delivers measurable gains in productivity, climate resilience, soil health, biodiversity, and livelihoods while reducing environmental footprints. The GFP offers a scalable, inclusive blueprint aligned with FAO's sustainable livestock transformation vision, the Sustainable Development Goals, and the Paris Agreement.By strengthening such collaborative networks, the livestock sector can produce more nutritious food with less impact, ensuring long-term viability for both planetary and human health.

Grazing management intensification increases pasture height and carrying capacity in native grassland livestock systems: early results from a long-term farmlet experiment

F. Montossi[1], T. Devincenzi[1], V. Porcile[1], J. Martin[1]
[1] INIA URUGUAY, Livestock Extensive Systems, Ruta 5, km 386, 45000 Tacuarembó, Uruguay

Native grasslands of the South American Campos biome support extensive livestock systems that deliver food production together with key ecosystem services. However, limited empirical evidence exists on how long-term grazing management strategies influence productivity, resilience, and sustainability at the scale of real livestock systems. This study evaluates the early system trajectories generated by increasing grazing management intensity in native grassland-based mixed livestock production systems. The GLENCOE long-term experimental platform was established in 2023 in northern Uruguay using a farmlet design with three independent 50-ha livestock systems differing only in paddock subdivision: low intensity (2 paddocks), intermediate intensity (8 paddocks), and high intensity (32 paddocks). All systems started with identical vegetation conditions and stocking rates (0.75 livestock units/ha) and were managed under a common adaptive decision framework based on pasture height, animal body condition, and seasonal climate outlooks. Each system integrates beef cow–calf production and lamb finishing under mixed grazing. During the first three years of evaluation, clear differences in system trajectories emerged among grazing intensities. The high-intensity system consistently maintained greater pasture height across seasons, reaching values frequently above 10 cm during favorable growth periods compared with approximately 8–9 cm and 6–8 cm in the intermediate and low-intensity systems, respectively. This enhanced capacity to capture and regulate forage growth enabled progressive increases in stocking rate, reaching approximately 1.08 livestock units/ha in the 32-paddock system compared with 1.04 and 0.91 livestock units/ha in the intermediate and low-intensity systems. Despite these increases in carrying capacity, animal body condition, reproductive performance, and wool production remained comparable among systems. In addition to productive responses, the platform integrates the evaluation of ecosystem services, including soil carbon dynamics, soil biological activity, water quality, plant biodiversity, and ecosystem integrity, together with indicators of animal performance, economic outcomes, and labour conditions. These early results indicate that greater spatial and temporal control of grazing can improve forage capture, increase carrying capacity, and enhance management flexibility in native grassland livestock systems. The GLENCOE platform provides a unique long-term experimental framework to evaluate how grazing management intensification shapes productivity, resilience, and ecosystem services in subtropical grassland biomes.

Summer-smart strategies for livestock production in temperate zones: impact of shade on performance of grazing cattle

P. Rovira[1]
[1] Instituto Nacional de Investigación Agropecuaria, Animal Production, Ruta 8 km 281, 33000 Treinta y Tres, Uruguay

Strategies associated with animal adaptability, resilience and resistance to hotter conditions become more important in a climate change scenario. The most cost-effective environmental modification to ameliorate detrimental effects of heat stress in cattle are shade structures. There is no doubt about the necessity of shade in tropical regions. However, some producers are reluctant to provide shade for livestock in temperate zones as they argue a decrease in animal performance due to the time that cattle spend in the shade instead of grazing. The objectives of this study were to characterize the meteorological conditions during summer in the 'Palo a Pique' long-term research platform located in a temperate region in eastern Uruguay (33.14° S, 54.15° W) and determine the effect of providing artificial shade on average daily gain (ADG) of 15 months old grazing Aberdeen Angus x Hereford steers (mean ± SEM: 303 ± 23 kg liveweight). The temperature-humidity index (THI) was recorded hourly during nine summers using automatic sensors (2007, 2009, 2011, 2013, 2021-2025). Conditions for heat stress were considered thermoneutral when THI < 74, alert (74 ≤ THI < 79), danger (79 ≤ THI < 84), and emergency (THI ≥ 84). In six summers, an independent controlled experiment was carried out in a completely randomized design with two treatments: control steers without access to shade (CONT) and steers with free access to shade in the grazing paddock (SHADE). Three experiments were conducted on Sorghum bicolor var. sudangrass (9.8% CP; 40% ADF; 63% NDF), while the other three experiments were conducted on native grasslands (6.7% CP; 45% ADF; 67% NDF). Stocking rates were 5.8 and 1.7 steers per ha for sudangrass and grasslands, respectively. Shade was provided by a black cloth (4 m2/animal) intercepting 80% of solar radiation mounted 4 m above the ground. A combined analysis of the six independent experiments was carried out using a linear mixed model with treatment as fixed factor and year as random effect. Across summers, mean THI (± SEM) was 70 ± 0.3. Cattle were exposed to the 'normal' category during 67 ± 1.5%, followed by "alert" (23 ± 0.9%), "danger" (9 ± 0.9%) and "emergency" (1 ± 0.5%) categories for heat stress. SHADE steers had higher ADG than CONT steers (0.63±0.10 and 0.54±0.11 kg/a/d, respectively (P < 0.05). As a result of the additional ADG due to the provision of shade (+0.09 kg/a/d), shaded steers would be 8.1 kg heavier than unshaded steers at the end of summer (90 days). Numerically, in none of the six experiments the ADG of CONT animals was greater than the ADG of SHADE animals. Based on the standard nutritive value of beef meat and considering a carcass yield of 52% at slaughter and that 63% of the carcass is available for retail products providing shade would allow the production of additional 6.7 Mcal of energy and 687 g of protein per steer during summer. By combining data from independent trials, which addresses the variability of treatment differences across several summers, we demonstrated that providing shade improved performance of grazing steers in a subtropical zone. This may be an important incentive for shade adoption by farmers as a strategy to improve farm income and animal welfare while contributing to food security objectives.

Dairy Soil and Water Regeneration Research: Filling Crucial Data Gaps

D. Busch[1]
[1] *University of Wisconsin-Platteville, School of Agriculture, 1 University Plaza, 53818 Platteville, United States*

The University of Wisconsin–Platteville (UWP) Agroecosystems Research Program is conducting an eight-year Dairy Soil and Water Regeneration (DSWR) research project at Pioneer Farm to evaluate the environmental performance and climate resilience of dairy forage production systems. The project is led by Dairy Management Inc. and the Soil Health Institute and includes multiple research institutions, including the USDA Agricultural Research Service and seven university partners located across major dairy-producing regions of the United States. The research aims to identify dairy production systems that maintain high forage productivity while reducing environmental losses and improving the climate-smart performance of livestock systems. At UWP, three dairy-focused crop production systems are being evaluated using a replicated watershed experimental design (n = 4). The first system, a Soil Health Management System (SHMS), includes corn silage fertilized with surface-applied flocculated manure solids, supplemental nitrogen applied according to soil nitrogen tests, and cover crops established immediately following harvest. The second system, Business as Usual (BAU), represents common regional practices in which corn silage is fertilized with fall-injected liquid dairy manure and additional nitrogen is supplied through spring urea applications incorporated by disking, with no cover crops. The third system, Managed Intensive Grazing (MiG), consists of forage-legume-forb pasture mixtures rotationally grazed by bred heifers or dry cows for short grazing periods followed by rest intervals to allow adequate regrowth. Each watershed is instrumented with meteorological stations and soil sensors to monitor air temperature, rainfall, soil temperature, soil moisture, and soil oxygen. Edge-of-field surface-water discharge is measured year-round using H-flumes equipped with ultrasonic stage sensors. Flow-weighted composite samples are collected during runoff events and analyzed for sediment and nutrient parameters including nitrogen and phosphorus species. Surface-water quality is further evaluated using rainfall simulations conducted on small plots (1 m × 2 m) with rainfall intensity of 2.75 inches per hour to replicate high-intensity precipitation events expected to increase under future climate conditions. Complementary monitoring of vadose zone leachate is conducted using undisturbed soil core lysimeters installed at the toeslope of each watershed. Preliminary results from 2024–2025 indicate that the BAU system produced significantly greater runoff volumes, soil loss, and nutrient export compared to both SHMS and MiG systems. Rainfall simulation experiments illustrate these differences, with mean soil loss of 305 lb acre^{-1} in the BAU system compared with 32 lb acre^{-1} in SHMS and 13 lb acre^{-1} in MiG. An exception to this trend was soluble reactive phosphorus, which was elevated in the SHMS and comparable to BAU losses, suggesting that surface-applied manure products may increase dissolved phosphorus transport risk. These preliminary results demonstrate how soil health management and perennial grazing systems can improve the environmental performance and climate resilience of dairy production systems while maintaining forage productivity. The presentation will highlight preliminary edge-of-field runoff, rainfall simulation, and vadose-zone leachate results collected during 2024 and 2025. This research is supported by the USDA Foundation for Food and Agriculture Research, Dairy Management Inc., and the Wisconsin Dairy Innovation Hub.

Differential sensitivity of milk protein and milk yield to heat stress load in a robotic pasture-based dairy system

F. Ahmadi[1], F. Dunshea[1,2]
[1] The University of Melbourne, School of Agriculture, Food, and Ecosystem Sciences, 3010 Melbourne, Australia, [2] The University of Leeds, Faculty of Biological Sciences, LS2 9JT Leeds, United Kingdom

The objective of this retrospective investigation study was to quantify the longitudinal impacts of the temperature-humidity index (THI) on milk yield (MY) and milk composition of Holstein-Friesian lactating cows within a robotic pasture-based dairy system. An 8-year dataset (2016–2023) comprising 2,594 herd records from University of Melbourne's Dookie robotic dairy farm, was matched with the meteorological data collected from the nearest weather station to the farm. Statistical analyses were conducted using PROC MIXED (SAS 9.4) for mean comparisons and segmented (broken-line) regression (PROC NLIN) to identify the critical THI breakpoints associated with MY and milk protein concentration. Adjusted THI, incorporating wind speed and solar radiation, was applied in the segmented regression analysis to better represent heat load under the high solar exposure conditions, typical of Australian pasture-based dairy systems. Pearson correlation analysis assessed the relationship between the same-day (d 0) and lagged THI (1–3 d) with MY and milk protein content. An increase in THI was associated with reduced average herd MY and milk protein concentration ($P < 0.05$). When stratified by a 30-kg threshold based on average daily herd milk production, stronger negative correlations with THI were observed above the threshold (≥30 kg/d), peaking at a 3-day lag ($r = -0.406$; $P < 0.001$), whereas associations were weaker and inconsistent below this threshold (i.e., < 30 kg/d). For milk protein content, there was an overall significant negative association between THI and milk protein content ($r = -0.495$ to -0.524; $P < 0.001$), with the strongest correlations observed at 3-day lag and the 3-day rolling average. The inverse relationship was more pronounced when average daily herd MY was below the lower threshold (either <25 or <30 kg/d) compared with upper threshold (≥25 or ≥30 kg/d), indicating greater protein sensitivity to heat load than MY at lower production levels. Segmented regression analysis based on adjusted THI identified significant breakpoints for milk protein concentration at approximately 41.7 for 3-day average THI to 43.5 for same-day (d 0) THI, beyond these determined THI breakpoints, milk protein declined significantly ($P < 0.001$). The greatest reduction was determined to occur for the 3-day average THI, indicating a cumulative heat load effect on milk protein concentration. In contrast, breakpoints for MY were estimated at approximately 55.2 to 57.1 THI units, but post-breakpoint slopes were not significant, suggesting that there is no evident evidence in MY decline beyond the determined breakpoints. In conclusion, in pasture-based, robotic dairy system, cumulative heat stress impaired milk protein concentration more consistently than milk production. Although MY showed stronger short-term associations with THI at a higher average daily herd MY, milk protein was more sensitive under lower production level and responded at lower adjusted THI thresholds. These results likely suggest that monitoring milk protein may enable earlier detection of heat stress and support proactive heat mitigation strategies in pasture-based robotic dairies.

Summer-smart strategies for livestock production in temperate zones: supplementation of grazing cattle

M. Verdaguer[1], P. Rovira[2]
[1] Facultad de Agronomía, Av. Eugenio Garzón 780, 12900 Montevideo, Uruguay, [2] Instituto Nacional de Investigación Agropecuaria, Animal Production, Ruta 8 km 281, 33000 Treinta y Tres, Uruguay

In the context of climate change and increased frequency of droughts, summer supplementation of grazing cattle may improve productivity and resilience of pastoral systems. The productive response to supplementation must be studied along with physiological indicators related to heat stress as feeding strategies may have consequences in heat production. The aim of this study was to evaluate the productive response of providing energy-protein supplements to growing steers grazing native grasslands in summer and to evaluate the effects of the supplementation on respiration rate (RR) and body temperature (BT) in a temperate region. Three independent studies were conducted over three summers (2020-2023) in the 'Palo a Pique' long term research platform located in eastern Uruguay (33.14° S, 54.15° W). Each experiment consisted of two treatments: control without supplementation (CONT) and supplementation (SUPPL) replicated in three 4-ha blocks in a completely randomized block design. Stocking rate varied between years (1.5 – 2.5 animals/ha) and steers had ad libitum access to artificial shade (4 m2/animal) and water on a continuous stocking system. SUPPL steers were group-fed in the morning three days per week with an energy-protein ration (16% CP, 13% ADF, 25% NDF, 78% TDN) at a level of 1.98% body weight (BW) on days of feeding. RR was measured by visual observation at 08:00 and 14:00 h, and BT was recorded continuously at 1 h intervals using an automatic sensor implanted subcutaneously. Data was analyzed using a mixed model with treatment and block as fixed effects and year as the random effect. According to the temperature-humidity index (THI), cattle were exposed to alert (74 < THI < 79), danger (79 < THI < 84) and emergency (THI ≥ 84) heat stress conditions 23%, 8%, and 1% of the experimental period, respectively. Sward height at the beginning of the grazing season was similar ($P > 0.05$) between treatments (CONT = 4.6 cm, SUPPPL = 4.2 cm, SEM = 0.2), but CONT paddocks had lower final sward height than SUPPL paddocks ($P < 0.05$) at the end of grazing (4.8 and 5.5 cm, respectively). The pasture had a medium-low content of protein (6.1 – 9.6% CP) and high content of fiber (60 – 64% NDF), which is typical of native grasslands dominated by C4 grasses in summer. Supplemented steers were heavier ($P < 0.05$) at the end of summer than CONT steers (347 and 313 kg/a; SEM = 5) due to ADG significantly greater ($P < 0.05$) than CONT animals (0.90 and 0.45 kg/a/d; SEM = 0.07). The use efficiency of the supplement was 6.8 kg of DM supplement consumed per kg of observed added gain (min. 10.1 and max. 5.1). RPM of SUPPL and CONT animals was similar at 08:00 h (43 ± 1 rpm; $P > 0.05$), but SUPPL animals showed higher ($P < 0.05$) RPM than CONT animals at 14:00 h (63 ± 1 rpm and 57 ± 2 rpm, respectively). Although the daily mean BT was similar between treatments ($P > 0.05$), SUPPL steers had higher BT ($P < 0.05$) than CONT steers between 08:00 and 12:00 h (38.8 ± 0.1 °C and 38.3 ± 0.1 °C, respectively), with the greatest difference after delivering the supplement (09:00 h) averaging 39.1 ± 0.1°C (SUPPL) and 38.1 ± 0.1°C (CONT). Summer supplementation improved the performance of grazing steers. Although it temporarily increased BT (morning) and RR (afternoon), daily average RR and BT were similar for both treatments. This 3-year evaluation provides novel experimental evidence that summer supplementation improves animal performance without significantly increasing the risk of heat stress in grazing animals in a temperate zone.

Fifty years of progress for beef cattle production in the United States

C. A. Rotz[1], J. Castano-Sanchez[2], D. Kniffen[3], M. Buyers[4], S. J. Werth[5]
[1] USDA-ARS, Pasture Systems & Watershed Management Research Unit, 532 Curtin Road, 16802 University Park, United States, [2] USDA-ARS, Food Systems Research Unit, 105 Carrigan Dr., 05405 Burlington, United States, [3] The Pennsylvania State University, Emeritus, Animal Science Dept., 439 Shortlidge Road, Room 109, 16802 University Park, United States, [4] Agri Beef, 1555 Shoreline Drive, Suite 320, 83702 Boise, United States, [5] U.S. Roundtable for Sustainable Beef, 9110 East Nichols Avenue, Suite 300, 80112 Centennial, United States

Many changes in feed production and the maintenance and genetics of cattle have occurred over the past 50 years which affect the efficiency, productivity and environmental impacts of beef cattle production. Trends in feed and animal productivity were determined through regression of historical annual data with time. The Integrated Farm System Model, following life cycle assessment procedures, was used to assess the impact of these changes by modeling representative cattle operations throughout the US in 1972 and 2022. Improvements in yields of feed crops, animal maintenance and genetics, machinery efficiency, and the production of resources such as fuel, electricity, and fertilizer have led to many reductions in the life cycle environmental impacts of beef cattle production. Fewer but larger cattle harvested in 2022 produced 23% more beef carcass weight than in 1972. Nearly the same total feed was consumed to produce beef in 2022 as used in 1972, but about 9% less forage and 43% more grain and other concentrate feeds were fed. Increases in crop yields, particularly corn yields, led to a 12% reduction in cropland and 11% reduction in total land use over the 50-yr period. Other predicted improvements included a 25% reduction in blue water use, 23% reduction in fossil energy use, and 6% reduction in methane emissions. There was little change in total reactive N losses related to beef cattle production with a 34% increase in ammonia emissions offset by decreases in N denitrification, leaching and runoff losses. Considering the increase in animal weight produced, reductions per unit of carcass weight included 21% less feed, 29% less land, 41% less blue water, 39% less fossil energy, 26% less methane, and 19% less reactive N loss. A sensitivity analysis showed that these results were not influenced much by changes in our assumptions on past animal and pasture management. These improvements reflect the continuing trend of the U.S. beef industry to increase productivity and efficiency for a more sustainable product to meet the growing demand for beef. Key words: beef cattle, Integrated Farm System Model, life cycle assessment

Climate change and thermal stress in cattle: Global projections with high temporal resolution

M. Neira[1], P. Georgiades[1], Y. Proestos[1], T. Economou[1,2], J. Araya[1], S. Malas[3], M. Omirou[4], D. Sparaggis[4], G. Hadjipavlou[4], J. Lelieveld[1,5]

[1] The Cyprus Institute, Climate and Atmosphere Research Center, 20 Konstantinou Kavafi Street, 2121 Nicosia, Cyprus, [2] Exeter University, Department of Mathematics and Statistics, Harrison Building, North Park Road, EX4 4QF Exeter, United Kingdom, [3] The Cyprus Institute, 20 Konstantinou Kavafi Street, 2121 Nicosia, Cyprus, [4] Agricultural Research Institute (ARI), Ministry of Agriculture, Rural Development, and Environment, Athalassa Experimental Farm, 1516 Nicosia, Cyprus, [5] Max Planck Institute for Chemistry, Hahn-Meitner-Weg 1, D-55128 Mainz, Germany

Cattle farming is a cornerstone of global agriculture, providing essential protein, dairy products, and livelihoods for billions of people. However, the industry is increasingly vulnerable to climate change, particularly thermal stress—the physiological strain caused by the combination of high temperature and humidity, which constitutes one of the most significant challenges to livestock welfare and economic viability. While previous studies have mapped general warming trends and their expected effects in the cattle industry, they lacked the high-resolution temporal data necessary to capture ”micro-dynamics” of heat stress, such as the duration of night-time recovery periods, and the expected frequency and duration of heatwaves. To quantify future risk, we based our analysis in the Temperature-Humidity Index (THI), a widely recognized metric for assessing the combined impact of heat and moisture on livestock physiology. By building on recent work that used a machine-learning model to convert daily climate projections into hourly THI values, our study projects the duration and intensity of thermal stress periods, as well as the frequency and duration of thermal stress waves, under different greenhouse gas emission scenarios, extending to the end of the 21st century. Our results reveal a progressive increase in both the intensity and duration of thermal stress across the globe, with severity largely dependent on future greenhouse gas emission trajectories. While currently most cattle throughout the world can experience sporadic periods of mild heat stress, conditions creating severe heat stress (where mortality risks rise) are quite rare. However, our data projects that under a ”business-as-usual” emissions scenario, the average duration of severe heat stress periods could increase up to 12-fold by the late century; and even under a moderate emissions scenario, the global average duration of severe heat stress is likely to increase nearly 6-fold during the same period. Our results also project a significant lengthening of the duration of Thermal Stress Waves. By late century, several regions will move from experiencing relatively short heat spikes to enduring prolonged and intense thermal stress waves, which are particularly concerning because they are strongly linked to increased mortality in livestock. When future thermal stress projections are combined with global cattle distribution, clear risk hotspots appear across several regions, including South and Central America, East and Central Africa, South and Southeast Asia, and parts of Oceania. These regions are expected to see a disproportionate share of negative impacts of heat stress on their cattle farming operations. We conclude that urgent mitigation and adaptation strategies are needed. Physical adaptations, including shaded structures, hydration stations, and optimized barn ventilation, must be prioritized in tropical and sub-tropical regions. The implementation of genetic improvement programs for breeding heat-tolerant animals would create another layer of resilience for the sector and the populations it supports.

Fans, sprinklers, or what else? Understanding Swedish farmers' experiences with cooling strategies

K. Berggren[1], L. M. Tamminen[1], N. Högberg[1], R. Båge[1], G. Olmos Antillón[1]
[1] Swedish University of Agricultural Sciences, Clinical Sciences, Box 7054, 75007 Uppsala, Sweden

Following the 2018 heat wave across Europe, Swedish dairy farmers have become increasingly aware of heat stress in cows, and fans on farms are becoming popular. Research from countries with warmer climates shows that fans in combination with evaporative cooling are the most effective mitigation strategies. Yet it is unknown whether such strategies are applicable in a Nordic climate like that in Sweden. Neither is it known what farmers' current experiences or views are on mitigation strategies for heat stress. Our aim was to better understand which short- or long-term cooling methods for cows were currently used by Swedish dairy farmers and the challenges they encountered. Based on a reflective thematic analysis of 13 interviews with Swedish dairy farmers, several patterns were identified regarding on-farm heat-stress mitigation. Fans were consistently described as the primary investment to alleviate heat stress. The majority reported installing them to complement the natural/passive ventilation in the barn or milking station. However, farmers who had installed fans described variable benefits. This suggests that fans might not be a complete solution, as animals were still reported to show signs of heat stress (e.g., reduced milk production, reduced activity, or panting). Reports on how farmers selected the type, number, or placement of fans reveal a lack of context-specific strategy or guidance in Sweden. Moreover, fan installations were often used not for actual cooling but to maintain or improve airflow in the barn on hot days, with the belief that this is key to preventing cows from going into heat stress. On the other hand, water-based cooling strategies were viewed cautiously. While some farmers experimented with improvised solutions, such as showering cows or constructing homemade sprinklers, concerns were often raised about increased barn humidity, increased manure volume, hygiene problems, and disease transmission, and in some regions, it was deemed infeasible due to water scarcity. Genetic selection was also discussed with farmers. This was seen as a potential long-term resilience strategy. Here, farmers perceived limited individual influence and often framed heat tolerance as already indirectly addressed through breeding for general robustness and disease resistance. Overall, heat stress mitigation was not described as a top priority due to the relatively short Swedish summer season. Thus, any actions undertaken on the farm were closely linked to alleviating major problems on farm. Heat mitigation strategies in Swedish dairy cows remains a low priority, as the belief is that the losses seen during summer events are offset by gains during the rest of the year. Currently, fans have shown the greatest uptake on farms but have not successfully resolved heat stress in cows. Thus, water-based solutions must be explored in a Swedish context, taking into account both old and new barn constructions to avoid humidity problems and issues with manure handling, which are seen as factors limiting uptake.

Aligning research gaps and innovation demands for ecosystem services in South American pasture-based livestock systems

F. Montossi[1]
[1] *INIA Uruguay, Livestock Extensive Systems, Ruta 5, km 386, 45000 Tacuarembo, Uruguay*

Pasture-based livestock systems dominate beef production across the Southern Agricultural Council (CAS) region of South America and play a key role in food security, rural livelihoods, and ecosystem services. However, increasing societal expectations regarding climate change mitigation, biodiversity conservation, water stewardship, and animal welfare require stronger alignment between scientific research agendas and technological innovation priorities. This study aimed to identify and prioritize scientific and technological gaps related to ecosystem services in pasture-based livestock systems in the CAS region. A structured consultation was conducted within the Sustainable Livestock Platform promoted by the Inter-American Institute for Cooperation on Agriculture (IICA) and the Inter-American Development Bank (IDB). A web-based survey, developed from a prior scientific review, evaluated four strategic domains: carbon balance, water balance, biodiversity, and animal welfare. Between seven and ten specific topics were assessed within each domain. A total of 106 regional experts from Argentina, Uruguay, Brazil, Paraguay, Chile, and Bolivia participated in the consultation, with 95 complete responses. Participants evaluated both knowledge gaps and R+D+i priorities using a five-level scale ranging from low to very high. Results revealed strong convergence between perceived scientific gaps and innovation demands across the four domains. In carbon balance, the highest priorities were systemic research on sustainable livestock systems, improved carbon management practices, and the development of robust greenhouse gas inventories. For water balance, climate change adaptation strategies and watershed-level approaches emerged as key priorities. Biodiversity results highlighted the need for greater understanding of livestock impacts on biodiversity and the establishment of long-term monitoring frameworks. In the animal welfare domain, stakeholder participation, training processes, and the development of practical assessment and monitoring indicators were identified as the main priorities. These findings highlight the need for integrated, long-term research programs addressing ecosystem services in livestock systems and strengthening regional research networks. Improved alignment between science, innovation, and stakeholder demands will be essential to enhance the environmental performance, social legitimacy, and global competitiveness of South American pasture-based livestock systems.

Effect of reproductive status on goat methane emissions

M. Moradi[1], A. Beasley[1], L. C. Hoffman[2], S. J. Meale[1]
[1] AGFS, School of Agriculture and Food Sustainability, Faculty of Science, The University of Queensland, 4343 Gatton, Australia, [2] QAAFI, Queensland Alliance for Agriculture and Food Innovation, The University of Queensland, 4343 Gatton, Australia

Goat production is the fastest-growing ruminant production globally and is vital for food security in tropical and subtropical regions. Reducing enteric methane is crucial to enhancing sustainability and productivity. While most studies have focused on nutritional effects, physiological factors such as reproductive status change nutrient demand, dry matter intake (DMI), and rumen function, potentially influencing methanogenesis. To our knowledge, the longitudinal effects of reproductive status on rumen function and methane emissions in goats remain unexamined. We evaluated the effects of reproductive status (dry, pregnant twin-bearing, and early lactation) on goat methane emissions. Forty two-year-old Boer × Rangeland does (n=20 dry; n=20 pregnant) were studied from week -4 prepartum to week +4 postpartum. Animals were housed individually and fed a maintenance diet (lucerne hay, barley hay, and commercial lactating pellets) formulated using the Small Ruminant Nutrition System. Methane emissions were measured using the sulphur hexafluoride (SF6) technique. Data were analysed using a mixed model in SAS (v9.4) with Kenward-Roger adjustment. Post-hoc pairwise comparisons were performed with LSMEANS/PDIF. Statistical significance was declared at $P \leq 0.05$; data normality was assessed with the Shapiro-Wilk test. Reproductive status markedly influenced intake patterns. DMI increased from 0.60 ± 0.08 in week -4 prepartum to 1.07 ± 0.05 kg/d at kidding ($P < 0.001$). Following parturition, DMI increased sharply to 1.35 ± 0.05 in week +1 ($P < 0.001$) and peaked at 1.75 ± 0.06 kg/d by week 4 of lactation ($P < 0.001$). In contrast, DMI in dry does remained stable throughout the experimental period (av. 0.51± 0.04 kg/d; $P > 0.1$). Body weight remained stable in dry and lactating does, while pregnant does showed increases consistent with advancing gestation, which together with weekly condition scoring suggest confirmation of a maintenance-level feeding strategy. Overall, pregnant goats had higher DMI than dry goats (0.62 vs. 0.43 kg/d, respectively; P=0.03). Despite this, both pregnant and dry does emitted comparable amounts of methane (26.51 and 27.06 g/d, respectively; P=0.85), resulting in pregnant does having a lower methane yield than their dry counterparts (47.26 vs 65.91 g/kg DMI, respectively; $P<0.001$). During the first month post-kidding, lactating does had higher DMI than dry animals (1.76 and 0.59 kg, respectively; $P < 0.001$). Similarly, lactating does had higher daily methane emissions compared to dry does (81.66 and 35.57 g/d; $P < 0.001$), yet methane yield in lactating animals was lower than their dry counterparts (47.22 and 60.75 g/kg DMI, respectively; $P<0.001$). Diets met maintenance and reproductive requirements, with pregnant and lactating does receiving higher quality, lower NDF rations, partly explaining lower methane emissions than dry animals. Methane production was primarily driven by DMI. Pregnant does, despite ~45% higher DMI, produced similar methane (g/d) to dry does, likely due to reduced rumen capacity and retention time, and late gestation hormone-driven alterations in rumen metabolism. Lactating does emitted more methane (g/d) due to higher DMI, but had lower methane yields, possibly reflecting faster passage rate and reduced rumen retention time. Overall, pregnant and lactating goats emitted less methane per unit of DMI suggesting lower methane intensity and improved efficiency.

Needs and Capacity building of advisors to support transitions towards climate-smart farming systems

F. Bedoin[1], C. Evrat-Georgel[1]
[1] French Livestock Institute (IDELE), Social Approaches and Transfer, 149 rue de Bercy, 75012 PARIS, France

Faced with the complexity of global challenges such as climate change, market dynamics and environmental sustainability, EU farmers are increasingly reliant on farm advisers to navigate political, technological, social and environmental imperatives (see for example, Ingram et al., 2022). Boosting the capacity of the EU agricultural advisory community to advance climate smart farming is therefore an urgent task. Recognising this urgency, the EU Horizon programme has funded Climate Smart Advisors (CSA) project, a pan-European multi-actor network covering 27 countries started in 2023. Its aim is to boost the EU agricultural advisory community in the field of climate smart farming by strengthening the advisors' capacity and role in the transition towards Climate-Smart (CS) Farming. Within CSA, a range of complementary activities are designed to strengthen the CS advisory capacity of the EU advisory community, including the following: (1) An EU-wide network of 260 advisory Communities of Practice (CoP) to support the development of 1500 advisors to form the core of CS knowledge exchange; (2) Expert training for 140 advisors on selected topics, relevant to their context and for facilitating a CoP; (3) Knowledge exchange in 12 thematic areas across the CoPs; (4) A knowledge repository for advisors with CS tools, practices, and approaches (5) Monitoring, evaluation, and formative learning activities to capitalize on lessons being learned within and outside the project. With this communication, we want to discuss the needs and capacities agricultural advisors require to support farmers in implementing sustainable and climate smart farming. It builds on the first two year of monitoring, evaluation, and learning within the Climate Smart Advisors (CSA) network. Our analysis draws from multiple sources, including a training needs assessment of 80 advisors, a literature review, advisors' focus groups, insights from the first-year evaluation of the CoPs and the learning questions identified by advisors in the CoPs. We first analyse farmers' needs and then dig-in into the advisors' needs to support farmers. The needs of advisors are related to (1) deeper and more nuanced knowledge about climate science, its impacts on agriculture, and the practical measures that can mitigate these effects. This includes understanding the specific challenges faced by different farming systems.(2) Second, advisors call for better tools and resources to aid their work. This includes digital platforms for data visualization, monitoring tools to assess climate impacts, and repositories of case studies and best practices that can be shared with farmers. Many CoPs of the network are working on building together such tools and ressources. (3) Finally, advisors express a need for guidance on engagement strategies, particularly when dealing with resistant or skeptical farmers. They seek methods for navigating difficult conversations, fostering collaboration, and maintaining momentum in group settings. (4) Additionally, advisors emphasize the importance of networking and collaboration with their peers, researchers, farmers and policymakers to stay informed, share experiences, and co-develop solutions that are both innovative and practical.

Integrating thermal load and metabolic indicators to support climate smart management decisions in dairy herds

Z. Vassilev[1], L. M. Dale[1], J. Bieger[1], A. Al Baqain[1], E. J. Strang[1], C. Eck[2], S. Weidmann[2], S. Fritsch[1]
[1] LKV Baden-Württemberg, Heinrich-Baumann-Str. 1-3, 70190 Stuttgart, Germany, [2] Agricultural Chamber Alsace, 2 Rue de Rome, 67300 Schiltigheim, France

More frequent and intense heat events challenge the resilience of dairy systems and threaten productivity and health of the animals , making climate-smart management essential for securing global protein supply. Conventional heat stress indicators such as the temperature–humidity index (THI) describe the environment but overlook individual metabolic responses that determine actual performance and welfare outcomes. Holistic indicators that combine barn climate, animal-level physiology and routine farm data could help farmers adapt to warming conditions while reducing avoidable losses and associated emissions. This study aimed to (i) quantify relationships between weather station (WS-mean3THI), barn- (Barn-mean3THI) and cow-level THI (Cow-mean3THI), housing type and key production, metabolic and energy-balance (EB-NEL) traits; (ii) evaluate how dry matter intake indicator (DMI) relates to energy-corrected milk (ECM); and (iii) assess whether combining THI with metabolic information improves interpretation of heat stress effects compared with THI alone, thereby supporting climate-smart management decisions. Data were collected during summer in commercial dairy herds of major dairy breeds housed in cold open barns or warm freestall barns. Environmental records were used to compute 3-day moving average THI. Milk yield (MY), ECM, milk composition (fat, protein, lactose, urea, somatic cell count), and detailed milk fatty acid (FA) profiles were combined with milk and blood biomarkers (e.g. BHB, NEFA, acetone), derived energy-efficiency traits (EE-NEL), feed efficiency (FE-ECM) and EB NEL and DMI. Correlation analyses explored associations among climate, production, metabolic and FA traits. General linear models (GLM) analysed (i) Cow-mean3THI increased with WS-THI class and was consistently higher in warm than in cold housing, indicating that warm barns increase effective heat loadunder comparable outside conditions. WS-mean3THI showed large, clearly separated differences between “cool”, “moderate” and “hot” classes, whereas the additional housing effect on barn THI was small. Higher THI was associated with less favorable EB-NEL, elevated ketone body concentrations and shifts in milk FA towards higher proportions of long-chain and preformed FA, consistent with increased body fat mobilization. In the ECM model, WS-mean3THI and housing type had significant effects, while the effect of Cow-mean3THI became negligible after including WS-mean3THI and DMI. DMI was strongly associated with ECM and EB-NEL traits, indicating that cows with lower DMI status produced less ECM under similar climatic conditions. The results confirm that housing design influences individual heat load and that WS-mean3THI provides a simple, operational indicator of transitions from comfortable to stressful conditions. However, THI alone does not adequately explain performance and health outcomes; combining THI with DMI and EB-NEL indicators substantially improves interpretation of heat stress impacts. Integrated milk spectral data indicators derived from on-farm sensor, milk-recording and laboratory data can act as early-warning tools for heat-related metabolic stress and ECM losses. In the context of climate-smart livestock systems, these holistic, data-driven indicators can support adaptive management by identifying high-risk periods, prioritizing vulnerable animals and guiding targeted interventions, thereby contributing to more resilient and resource-efficient dairy production.

Effects of dietary supplementation with a novel marine algae–derived prebiotic feed additive (MAFA) on growth performance, gaseous emissions and manure characteristics from a commercial finishing pig facility

I. M. Aroh[1,3], G. Mccutcheon[3], R. Kuneš[2], S. Conolly[4], E. G. Manzanilla[3], T. P. Curran[1], L. Clarke[3]
[1] University College Dublin, School of Biosystem and Food Engineering, University College Dublin, D04 F6X4 Dublin, Ireland, [2] University of South Bohemia, Department of Technology and Cybernetics, Faculty of Agriculture and Technology, Ceske Budejovice, 1668, 37005 Ceske Budejovice, Czech Republic, [3] Teagasc, Pig and Poultry Development, Moorepark, Fermoy, P61 C996 Cork, Ireland, [4] Teagasc, Environment, Soils and Land Use Department, Johnstown Castle, Y35 TC97 Wexford, Ireland

Ammonia and greenhouse gas (GHG) emissions from agriculture pose significant environmental and health concerns. Nutritional strategies, including the use of feed additives, have been proposed to enhance animal performance while reducing gaseous emissions from livestock facilities. This study evaluated the effects of dietary supplementation with a marine algae–derived prebiotic feed additive (MAFA) on growth performance, gaseous emissions and manure characteristics of finishing pigs housed in a fully slatted, mechanically ventilated commercial facility. Two experiments were conducted using pigs of uniform initial body weights. The studies utilized two separate and identical fully slatted finishing pig rooms, measuring 12 m × 9 m, with manure tanks depth of 1.4 m. Each room is equipped with a negative-pressure ventilation system. Pigs were moved into the finisher room 2 weeks before the start of the trial, were arranged into pens of 10-11 pigs of similar weight and were fed the control diet. At the same time, slurry pits were emptied to similar levels across all rooms. A total of 164 pigs were used in the first experiment and 185 pigs in the second. Diets were supplemented with MAFA at inclusion levels of 0.5 or 1.0 kg/tonne and compared with unsupplemented controls. The first experiment (0.5 kg/tonne) was conducted from March to May 2025, while the second experiment (1.0 kg/tonne) was conducted from June to September 2025. Ammonia and greenhouse gas emissions were monitored for 56 days (0.5 kg/tonne) and 53 days (1.0 kg/tonne) using a Gasera photoacoustic gas analyser. Gaseous monitoring followed the VERA test protocol and emission calculations accounted for outliers, mortality, pig numbers and incomplete monitoring days. Productive performance data were analysed using a general linear model, while model assumptions and homogeneity of variance were verified prior to applying appropriate parametric or non-parametric tests. Results found that MAFA supplementation did not affect productive performance ($p > 0.05$) at either inclusion level. Ammonia emissions were also unaffected ($p > 0.05$). Greenhouse gas responses were gas-specific and dose-dependent. Carbon dioxide emissions differed at 0.5 kg/tonne ($p = 0.030$), whereas no differences were observed at 1.0 kg/tonne ($p > 0.05$). Methane emissions were unchanged at 0.5 kg/tonne but decreased by 41.8% at 1.0 kg/tonne ($p < 0.001$). In contrast, nitrous oxide emissions increased at both inclusion levels ($p < 0.001$). Manure analysis showed a modest reduction over time ($p < 0.05$) in fresh manure pH with MAFA supplementation at 1.0kg/tonne, along with changes in dry matter and nutrient composition, including ammonium-N, phosphorus, and potassium concentrations. However, these changes were insufficient to reduce ammonia emissions at the housing level. Overall, supplementation with a marine algae–derived prebiotic feed additive under commercial finishing conditions did not improve productive performance or reduce ammonia emissions but influenced greenhouse gas dynamics and manure chemistry.

Impact of dietary calcium and phytase on mineral digestibility and skeletal mineral accumulation in growing pigs.

J. Labarre[1,2], P. Schlegel[3], P. Schmidely[2], T. D. Crenshaw[4], D. Bueno Dalto[5], M. Jlali[6], A. Narcy[7], M. P. Létourneau-Montminy[1]

An optimal dietary calcium (Ca) to phosphorus (P) balance is essential to minimize the use of inorganic phosphates in pig diets. This study evaluated the effects of dietary Ca and microbial phytase (PhytM) supplementation on nutrient digestibility and bone mineralization in growing pigs, with PhytM added by partially replacing monocalcium phosphate and limestone. A total of 240 pigs were allocated to 40 pens. Each pen was assigned to one of five diets: a control Ca diet without PhytM (CCa-PhytM0), CCa + 500 FTU/kg PhytM (CCa-PhytM500), CCa + 2000 FTU/kg PhytM (CCa-PhytM2000), low Ca (LCa-PhytM0), and LCa + 500 FTU/kg PhytM (LCa-PhytM500). All diets were formulated to provide 85% of the P requirements for 25-to 50-kg pigs. Total Ca to digestible P ratios were 2.3 for the CCa diets (CCa-PhytM0, CCa-PhytM500, CCa-PhytM2000) and 1.3 for the LCa diets (LCa-PhytM0, LCa-PhytM500). Body composition was assessed by using dual-energy X-ray (DXA) absorptiometry scans at the start and end of the experiment and Ca and P deposition were calculated from these values. Statistical analyses were performed using a one-way ANOVA. The first set of contrasts tested the effects of dietary Ca, PhytM, and their interaction using the LCa-PhytM0, LCa-PhytM500, CCa-PhytM0, and CCa-PhytM500 diets. A second set compared CCa-PhytM2000 with CCa-PhytM500. Relationships between femur bone mineral content (BMC) and whole-body BMC, as well as metacarpal BMC and whole-body BMC were evaluated using linear regression models. Pigs fed PhytM500 diet improved apparent total tract digestibility (ATTD) of P ($P = 0.003$) and Ca ($P = 0.002$) but reduced daily deposition of bone ($P = 0.004$), Ca ($P = 0.004$), and P ($P = 0.03$) compared with PhytM0. LCa diets decreased daily bone ($P < 0.001$), Ca ($P < 0.001$), and P deposition ($P < 0.001$) without affecting ATTD of P ($P = 0.75$). Pigs fed CCa-PhytM2000 diet had higher daily deposition of bone ($P = 0.02$), Ca ($P = 0.03$) and P ($P = 0.03$) than CCa-PhytM5000. However, the ATTD of P ($P = 0.71$) and Ca ($P = 0.12$) were similar between CCa-PhytM2000 and CCa-PhytM500 pigs. The regression analysis showed that whole-body BMC was strongly associated with femur BMC ($P < 0.001$) but not with metacarpal BMC ($P = 0.65$). Overall, the improvement in P and Ca digestibility with PhytM measured at 21 days was not reflected in Ca and P deposition for 21 days, because digestibility shows status at a specific point in time, whereas body composition reveals a cumulative effect. Accordingly, the current results showed that apparent digestibility does not consistently capture the true impact of PhytM on bone mineral accretion. These findings underline the need to combine digestibility measurements with physiological indicators or bone mineral responses to obtain a reliable evaluation. Additionally, this study emphasises the need to use a bone that is truly responsive to dietary strategy.

Nutritional Strategies to Enhance Phosphorus Utilization Efficiency in Pigs

N. Coquil[1,2], M. P. Létourneau-Montminy[1]
[1] University Laval, Sciences animals, 2425 Rue d'Agriculture, G1V0A6 Québec, Canada, [2] INRAE, MoSAR UMR, 22 Place de l'agronomie, 91120 Palaiseau, France

Optimizing phosphorus (P) nutrition in growing pigs is essential for improving the sustainability of the swine industry and the food system. Plant-derived phosphorus is the primary source of P in pig diets, with approximately 70% present as phytic P (PP). However, this form is largely indigestible for growing. Consequently, supplementation with inorganic phosphate sources is typically required to meet the animals' phosphorus requirements. The main feeding strategy to improve PP utilization is the inclusion of phytase in pig diets. With the high efficacy new generation of phytases, it is now possible to meet P requirements without the addition of inorganic phosphate sources, except during the early growth phase. Animals possess adaptive mechanisms to cope with certain mineral deficiencies, particularly P and calcium (Ca) by enhancing digestive utilization and increasing the efficiency of utilization of the limiting nutrient. This study aimed to evaluate the effects of different feeding strategies on growth performance, bone mineral content (BMC), and the efficiency of total P and digestible P (dP) utilization. To achieve this objective, two experiments were conducted in 2025 using pigs of the same genetic line and control diet. Animals had ad libitum access to water and feed meeting nutritional requirements of growing pigs (NRC, 2012), except for P and Ca. In experiment 1, 192 pigs (31.2 kg) were randomly allocated to 24 pens (6 pigs/pen) and received four dietary treatments across three phases (21, 28, and 28 d) until 130 kg: (1) NRC (85% maximal bone mineralization), (2) Control (Lautrou et al. (2020); 100% dP and Ca), (3) High (150% of treatment 2), and (4) Phytase (1,000 FTU; equivalent to treatment 2 in phase 1 and treatment 3 in phases 2–3 without phosphate). In experiment 2, 114 pigs (38.7 kg) were housed in pens of 12 and received either Control or Depletion (60% dP and Ca of treatment 2) across two phases (28d depletion, 56d repletion (fed with control feed)) until 130 kg. Eight pigs per treatment were scanned by Dual-X-ray (DXA) to determine BMC, which was converted to body P and Ca allowing to calculate the efficiency as P retained/P total or dP intake. The different feeding strategies did not affect average daily feed intake, average daily gain, or feed conversion ratio. However, daily BMC gain was higher in High (+25%) and Phytase (+26%) compared to Control ($P < 0.001$). This indicate that although body weight was not affected, BMC increased with higher dietary P and Ca levels. Total P utilization efficiency was influenced by feeding strategy ($P = 0.01$). The Phytase (55%) treatment showed better P utilization than the High (46%; $P < 0.001$), Depletion (49%; $P = 0.034$), and NRC (47%, $P < 0.001$), and tended to be higher than the Control diet (51%; $P = 0.07$). Feeding strategy also affected dP utilization efficiency ($P < 0.001$). The Depletion (90%) treatment showed greater efficiency than the Control (78%; $P < 0.001$), NRC (73%; $P < 0.001$), Phytase (68%; $P < 0.001$), and High (62%; $P < 0.001$), with significant differences observed among treatments. This indicate that depletion allow to retain more dP probably due to homeostasis mechanisms. Overall, this study demonstrates that growing pigs can be fed diets supplemented with phytase without the need for inorganic phosphate, achieving the highest total P utilization and, the lowest P excretion. The results also indicate that when dP is limited, pigs can partially compensate through adaptive regulatory mechanisms that enhance P utilization. Incorporating P utilization efficiency into feed formulation strategies could therefore offer both economic benefits and environmental advantages.

Valorization of native trace minerals in alternative feed ingredients for sustainable pig production

Phytase supplementation is widely used in pig nutrition to improve the availability of phosphorus (P) and trace minerals bound to phytate in plant-based feeds. While effective in grain-rich diets, its efficacy may differ in diets with inherently low phytate levels, such as those containing processed animal proteins (PAP). In such systems, relying solely on phytase may not provide sufficient P and trace minerals to meet piglet requirements. This study evaluated the effect of withdrawing inorganic phosphorus and trace mineral supplementation on mineral bioavailability and performance in PAP-based nursery diets. A total of 192 piglets (Pietrain × TN70), weaned at 21 days with an average body weight of 6.8 kg, were assigned to six dietary treatments with four pens of eight pigs per treatment. Diets differed in protein source (soybean meal, SBM, or PAP from black soldier fly meal) and in the inclusion of phytase and mineral supplementation (trace minerals + monocalcium phosphate) during the 4-week of trial. Treatments included SBM diets with (SBM+) or without mineral supplementation (SBM−), PAP diets with (PAP+) or without mineral supplementation (PAP−), and two PAP-based negative controls formulated without phytase (NC) or with mineral supplementation only (NC+minerals). Diets were formulated to be isoenergetic and isonitrogenous and produced by ILVO. Growth performance, fecal parameters, serum mineral concentrations, bone mineralization, and mineral retention were measured. Mineral supplementation significantly improved final body weight, average daily gain, feed intake, and feed efficiency ($P < 0.05$). Pigs fed PAP-based diets performed worse than those fed SBM-based diets, suggesting that assumed nutrient values may have overestimated the actual nutrient contribution of PAP ingredients. Phytase supplementation did not significantly affect growth performance. Within PAP diets, mineral supplementation significantly improved performance, whereas phytase alone did not compensate for the removal of minerals. Serum mineral concentrations were largely unaffected, although higher serum P levels were observed with mineral and phytase supplementation at the end of the trial. Phytase supplementation significantly increased bone crude ash, Zn, P, and Mg concentrations and improved Zn retention. However, positive effects of phytase on Zn retention were only observed when minerals were not supplemented. Overall, removing inorganic phosphorus and trace minerals from piglet diets negatively affected growth performance, mineral status, and mineral retention. While alternative protein sources such as PAP contribute to more sustainable pig production, the results highlight the importance of careful mineral nutrition strategies to avoid deficiencies when formulating low-phytate diets.

Terrestrial ecotoxicity and phosphorus excretion are reduced by increasing phytase and reducing nutrient concentrations in growing pig diets

G. Mota[1], B. Taynah[1], M. Souza[1], W. Sardi[1], G. Araújo[1], T. Cabral[1], B. Oliveira[1], R. Nunes[2], P. Pozza[1]
[1] State University of Maringá, Animal Science, Colombo Avenue, 5790, 87202900 Maringá, Brazil, [2] Western Paraná State University, Animal Science, Pernanbuco Street, 1777, 85960-000 Mchal Cândido Rondon, Brazil

Environmental impacts must be considered in pig production, and dietary phytase may be an alternative to mitigate some of them. In this context, the aim of this study was to evaluate increasing dietary phytase levels with the respective reductions in phosphorus (P), calcium (Ca) and standardized ileal digestible (SID) amino acid concentrations on the environmental impacts of growing pig production, assessed by life cycle assessment (LCA), as well as on P and nitrogen (N) excretion. Two experiments were conducted. In Experiment 1, Forty crossbred barrows (30.32 ± 0.88 kg initial body weight) were allotted in a randomized block design with four treatments and ten replicates to determine growth performance until 50 kg of body weight. In Experiment 2, twenty-four crossbred barrows (36.55 ± 2.16 kg initial body weight) were housed in metabolic cages and allotted in a randomized block design with four treatments, six replicates, and one animal per experimental unit to determine N and P balances in growing pigs. In both experiments, treatments consisted of diets containing four phytase levels (0, 250, 500, and 1000 FTU) with the respective reductions in P (0.357, 0.297, 0.237, and 0.117%), Ca (0.722, 0.662, 0.602, and 0.428%), SID lysine (0.007% per 250 FTU), SID methionine (0.004% per 250 FTU), SID threonine (0.004% per 250 FTU), SID valine (0.002% per 250 FTU), and SID tryptophan (0.001% per 250 FTU). Based on data obtained from Experiments 1 and 2, environmental impacts were calculated per kg of body weight gain using LCA, including global warming potential (GWP), acidification potential (AP), eutrophication potential (EP), cumulative energy demand (CED), terrestrial ecotoxicity (TE), and land occupation (LO). Data on N and P balance, as well as LCA-derived environmental impacts, were subjected to regression analysis when a significant effect was detected by ANOVA. Nitrogen excretion was not affected ($P > 0.05$) by dietary phytase inclusion. However, P excretions in feces ($P < 0.0001$) and urine ($P < 0.0001$) decreased linearly as phytase levels increased, resulting in a linear reduction in total P excretion ($P < 0.0001$). These results may reflect the linear decrease in P intake ($P = 0.0075$). However, the retained-to-intake P ratio improved ($P = 0.0007$) as phytase levels increased, demonstrating the effectiveness of phytase as a nutritional strategy. The LCA showed no differences for GWP ($P = 0.3501$), AP ($P = 0.2552$), EP ($P = 0.8556$), CED ($P = 0.8300$), or LO ($P = 0.5453$). However, increasing dietary phytase levels resulted in a linear reduction in TE ($P = 0.0001$), from 9.44 to 7.95 g 1,4-DBC-eq, indicating reduced adverse effects on soil ecosystems, microorganisms, plants, and fauna. In conclusion, increasing dietary phytase levels with the respective reductions in P, Ca, and SID amino acid concentrations reduced terrestrial ecotoxicity and phosphorus excretion, thereby mitigating some environmental impacts of growing pig production.

Comparative Analysis of Three Approaches for Estimating Phosphorus Retention in Growing Pigs: Implications for Phosphorus Excretion Estimates

K. R. Aklikokou[1,2], L. Cappelaere[1], F. Garcia-Launay[2], M. P. Létourneau-Montminy[1]
[1] Université Laval, Sciences animales, 2425 Rue de l'Agriculture, G1V0A6 Québec, Canada, [2] INRAE, UMR PEGASE, 16 Le Clos Domaine de La Prise, 35590 Saint-Gilles, France

Phosphorus (P) is essential for crops and animals, and its use must be optimized to support sustainable agriculture as it's a non-renewable resource. Dietary strategies have been developed to reduce P excretion in animal production, and large variations in both intake and excretion can occur without affecting growth performance. By accurately predicting P retention and excretion in pigs, it may be possible to tailor dietary strategies to match crop P requirements. Accurate estimation of P excretion in pig production depends especially on reliable predictions of body P retention. However, retention estimates change based on the method used to determine body P content. This study aimed to compare three approaches for estimating P retention in growing pigs and to assess their capacity to predict P excretion from known P intake. The experiment was conducted with 96 growing pigs allocated to a 2 × 2 factorial design crossing two levels of dietary nitrogen and phosphorus, resulting in four treatments. The experimental unit was the chamber (four pigs per chamber; n = 12 x 2 batches). Body composition was assessed using dual-energy X-ray absorptiometry (DXA). Two pigs per chamber were scanned and average lean and fat values were used to represent each chamber. Three approaches were compared at chamber level: (1) DXA, a DXA-based approach to estimate body P content and retention over the experimental period; (2) BodyComp, an approach based on tissue composition in Ca and P assuming a fixed protein and lipid body composition combined with prediction of Ca and P into bone and tissues, (3) Gain, an approach using a fixed coefficient of P retention per kg of body weight gain. For each method, P excretion was calculated as P intake minus P retention and compared with measured P in slurry. The capacity of prediction was assessed using R^2 and Mean Square Prediction Error (MSPE, %) which was decomposed into error of central tendency (ECT), error of regression (ER) and error of disturbance (ED). All methods showed high $R^2 = 0.83–0.90$ and low MSPE (below 5%). The DXA approach resulted in substantially lower MSPE (1.31%) compared with BodyComp (4.26%) and Gain (3.73%). The DXA error is mainly ED (46%) followed by ER (38%) suggesting a tendency to slightly underestimate P retention. The BodyComp approach error of prediction was mainly ECT (65%), indicating a systematic underestimation of retention. Finally, the Gain method showed 44% ECT and 31% ER. Despite not using DXA information, the BodyComp model achieved a same coefficient of determination (0.90) comparable to the DXA-based approach with an ECT that can be easily corrected. These results suggest that refining non-DXA approaches could improve predictive performance and support reliable large-scale estimations of P retention and excretion with growth performance information only. Refining this approach will allow the P supply to pigs to be adjusted to align with that of crops.

Pig gut microbiome functional genes associated with protein metabolism along the gastrointestinal tract

D. Lee[1,2], N. Sarpong[2], J. Seifert[1,2], A. Camarinha-Silva[1,2]
[1] Hohenheim Center for Livestock Microbiome Research (HoLMiR), University of Hohenheim, Leonore-Blosser-Reisen Weg 3, 70599 Stuttgart, Germany, [2] Institute of Animal Science, University of Hohenheim, Emil-Wolff-Str. 10, 70599 Stuttgart, Germany

The pig gut microbiome is involved in nutrient digestion, and its functional capacity changes along the gastrointestinal tract (GIT). Understanding how local microbial communities affect protein utilization is important for improving nitrogen use efficiency (NUE) in pig production. Studies using shotgun metagenomics to investigate the pig gut microbiome along the GIT are still limited. This study aimed to characterize gut microbiota composition and functional gene profiles, with a focus on peptidases, across GIT sections and to assess their association with protein digestion and fermentation in pigs. Forty-eight male pigs received a two-phase diet based on barley, wheat and soybean meal. During the main phase, digestible lysine covered 90% of the requirement to challenge protein utilization. At 21 weeks of age, pigs were euthanized and digesta were collected from stomach, small intestine, caecum and colon. Urinary and faecal nitrogen excretion and blood metabolites were measured and used together with digestible nitrogen intake to estimate NUE by multiple regression. Short- and branched-chain fatty acids and amino acids were quantified in digesta by NMR spectroscopy. Shotgun metagenomic sequencing (Illumina NovaSeq 6000) was performed on DNA extracted from digesta. Taxonomy was assigned with Kraken2. Metagenome-assembled genomes (MAGs) were reconstructed, and peptidase-encoding genes were identified by annotation against the MEROPS database. Gut microbial community structure differed between GIT sections. Bifidobacterium was most abundant in the small intestine, whereas Segatella dominated the large intestine. Lactobacillaceae was the most abundant family in all sections, and genus-level diversity was higher in the large intestine than in the stomach and small intestine. Predicted transcripts per million (TPM) of microbial peptidases were higher in the stomach and small intestine than in the large intestine. In total, 610 MAGs with completeness above 70% and contamination below 10% were recovered. Peptidase gene copy numbers were highest in Pantoea, Escherichia and Ralstonia. Streptococcus alactolyticus contributed strongly to extracellular peptidase S15, with increasing contribution from proximal to distal GIT sections. Volatile fatty acid concentrations increased in caecum and colon and showed a positive correlation with Bifidobacterium abundance. NUE was positively associated with several functional genes, and these associations differed by GIT section. This study describes the spatial organisation of the pig gut microbiome and its potential role in protein metabolism along the gastrointestinal tract.

Transcriptomic signatures of nitrogen use efficiency in liver and muscle of Swiss Large White pigs under protein-restricted feeding

B. Monney[1], C. Kasper[1]
[1] Agroscope, Animal GenoPhenomics, Tioleyre 4, 1725 Posieux, Switzerland

Improving nitrogen use efficiency (NUE) in pigs is an important strategy to reduce nitrogen emissions from livestock production while maintaining productivity. However, the molecular mechanisms underlying variation in NUE remain poorly understood. In this study, we investigated transcriptional differences between pigs with high and low NUE in two key metabolic tissues, liver and skeletal muscle. Animals were selected from a population of Swiss Large White pigs raised under a protein-restricted diet and phenotyped for NUE based on feed intake and carcass protein deposition measured using dual-energy X-ray absorptiometry. Individuals from both ends of the NUE distribution were targeted for RNA sequencing of liver and longissimus thoracis muscle. Differential expression analysis identified 177 genes in liver and 133 genes in muscle that differed between high- and low-NUE pigs. Functional enrichment analyses revealed that overrepresented and enriched pathways and ontologies in liver were predominantly associated with amino acid metabolism, nitrogen recycling and amino-acid catabolism, including pathways related to serine, glycine and cysteine metabolism. Several genes involved in inflammatory signalling and acute-phase responses were downregulated in high-NUE pigs, suggesting reduced allocation of nitrogen to immune processes. In muscle, pathways and ontologies were linked to nutrient partitioning, mitochondrial metabolism and protein turnover, including genes involved in lipid uptake, translation initiation and muscle growth pathways. Only one gene (SHMT2), involved in mitochondrial one-carbon metabolism, was differentially expressed in both tissues. Together, these results indicate that variation in NUE reflects coordinated, tissue-specific metabolic adaptations involving amino-acid metabolism, immune activity and nutrient partitioning. These findings provide new insights into the biological mechanisms underlying NUE and may help prioritize candidate genes for genomic selection aimed at reducing nitrogen emissions in pig production.

Phenotypes for implementing proxies of mineral utilisation and bone turnover in pig breeding

A. K. Solomon[1], M. Oster[1], H. Reyer[1], M. Scheeder[2], M. Leible[2], J. Massmann[3], K. Wimmers[1,4]
[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [2] SUISAG, Allmend 10, 6204 Sempach, Switzerland, [3] POROUS GmbH, Am Mühlenberg 11, 14476 Potsdam, Germany, [4] University of Rostock, Faculty of Agricultural, Civil and Environmental Engineering, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany

Phosphorus is an essential mineral for skeletal development in pigs; however, its utilization efficiency remains a challenge in modern pig production. Phosphorus and calcium homeostasis are regulated through complex physiological mechanisms involving absorption, retention, and excretion processes mediated by multiple sensing and regulating factors, including the parathyroid hormone (PTH), vitamin D, fibroblast growth factor 23 (FGF23), and the calcium-sensing receptor (CASR). Variability in these physiological pathways may result in measurable differences in circulating mineral concentrations and bone turnover markers. Increasing evidence suggests that part of this variability is genetically determined, influencing mineral absorption, bone mineral deposition, and remodeling activity. Therefore, phenotypes derived from serum mineral levels and biochemical markers of bone formation and resorption may serve as biologically meaningful proxies of mineral utilization efficiency. Understanding the genetic architecture underlying these indicators is essential to evaluate their suitability for incorporation into breeding programs aimed at improving skeletal health and nutrient efficiency. A recent Genome-Wide Association Study conducted by our research group identified genetic loci associated with circulating vitamin D metabolites and bone remodeling markers in Landrace pigs, highlighting genomic regions potentially contributing to bone integrity. This study aims to estimate the variability of phenotypic markers related to phosphorus homeostasis and bone integrity, identify candidate genes through genome-wide analysis as well as validate and integrate new phenotypes reflecting phosphorus utilization and bone integrity in breeding programs. In the first phase, phenotypic variability of serum traits and structural and functional bone properties was assessed to establish a representative sample panel of 160 performance-tested animals from seven pig breeds and commercial crossbreds. All tested traits showed a considerable variation. Overall mean serum concentrations of inorganic phosphorus and calcium were 11.10 mg/dL and 10.30 mg/dL, respectively, ranging from 7.90 to 14.60 mg/dL and 6.50 to 13.80 mg/dL. The bone remodeling markers, such as bone-specific alkaline phosphatase and C-terminal telopeptides of type I collagen also showed considerable variability, ranging from 25.06 to 81.17 µg/L and 0.09 and 0.69 ng/mL, respectively. Principal component analysis to select divergent animals for the development of an ultrasound-based bone assessment method showed major contributions from metacarpal bone circumference, inorganic phosphorus, and ß-CTX. The second phase will comprise 1,000 Swiss Large White pigs to integrate phenotypic and genomic datasets to develop selection tools for improved skeletal health and mineral efficiency. These results are expected to enhance phosphorus utilization efficiency and bone stability, thereby improving animal welfare and reducing the environmental impact of pig production. This work has received funding from the Federal Ministry of Research, Technology and Space (BMFTR) in Germany and Innosuisse – Swiss Innovation Agency in Switzerland – Project number 4908.

A mechanistic model to simulate the digestive fate of calcium and its interaction with phytate and phytase in growing pigs.

J. Labarre[1,2], P. Schmidely[2], A. Narcy[3], M. Jlali[4], P. Schlegel[5], C. Loncke[2], M. P. Létourneau-Montminy[1]
[1] Laval University, Department of Animal Sciences, 2425 rue de l'Agriculture, QC G1V 0A6 Québec, Canada, [2] INRAe, AgroParisTech, Université Paris-Saclay, UMR Modélisation Systémique appliqué aux Ruminants, 22 place de l'Agronomie, 91120 Palaiseau, France, [3] INRAe, Université de Tours, UMR Biologie des Oiseaux et Aviculture, INRAE Val de Loire Center,, 37380 Nouzilly, France, [4] Adisseo France S.A.S, European Laboratory of Innovation, Science and Expertise, 20 Rue Prosper Monnet, 69190 Sainte-Fons, France, [5] Agroscope, Swine Research Group, Route de la Tioleyre 4, 1725 Posieux, Switzerland

Calcium (Ca) plays a central role in growth, skeletal development and bone mineralization in growing pigs, but may be an antagonism to phosphorus (P) utilization. As its digestive fate is influenced by interactions with phytate and exogenous microbial phytase (PhytM), a deeper understanding of the mechanisms underlying Ca interaction with phytate degradation in the gastrointestinal tract could help maximising phytase efficacy. A mechanistic representation of Ca, and P fluxes along the intestine would also improve our understanding of the factors influencing their bioavailability and the extent to which phytase improves it. Modelling provides a framework to integrate existing knowledge and test hypotheses regarding the functioning of biological systems. The model simulates the process of Ca, P and phytic phosphorus (PP) digestion in the gastrointestinal tract of a growing pig. The stomach is considered as a single compartment well mixed in which solubilization of Ca and P forms and hydrolysis of PP by PhytM are represented. These fluxes are driven by transit time and pH, the latter being dynamically represented considering diet pH and acid binding capacity. To represent the interaction among Ca, P and Zn and the tubular structure of the small intestine (SI), SI is represented as a serie of repeated structural units referred to as segments. Each segment consists of 14 state variables representing mineral pools in soluble and insoluble forms. Insolubilization of PP in the SI is the driving force of formation of Ca-PP complexes considering that one mole of PP binds up 3 moles of Ca. Absorption of soluble Ca, P, and Zn from the intestinal lumen to the blood was assumed to occur via both saturable transporters and passive mechanisms. Model was evaluated using the predictions of the apparent digestibility (AD) of Ca, P and PP. Results were evaluated against independent literature data on apparent digestibility (5 studies; 29 dietary treatments for PP, 15 studies; 79 dietary treatments for Ca, and 22 studies; 111 dietary treatments for P). Only studies published after 2018 and focusing on the response to PhytM were considered. Model performance was assessed by calculating the root mean square prediction error (RMSPE, expressed as % of observed mean). The AD of PP (observed mean = 58 ± 34 vs. predicted mean = 63 ± 33 %, RMSPE = 11.8 %) and P (57 ± 17 vs. 63 ± 16 %, RMSPE = 21.2 %) were slightly over-predicted, whereas Ca AD was slightly under-predicted (63 ± 15 vs. 60 ± 11 %, RMSPE = 18.3 %). The simulated dose–response to PhytM indicated that supplementation with 300, 500, 1000, 2000, and 4000 FTU/kg released 0.7, 0.8, 1.5, 1.8, and 2.0 g of total Ca, respectively, assuming a Ca digestibility coefficient of 60%. The proposed model helps identifying key drivers of Ca-phytate interactions, phytate degradation and Ca and P absorption. The model provides a basis for future integration with post-absorptive metabolism to account for mineral homeostasis and homeorhetic regulation.

Meta-analysis of urinary calcium and phosphorus excretion as predictors of mineral status and dietary imbalances in growing pigs

P. Floradin[1], M. P. Létourneau-Montminy[1]
[1] Laval University, Department of Animal Sciences, 2425 Rue de l'Agriculture, G1V0A6 Quebec, Canada

Kidneys are major regulators of calcium (Ca) and phosphorus (P) homeostasis by excreting the excess of absorbed minerals over effective retention in the body. As a result, urinary excretion of Ca and P, as well as their ratio, have been proposed as non-invasive indicators of mineral status. However, the large variability observed in urinary mineral excretion in pigs highlights the need to better quantify the nutritional factors modulating these responses. The objective of this meta-analysis was to assess the impact of dietary Ca, standardized total tract digestible P (STTD P) levels, and microbial phytase (Phytm) on urinary excretion of Ca, P, and their ratio. Sixty-five papers published between 1974 and 2025, including 70 experiments with 390 treatments, in which total daily urinary mineral losses were measured, were included in this study. Pigs body weight varied from 6 to 60 kg. Dietary STTD P and Ca were recalculated based on NRC (2012) feedstuff tables and were expressed in % of requirements using NRC (2012). All statistical analyses were carried out using GLM procedure of Minitab software, including experiments as a fixed effect. Results showed that urine Ca increased linearly ($P < 0.001$) and quadratically ($P < 0.001$) when dietary Ca increased. However, the losses of Ca in urine are influenced by STTD P (STTD P, STTDP x STTD P, STTD P x Ca, $P < 0.001$); when STTD P is below the requirement, increasing Ca results in higher losses because Ca cannot be deposited into bone. Urinary P excretion increased only quadratically ($P < 0.001$), showing really low losses below STTD P requirements, which increased with dietary STTD P due to excess for retention into bone and especially when Ca is below requirement (Ca x Ca, Ca x STTD P, $P < 0.001$) because of a lack of Ca to retain P into bone. Results showed that at low STTD P, urinary P is negligible and increases rapidly once requirements are met. Urinary Ca increased linearly with dietary Ca but then reached a plateau and subsequently decreased when Ca intake exceeded requirements, suggesting the formation of insoluble complexes that reduce Ca absorption. The Ca:P ratio in urine increased linearly ($P < 0.001$) and quadratically ($P < 0.001$) when dietary Ca increased and decreased linearly when increasing STTD P ($P < 0.001$), especially when STTD P is below the requirement (Ca x STTD P, $P < 0.001$). Increasing phytase decreases the Ca:P ratio in urine ($P < 0.001$). The highest ratios were obtained in pigs fed below STTD P requirements while the Ca requirement was fulfilled. These findings confirm that urinary mineral concentrations depend on the balance of the supply of dietary Ca and STTD P, as well as phytase supplementation. The information generated will be useful in ensuring that growing pigs receive adequate levels of Ca and STTD P, which are essential for proper bone development and the optimization of P utilization.

Health and management of unweaned calves on conventional and regenerative dairy farms

E. Bokkers[1], J. Threels[1], F. Braakhuis[1], E. De Olde[1]
[1] Wageningen University, Animal Production Systems, P.O. Box 338, 6700AH Wageningen, Netherlands

Regenerative agriculture aims to increase soil health and biodiversity, enhance ecosystem services, and contribute to a more sustainable food production. In dairy farming regenerative practices include for example maintaining species rich grassland, sowing mixed herbal leys (mixture of grass, legumes, and herbs), applying solid manure and not using artificial fertilizers, limiting the amount of external feed input, and applying rotational grazing. Regenerative practices are also expected to improve animal welfare, including a positive effect on calf health. However, it is unknown whether these calves are managed differently than calves on conventional farms, and to date no studies have been conducted to assess the health of calves on such farms. The aim of this study was therefore to map calf management and living conditions and to assess the health of unweaned calves on regenerative and conventional dairy farms. Eight conventional and eight regenerative (of which six organic) Dutch dairy farms (mean ± standard deviation: 152 ± 70 versus 79 ± 38 calves born per year), which voluntarily participated in this study, were visited in the autumn of 2025. Farmers were first interviewed about calf management, whereafter unweaned calves were assessed for seven animal-based clinical health indicators, with a simple 'yes' or 'no' abnormality observed, using a predefined protocol. Additionally, four environmental elements were assessed for cleanliness. Calves were housed individually or in groups. Numerical data were analysed with Mann-Whitney-Wilcoxen test, whereas observed frequencies of animal (individual level) and environmental-based data (pen level) were analysed with either Chi-square or Fisher exact test. The conventional farms had a median of 16.5 (range 9-23) unweaned calves and the regenerative farms of 11 (range 4-20) either in individual (68 vs. 38 calves) or group housing (65 vs. 53 calves). Two conventional and 7 regenerative farms fed whole milk (5.7±1.1 L/calf/d), the others fed milk replacer (7.2±1.6 L/calf/d; $P<0.05$). Calves in individual housing had less space on conventional farms than on regenerative farms (1.5±0.4 vs. 3.5±1.4 m^2; $P<0.05$), whereas no difference was found for group housing (on average 4.3±2.7 m^2 /calf). Preliminary results showed a farm effect for all clinical health indicators. Nasal discharge was found less on conventional than regenerative farms (0.8% vs. 5.6%; $P<0.05$), and calves tended to be less responsive on conventional farms than on regenerative farms (12.1% vs. 4.5%; $P=0.05$). No statistical differences between the two systems were found for cleanliness of carpal joints, diarrhea, hairless spots, ocular discharge and lesions (average over both systems: 15.6%, 15.9%, 12.0%, 9.4%, 3.4% of the calves). Calf mortality (6.1%), calf weaning age (10 weeks) and cow replacement rate (29%) were also similar for both systems. With respect to cleanliness of environmental elements, conventional farms tended to have more dirty feeding troughs (52.3 vs. 25.0%; $P=0.06$) and milk feeding equipment (71.7 vs. 54.8%; $P=0.09$) than regenerative farms. No difference was found for cleanliness of drinking water facilities and of the floor within the pens (on average over both systems 67.8% and 49.7% was clean). Based on the limited number of farms included in this study, it seems that the variation in calf health and management is larger within than between the conventional and regenerative systems.

Implications of birth order on piglet survival

R. Muns[1], C. Mulvenna[1]
[1] Agri-Food and Biosciences Institute (AFBI), Large Park, BT26 6DR Hillsborough, United Kingdom

Larger litter size usually results in longer farrowing duration which is often linked to piglets suffering from asphyxia during birth, compromising their viability. We assessed the relationship of birth order with key pig viability indicators: birth weight, 24-hour growth (as a proxy for colostrum intake) and survival. We hypothesised that pigs born later in the farrowing process would have higher mortality and lower early growth. We collated data from five studies in which we recorded birth order (n=2016), birth weight (n=2016), weight at 24 hours (n=1960) and at weaning (28 days, n=1792), rectal temperature (RT) at 24 hours (n=1186), survival/mortality (n=2016). All sows (n=141) were Landrace x Large White and all the studies were conducted in our pig research farm, in the same facilities and under similar management. Based on their birth order, we classified piglets as 'Early' (pig born 1st to 5th), 'Middle' (born 6th to 10th) and 'Late' (born ≥11th). Based on their survival, we classified piglets as 'Stillbirth' (died during farrowing), 'Early death' (died within 24h), 'Late death' (died before weaning), 'Post-weaning death' (died after weaning) and 'Alive' (survived the rearing period). Statistical analysis was done in Genstat (Version 24.1). For weight at birth, 24h and weaning, RT at 24h, birth-24h growth, 24h-Wean growth, separate two-way ANOVA was conducted with birth order and live status as main effects. Statistical significance was determined if P<0.05. Birth weight of piglets did not differ based on birth order (av. 1.33 ± 0.018kg, P>0.05) nor did weight at 24h (av. 1.40 ± 0.021kg, P>0.05) or at weaning (av. 8.11 ± 0.110kg, P>0.05). However, body weight gain in the first 24 h was higher in 'Early' compared to 'Late' piglets, but no different to 'Middle' piglets (0.073a, 0.054ab, 0.048b ± 0.0065 kg; respectively, P<0.001). There was no birth order effect on RT at 24h (av. 37.7 ± 0.06ºC, P>0.05). Overall survival for 'Early', 'Middle' and 'Late' piglets was 83%, 85% and 77%; respectively. 'Alive' piglets had higher weight at birth (1.38 vs. 1.11 ± 0.031kg, P<0.001), weight at 24 h (1.45 vs. 1.12 ± 0.038kg, P<0.001) and RT at 24 h (37.71 vs. 37.06 ± 0.066ºC, P<0.001) than piglets that did not survive. Among the piglets that didn't survive, 'Post-weaning death' were heavier than 'late death' piglets (1.216 vs. 1.054 ± 0.0528 kg, P<0.05), but no other differences were observed. On average, both 'Early death' and 'Late death' piglets lost weight during the first 24h (-0.035 and -0.009 kg, respectively), being significantly lower (P<0.001) than 'Post-weaning death' and 'Alive' pigs (0.060 and 0.069 kg, respectively). When we investigated the distribution of mortality across 'Early', 'Middle' and 'Late' born piglets, Stillbirths were 0.8%, 1.5% and 5.2%; 'Early death' was 4.1%, 2.6% and 7.5%; 'Late death' was 7.9%, 7.6% and 7.1%; and 'Post-weaning death' was 4.2%, 4.6% and 3.3%; respectively. Birth order had no relationship with birth weight although birth weight was related with survival, with pigs that died having lower weight at birth. Although not significant, piglets born 'Late' had 6 to 8% less overall survival rate. Birth order was related with body weight gain in the first 24 h, suggesting that piglets born 'Early' have higher colostrum intake. Meanwhile, piglets that died after farrowing and during lactation had little to no weight gain in the first 24h. Longer time spent in the birth canal and reduced colostrum intake could explain the higher values in stillbirth and early deaths observed among pigs born 'Late' in the farrowing process.

Risk factors in fattening rabbit housing: The role of animal density and bedding

S. Cazzato[1], S. Gebhardt-Henrich[2,3], H. Würbel[3], D. Wiederkehr[4], J. Schwarz[1]
[1] Bern University of Applied Sciences, School of Agricultural, Forest and Food Sciences, Länggasse 85, 3052 Zollikofen, Switzerland, [2] , Veterinary Public Health Institute, University of Bern, Center for Proper Housing: Poultry and Rabbits, Burgerweg 22, 3052 Zollikofen, Switzerland, [3] Veterinary Public Health Institute, University of Bern, Animal Welfare Division, Länggassstrasse 120, 3012 Bern, Switzerland, [4] Small Ruminant Health and Advisory Service, Industriestrasse 9, 3362 Niederönz, Switzerland

Large scale rabbit meat production is very demanding, and animal losses are a major problem in Switzerland, despite high husbandry standards. Some Swiss animal welfare labels as well as the public demand group housing and environmental enrichment including adequate bedding. However, group housing and bedding may increase animal dirtiness and infection risk. The type of bedding can affect hygiene, ammonia levels and mortality and should therefore be carefully considered. Animal density plays a critical role, as increasing density may improve economic efficiency, yet it simultaneously elevates pathogen pressure and the potential for disease spread. This experimental study was aimed at gaining a better understanding of how bedding type and animal density influence disease and mortality in group housed fattening rabbits in view of improving their health and wellbeing and reducing medication (especially antibiotics) while complying with Swiss animal welfare labels. We hypothesized that bedding type and animal density interact and that wood shavings and lower density lead to better health and lower mortality compared to straw and higher density. To this end, the 2 most popular bedding materials, straw and wood shavings were tested across 3 population densities in a completely crossed design on health and performance parameters of fatteners. For this, the maximum density allowed by the Swiss animal welfare ordinance (0.15 m²/animal) with 25 animals per pen, the maximum density allowed by the label IP-Suisse (0.25m²/animal) with 15 animals per pen, and a lower density (0.39 m²/animal) with 10 animals per pen were compared. Three trials with 2 groups of each of the 6 different treatment combinations were conducted, resulting in 12 groups per trial and 6 groups per treatment combination. Data was collected according to predefined protocols and analyzed using R. Survival analysis was applied to assess mortality, mixed-effects models were used for slaughter weight and weight gain, ammonia levels were compared using a t-test, and a generalized linear model was fitted for carcass section outcomes. The results showed no differences in mortality between the groups, with rates within the expected range according to the national average. Weight gain and slaughter weight were increased in groups of 10 animals compared to groups of 25 animals. Ammonia levels did not differ, but visual inspection of bedding material indicated that wood shavings were associated with lower moisture levels and reduced mold formation. Necropsy revealed that the intestines were more affected than the lungs, regardless of the group. However, bedding type influenced the extent to which the lungs were affected compared to the intestines, with straw having a worse impact on the lungs. These findings suggest that, within the tested density range, stocking density may not be a critical factor for survival, while other management or environmental factors may be more important. However, they indicate that stocking density and litter quality may affect the clinical condition of the animals and contribute to the cause of mortality, while wood shavings may help maintain a drier and less harmful microenvironment compared to straw. Furthermore, animals housed at lower densities may achieve a higher final weight.

Effect of group housing on behaviour and welfare of rabbit does in Mediterranean farming conditions

C. L. Manuelian[1], K. Guirrati[1], A. Torra[1], A. A. K. Salama[1], X. Such[1], J. L. Ruiz De La Torre[1], C. Casas[2], F. X. Mora[1]
[1] Universitat Autònoma de Barcelona, Dep. of Animal and Food Sciences, Campus UAB Bellaterra, 08193 Cerdanyola del Vallès, Spain, [2] Granja Riera, Granja Riera, 8480 L'Atmella del Vallès, Spain

New EU regulation on rabbit farming will likely establish group-housing requirements for growing rabbits to improve animal welfare. However, its applicability to rabbit does remains uncertain, particularly under Mediterranean farming conditions. Part-time group housing has been associated with chronic stress, increased aggression, and injuries in does. Moreover, part-time group housing is labor-intensive, which may limit its practical adoption by farmers. The study evaluates the feasibility of full-time group housing for rabbit does at 4, 6, or 8 does/group, and assesses the impact of group establishment timing (mid-gestation or during rearing). Three experimental blocks of 20 nulliparous does were used. In Block 1, does were divided into 3 groups formed at mid-gestation: G1 (8 individual does), G4 (4 does/group), and G8 (8 does/group). In Blocks 2 and 3, does were divided into one G1 group and two G6 groups (6 does/group), formed during rearing. Blocks 1 and 2 were inseminated, whereas Block 3 used natural mating. "A" and "B" refer to insemination events. Weekly welfare assessments included skin injury scores (0=no wounds to 3=bleeding wounds), presence of hairless areas (≥2 cm), and pododermatitis degree (0=healthy pad to 4=open wound). Ear wounds were recorded when >2 cm. Behavior was evaluated daily using 5-min focal sampling of the group, 3 times/d. Group fertility was calculated as (number of births/number of inseminations × 100). Data were analyzed using Kruskal-Wallis test for ordinal variables and the Chi-squared or Fisher's exact test for categorical variables. In G1, fewer injuries were detected than in group housing ($P<0.05$), but stereotypies (cage biting, scratching at the feeder, pulling hair) were observed ($P<0.05$). In G4, does presented moderate injuries (score 1), which healed quickly without intervention; fights occurred sporadically, mainly causing minor ear-tip wounds. In G8, fight frequency and intensity increased over time ($P<0.05$), causing severe ear wounds (score 3) in 2 rabbit does, which required ending the experimental block. In G6 (formed during rearing), rabbit does showed more affiliative behaviors (body contact, nose-body contact, sniffing, nose-to-nose contact, grooming, and sleeping together) than G4 and G8 ($P<0.05$). Only one G6 group displayed agonistic behaviors requiring the separation of 2 does. Stereotypes were not recorded in any group-housing treatment. In all group-housing groups displayed some agonistic behaviors (chasing each other, biting). Fertility was similar among experimental groups within blocks and insemination/mating event (Block 1A, 80%; Block 2A, 50%;Block 2B, 62%; Block 3A, 83%), except for the second insemination in Block 1, where individual cages had a greater fertility (100%) than group-housing (0% and 12.5%; $P<0.001$). Natural mating resulted in higher fertility (82%) than insemination (58%; $P=0.021$). In both G8 and G6, two does shared a nest without triggering aggression or reducing kit survival, and the number of kits weaned did not differ among blocks (Block 1, 8±1.5; Block 2, 10±1.1; Block 3, 11±0.89; $P>0.05$). In conclusion, forming stable groups during rearing promotes better socialization, reduced aggression, and increases affiliative behaviors, thereby improving welfare and potentially fertility. Fertility is also improved by natural mating. Nest sharing was not problematic, although nest-box dimensions warrant reconsideration. A group of 6 does (0.4 m²/doe) appears suitable for maintaining good welfare, although further studies are needed.

Effects of housing and management strategies on productivity and welfare of young rabbit does

M. Molin[1], F. Bordignon[1], M. Pravato[1], A. Zuffellato[2], A. Trocino[1,3], G. Xiccato[1]

Agricola Italiana Alimentare S.p.A, Piazzale Apollinare Veronesi 1, 37036 San Martino Buon Albergo (VR), Italy, [3] University of Padova, Department of Comparative Biomedicine and Food Science (BCA), Viale dell'Università, 16, 35020 Legnaro (PD), Italy

Under standard farming practices, crossbred young rabbit females replacing culled does are moved to the farm between 10 and 14 weeks of age and housed in individual cages. During the rearing period, young females are fed commercial diets characterised by moderate energy and high fibre concentrations, like those administered to growing rabbits during the post-weaning period, and then mated for the first time at 18–20 weeks of age. Few studies have evaluated the effects of the diet and the age at first insemination on the live weight at insemination and reproductive performance during the first pregnancy and kindling. In addition, in a context where public opinion and European legislation promote group housing of both growing and reproducing rabbits, the effects of group housing on the welfare of young nulliparous does need to be explored. Thus, this study evaluated the effects of housing (single vs. paired), age at first insemination (19 vs. 21 weeks), and diet (F, high fibre vs. S, high starch) in 192 crossbred rabbit does (Hyplus Grimaud Frère) allocated at 14 weeks of age to eight experimental groups in a 2 × 2 × 2 factorial arrangement (2 group size × 2 ages × 2 diets). The diet F was characterised by 24.5% ADF and 5.7% starch, whereas the diet S by 21.0% ADF and 8.4% starch. During the 7 weeks of growth, housing in pair reduced body weight at the first insemination (−4.7%; P<0.01), daily growth rate (−21%; P<0.001), and feed efficiency (−20%; P<0.001). Fertility rate was lower in rabbits housed in pair (74.7% vs. 86.3%; P<0.05), while weight gain during pregnancy (222 vs. 65 g; P<0.001) and live-born kit weight (59.3 vs. 55.3 g; P<0.05) were higher. Delaying first insemination from 19 to 21 weeks increased doe body weight at first insemination (+5.4%; P<0.001) and fertility rate (74.4% vs. 86.6%; P<0.05). During pregnancy, weight gain (243 vs. 46 g; P<0.001) and feed intake (−8.9%; P<0.001) were lower in does inseminated at 21 weeks of age compared to 19 weeks. The age at insemination did not affect lesion frequency and severity in pair-housed young does. Diet S enhanced daily growth rate (+18%; P<0.01) and improved feed efficiency (+25%; P<0.001) from housing to the first insemination compared to diet F. Conversely, the same diet S reduced feed intake during pregnancy (−6.9%; P<0.001) and the total weight of kits born alive (−11%; P<0.05) in comparison with diet F. In conclusion, pair housing of young does proved disadvantageous for both productivity and fertility. In contrast, delaying first insemination from 19 to 21 weeks increased fertility without negatively affecting growth performance, feed intake, and lesion occurrence in pair-housed young does. The administration of a diet richer in starch improved growth and feed efficiency, but decreased the weight of litter at kindling, without affecting doe fertility. Acute ammonia concentration peaks present a delayed effect on reproductive and productive performance of rabbit does

A. Villagrá García[1], S. Calvet Sanz[2], J. Sahuquillo[2], F. Estelles Barber[2]
[1] Instituto Valenciano de Investigaciones Agrarias, CITA-IVIA, Poligono La Esperanza, 100, 12400 Segorbe, Spain, [2] Universitat Politecnica de Valencia, ICTA, Camino de Vera s/n, 46022 Valencia, Spain

Intensive rabbit production under Mediterranean relies on highly environmental controlled buildings, thus being very sensitive to ventilation misfunctions. Ammonia (NH_3) is a key contaminant in livestock buildings and concentrations above 8–10 ppm are considered detrimental for animal health. The objective of this study was to quantify both immediate and delayed effects of an acute NH_3 peak on reproductive and productive parameters in a commercial rabbit farm. In this work, environmental variables were continuously monitored in a semi-intensive rabbit house equipped with mechanical ventilation and evaporative cooling. In July 2023, a short-term reduction in ventilation was produced due to a power failure. Consequently, NH_3 concentration increased from baseline values of approximately 4 ppm to average levels of 29 ppm, with short transient peaks reaching 58.85 ppm. Indoor temperature rose moderately from 25.5 to 29 ºC, while relative humidity remained high (around 90%), within the typical summer range for Mediterranean production systems. Then, several productive parameters were evaluated, both during the failure and during the following 6 weeks, including mating acceptance, fertility (positive palpation at day 12), abortion rate, stillborn percentage and mortality at weaning. Logistic regression was applied to dichotomous variables and T-tests to continuous outcomes. Fertility and abortion rate were not significantly affected by the NH_3 episode. However, significant alterations were observed in mating behaviour ($P<0.05$) and offspring viability ($P<0.01$). Does mated during the week following the NH_3 peak showed a clear reduction in mating acceptance, indicating a short-term carry-over effect after environmental restoration. A marked increase in stillborn rate was detected in litters born during days of elevated NH_3 concentration or immediately afterwards, reaching 42.5% in parturitions occurring just after the peak. Furthermore, a second increase in stillborn kits was observed at the end of August, corresponding to does mated during the NH_3 peak, suggesting impaired implantation or early embryonic development. This pattern indicates a delayed reproductive effect associated with exposure during the peri-implantation period. Mortality at weaning did not increase in kits weaned immediately after the episode. Nevertheless, a pronounced rise was recorded in animals that were six days old at the time of the NH_3 peak and in offspring from does mated shortly before or after the event, indicating increased vulnerability linked to early-life exposure and early gestational stress. These results demonstrate that short-term ventilation failures during summer conditions, such as those caused by brief power outages, may generate acute NH_3 peaks that do not necessarily affect fertility but can induce both immediate and delayed effects on implantation success, stillbirth rate and early kit survival.

Selected best practices for improving on farm welfare of rabbits: interrelationships with sustainability pillars

C. Tolini[1,2], A. Miolo[2], S. Rota Nodari[1], Z. Sudiak[3], G. Aubin-Houzelstein[4], F. Bordignon[2], M. C. Ceballos[5], E. Fàbrega[6], G. Xiccato[2], F. Fusi[1], A. Trocino[2]

Bianchi, 9, 25124 Brescia, Italy, [2] University of Padua, Viale dell'Università, 16, 35020 Legnaro, Italy, [3] NRIAP, Sarego Street, 2, 31-047 Kraków, Poland, [4] INRAE, CNR, BEA, UAR CODIR, 75338 Paris, France, [5] University of Calgary, University Drive NW, 2500 T2N 1N4 Calgary Alberta, Canada, [6] IRTA, Torre Marimon Caldes de Montbui, 08140 Barcelona, Spain

Improving welfare and sustainability in rabbit farming is crucial to ensuring the future of this sector. However, to date, there is no structured knowledge linking welfare and rabbit farm sustainability. One of the key actions of the European Partnership for Animal Health and Welfare (EUPAW) is to review and identify best practices that enhance animal welfare. Then, the process has considered to evaluate how these practices interact—both positively (synergies) and negatively (trade-offs)—with the three pillars of sustainability: environmental (EV), economic (EC), and social (SO). To achieve this, dedicated working groups have been established for each major farm animal species, including rabbits. A scoping review of the available scientific literature was then performed using pre-selected string searches in Web of Science and Scopus for selected BP (tot=14, 9 on-farm, 4 during transport). The search was combined with a set of keywords related to sustainability, agreed upon and shared with all working groups and focusing on kits, growing rabbits and reproducing does as production categories. The aim was to identify both available knowledge and gaps in existing literature. All stages of the work were conducted in accordance with a Standard Operating Procedure (SOP) to ensure consistency and uniformity across the different species-specific research teams. The results were then collected and screened to exclude papers that were not relevant according to the SOP, as well as reviews and mini-reviews. The information contained in the remaining articles was extracted and cataloged to gather existing evidence on the relationship between the selected BP and each sustainability pillar. In this context, the methods employed to conduct the scoping review have been described, with preliminary results to be presented subsequently. As for rabbits, each BP will be introduced separately and the extracted information from each sustainability pillar will be discussed both in view of direct and indirect relationships with the BP. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW.

On-farm hatching in broiler production: Field experiences with slow- and fast-growing genotypes in Germany

B. Spindler[1], S. C. M. Vossler[1], S. Schäfers[1], J. Heck[2], M. C. Bosello[2], E. Rauch[2], H. Louton[2,4], P. Hiller[3], F. Dietzel[4], N. Kemper[1], A. Schwarz[1]

[1] Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour (ITTN, University of Veterinary Medicine Hannover, Foundation, Bischofsholer Dam 15, 30173 Hannover, Germany, [2] Chair of Animal Welfare, Ethology, Animal Hygiene and Husbandry, Veterinary Faculty, LMU Munich, Ludwig-Maximilians-Universität München Veterinärstr. 13/R, 80539 Munich, Germany, [3] Department 3.7. Research Livestock, Chamber of Agriculture Lower Saxony, Mars-la-Tour-Str. 6, 26121 Oldenburg, Germany, [4] Professorship for Animal Welfare and Animal Health, Faculty of Agriculture, Civil and Environmental Engineering, University of Rostock, Justus-von-Liebig-Weg 6b, 18059 Rostock, Germany

On-farm hatching is an alternative hatching method where the hatching eggs are brought to the broiler house on approximately the 18th day of incubation and the chicks hatch between day 19 and 20. The chicks have direct access to feed and water, and there is no need for handling the chicks in the hatchery (for example separating from the eggshells, conveyor belts, packing in boxes) nor transportation. Furthermore, the chicks hatched in this way do not have to get used to a new housing environment, and possible temperature fluctuations from the hatchery through handling and transport to the broiler house are avoided, too. The aim of this practical study was to investigate the effects of on-farm hatching on animal health and welfare in fast and slow-growing broiler genetics. The investigations of chicks hatched on farm (OH) and in the hatchery (HH) took place on seven commercial farms; each farm raised OH and HH chicks in different houses at the same time. Four of these farms kept fast-growing broiler chickens (FG) (Ross 308 and Cobb 500) and three kept slow-growing genetics (SG) (Ranger Classic, Hubbard 757, and Hub-JA-Coloryield 57 Brown). A total of 52 OH fattening runs (37 FG and 15 SG) and 41 HH runs (26 FG and 15 SG) were monitored. In addition to performance parameters (hatchability, weight development, mortality), chick quality (Pasgar scores with evaluation of navel, beak, legs, belly, and reflexes; with a score of 5-10, where 5 indicates poor chick quality and 10 indicates chicks with no findings) on day 1, as well as antibiotic use were assessed. The results for hatching rate for OH-chicken (OH: 84.9% ±7.5 and HH: 84.0% ± 8.8), 7- day mortality (FG: 1.60% ±1.62 OH vs 0.74% ±0.84 HH and SG: 1.16% ±0.98 OH vs. 1.16% ±0.72 HH) and total mortality (FG: 3.31% ±2.18 OH vs. 2.55% ±1.70 HH and SG: 2.91% ±1.29 OH vs. 2.79% ±1.25 HH) for both slow- and fast-growing genetics were comparable to the chicks hatched in the hatchery (all $p>0.05$). OH-chicken were significantly havier on d 1 (FG: 58,7g ±12,0 OH vs. 55,5g ±11,6 HH and SG: 51,2g ±7,2 OH vs. 49,8g ±5,7HH) ($p<0,001$) but had lowerchick quality (FG: 8.91±0.90 OH vs. 9.21 ± 0.86 HH and SG: 9.48 ± 0.67 OH vs. 9.72 ± 0.50 HH) ($p< 0,001$). The frequency of antibiotic treatment between the hatching forms (OH 13.3% vs. HH 13.3%) in SG was lower than in FG (OH 89.2% vs. HH 92.3%), with a tendency to more antibiotic use in FG for HH-chicken. The field study show that on farm hatching can be an alternative to conventional hatching in the hatchery for fast and slow-growing broilers without adverse effects on production and health parameters. The effect of on-farm hatching on the stress levels of the animals is the subject of further investigation. This work (Model- and Demonstration Project for animal welfare) is financially supported by the Federal Ministry Agriculture, food and Regional Identity based on a decision of the Parliament of the Federal Republic of Germany, granted by the Federal Office for Agriculture and Food (FKZ: 2820MDT240).

Minimal evidence for locomotor imitation in pullets: Insights from a ramp vs. jump two-action procedure

K. Walsh[1], L. Nicklas[1], B. Tobalske[2], E. Planchon[1], N. Van Staaveren[1], D. Powers[3], T. Widowski[1], B. Willie[4], A. Harlander[1]

[1] University of Guelph, Campbell Centre for the Study of Animal Welfare, 50 Stone Rd East, N1G2W1 Guelph, Canada, [2] University of Montana, 32 Campus Drive, 59812 Missoula, United States, [3] George Fox University, 414 N. Meridian St., 97132 Newberg, United States, [4] Utah State University, 0100 Old Main Hill, 84322-0100 Logan, United States

Social learning can shape foraging and resource use in chickens, but the evidence for copying specific locomotor actions is limited. We used a two-action procedure (ramp vs. jump) to examine if pullets copy an observed ascent method demonstrated by same-age birds when both options provide access to a platform with rewards. This approach was intended to assess action matching while limiting alternative mechanisms such as social facilitation and local/stimulus enhancement. Observer pullets were assigned to one of three treatment contexts: 1. Trained demonstrator (conspecifics trained to ascend via ramp-left, ramp-right, jump-left, or jump-right), 2. Untrained demonstrator (arena acclimated but untrained, free to choose ramp or jump), and 3. No demonstrator. Day-old white-feathered female chicks (n=48) were housed in six floor pens (12 birds/pen) with a 15 cm high, 150 cm long perch and water drinker lines positioned at bird eye-height, but no other elevated structures. Prior to testing, all chicks were familiarized with the test arena to reduce novelty effects. At 7 weeks of age, birds viewed the assigned context on 5 consecutive observation days in a test arena with a start box, a 40 cm high platform, and a 15 cm wide, 65 cm long ramp set to 50°. This set-up ensured ramp use and jumping were comparable in potential energy gain and likely to involve wing use. Before each session, observers were individually shown and allowed to consume a high-value reward (sweet corn, raisin, mealworm mix) and to join their conspecifics in a crate (social attraction). On day 5 of observations, each observer was tested individually: the same luxury reward/social attraction was shown beforehand, birds were released from the start box and given 5 minutes to reach the platform via ramp use or jumping while the food reward and conspecifics were present on the platform. Data were analyzed using a generalized linear mixed model (SAS), with demonstrator treatment as a fixed effect and pen as a random effect. Fisher's exact test was used for sparse sub-groups. Out of 48 pullets 19 reached the platform (39.6%). Of the birds that reached the platform; 45.7% had no demonstrator, 37.5% trained demonstrator, and 37.5% untrained demonstrator, with treatment having no effect on platform reaching ($p = 0.8843$). Thus, most pullets did not reach the platform, and demonstrator exposure had no overall effect. Few birds jumped to reach the platform (2/19; 10.5%). Pullets that observed a trained demonstrator ($n = 12$) could choose to copy the ascent method shown. While jumping was rare, observing a trained ramp demonstrator led to more pullets copying ramp use ($p = 0.0101$). This suggests copying within this subgroup, but the effect is limited in scope and sample size as only 5/48 (10.4%) reached the platform and matched the trained demonstrator's method showing minimal locomotor imitation under the present conditions. This indicates that young pullets primarily rely on individual learning when tasks are readily discoverable. When copying occurs, it emerges only in the lower-risk ramp action suggesting that individual exploration, not same-age demonstration, is the dominant mechanism shaping how young birds learn to navigate 3-D space.

Opinion of the FRCAW on the impacts of loading density on fall and injury risks in cattle and pigs, and on piling-up behaviour and injury risks in poultry

C. Bezançon[1], L. Kremer[1], V. Colson[1], A. L. Dauphiné-Morer[1], A. Tiret[1], Frcaw Panel Of Experts[1], G. Aubin-Houzelstein[1]

[1] INRAE, UAR CODIR, French Reference Centre for Animal Welfare (FRCAW-CNR BEA), 147, rue de l'Université, 75338 Paris, France

In 2023, the European Commission published a proposal for a new regulation on the protection of animals during transport, aiming to repeal Council Regulation (EC) No 1/2005. This draft regulation seeks to increase the space allocated to animals, based on the recommendations of the EFSA scientific opinions on animal welfare during transport, which cover pigs, cattle, domestic birds, rabbits, equids, and small ruminants. At the request of the Animal Welfare Office (BBEA) of the General Directorate for Food (DGAL) at the French Ministry of Agriculture, the French Reference Centre for Animal Welfare (FRCAW) studied whether the loading densities proposed in the draft regulation led to more falls and injuries during transport. The FRCAW focused its analysis on three specific groups of species – pigs, cattle, and poultry- through three dedicated reports. These reports summarize the key points of the EFSA opinions, with a particular emphasis on falls, piling-up behaviour (in poultry), and injuries associated with loading density during transport. Additionally, the FRCAW reports provide an in-depth analysis of the scientific literature -primarily sourced from the Web of Science – on the impacts of varying loading densities and space allowances on critical welfare indicators, including behaviour, physiology, mortality, and carcass quality. They also identify the factors that increase the risk of falls and injuries in cattle and pigs during transport and propose strategies to mitigate these risks. However, few studies have specifically examined animal falls, piling-up behaviour in poultry, or injuries at the space allowances proposed in the new regulatory framework. As for the key findings, in pigs, no evidence suggests that the proposed loading densities would increase the risk of falls or injuries. Some studies indicate that space allowances similar to those proposed in the draft regulation are associated with fewer haematomas and shorter fight durations (a known cause of injuries). Increased space also enables pigs to sit or lie down, further reducing fall risks. In cattle, current evidence indicates that the space allowances proposed in the new regulation are associated with fewer injuries in calves compared to the current standards. For adult cattle, the single comparative study available shows that injuries are reduced under the proposed allowances, without any significant change in the number of falls. Importantly, no studies suggest that the new space allowances would worsen fall or injury risks compared to the existing regulatory requirements. In poultry, greater available space (floor area and crate height) mitigates the negative effects of restricted movement, although increasing floor area alone may correlate with a higher incidence of injuries—though the underlying causes remain unclear. Temperature, time spent in crates, and bird-catching methods are identified as additional factors influencing the impact of loading density. In conclusion, while current findings suggest potential welfare benefits from increased space allowances, further research is needed to confirm these results. Since animal welfare during transport is influenced by multiple interacting factors, reducing falls and injuries requires a holistic approach. Key parameters to consider include driving quality, route conditions, vehicle design, in-vehicle environmental conditions (temperature, ventilation), as well as journey duration and distance.

Catching and loading of end-of-lay laying hens: effects of body position on endocrine and respiratory stress responses

L. Jung[1], A. Schwarz[1], C. Touma[2], T. Wolf[2], N. Kemper[1], B. Spindler[1]
[1] University of Veterinary Medicine Hannover, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] Osnabrück University, Barbarastr. 11, 49076 Osnabrück, Germany

Depopulation of end-of-lay laying hens represents a critical phase with regard to animal welfare. In Europe, hens are commonly caught by one leg and carried inverted, a practice that may induce anxiety, respiratory impairment and physiological stress. Current EU legislation prohibits handling methods that cause unnecessary pain or suffering, yet scientific data quantifying the physiological burden associated with different catching techniques are scarce. Upright catching, in which hens are carried in a vertical position with the wings restrained against the body, has been proposed as a welfare-friendly alternative, but its physiological impact has not been sufficiently evaluated, yet. Therefore, the aim of our experimental study was to quantify and compare the physiological stress responses of laying hens during depopulation using two different catching methods (inverted vs. upright) under controlled conditions. Special emphasis was placed on acute endocrine stress reactions and potential respiratory impairment during handling. In total, 100 Lohmann Brown end-of-lay laying hens (110 weeks of age) were divided into ten experimental groups with 10 birds each. Eight groups were handled under experimental conditions simulating commercial depopulation, two groups served as controls (N=20 hens per treatment/control). Birds were caught either conventionally by both legs and carried inverted or caught upright using both hands around the abdomen with wing fixation. Handling durations of 5 s (typical commercial practice) and 60 s (upper limit defined in EU Regulation 1099/2009) were applied. Acute stress responses were assessed by collecting blood samples two minutes after handling to measure plasma corticosterone concentrations and heterophil-to-lymphocyte ratio. Acoustic cardiorespiratory signals were recorded using an electronic stethoscope during handling. Heart rate ranged from 126–578 bpm in upright hens (272 ± 164 bpm) and from 147–567 bpm in inverted hens (367 ± 180 bpm). Inverted hens showed elevated cardiac activity and shorter inter-beat intervals (213 ± 109 ms vs. 285 ± 120 ms), indicating increased cardiovascular activation. To avoid confounding effects of pre-slaughter fasting, birds were not feed-deprived prior to handling. The same experimental procedure was applied to end-of-lay laying hens of a white genotype. The study provides comparative data on endocrine stress indicators and respiratory responses associated with inverted and upright catching methods. Differences between handling durations and genotypes further elucidate factors influencing stress susceptibility during depopulation. Analyses are ongoing and results will be presented at the conference. The results contribute to evidence-based recommendations for welfare-oriented depopulation practices and support refinement of current handling procedures in commercial aviary systems.

Comparative assessment of euthanasia methods for RNA integrity in rainbow trout (Oncorhynchus mykiss) larvae

I. Kilic[1], S. Rosenau[1], A. C. Mott[1], S. Zeidler[1], F. J. Gentz[1], J. Tetens[1]
[1] University of Goettingen, Department of Animal Sciences, Burckhardtweg 2, 37077 Goettingen, Germany

In the European Union, research involving fish is governed by animal welfare regulations. The onset of independent larval feeding marks the crucial developmental stage at which Directive 2010/63/EU on the protection of animals used for scientific purposes applies. Earlier developmental stages are generally exempt from this directive, provided the larvae are euthanized before reaching this point. However, standardized euthanasia protocols for larvae are lacking, namely due to differences in overall sensitivity compared to adults and between species (e.g. zebrafish and rainbow trout). This raises animal welfare concerns regarding the humaneness of common euthanasia methods, as well as their potential to compromise mRNA expression and integrity, thereby limiting suitability for transcriptomic analyses. The present study therefore aimed to identify a suitable euthanasia method for cold-water fish larvae that ensures both animal welfare and scientific reliability. This study evaluated the effects of three commonly used anesthetics, each applied at two concentrations, on RNA yield and integrity in rainbow trout yolk-sac larvae: tricaine mesylate (MS-222; 5 g/L [MS5], 10 g/L [MS10]); clove oil (eugenol; 2 mL/L [E2], 4 mL/L [E4]); and 2-phenoxyethanol (10 mL/L [PE10]), 15 mL/L [PE15]). Five larvae of each euthanasia group and two control groups (killed in liquid nitrogen [LN2], and by decapitation respectively), were used for RNA analyses. RNA extraction was performed with a standardized method using a commercial kit. The RNA yield was determined at a wavelength of 260 nm, and purity was assessed by absorbance at 230 and 280 nm. The RNA integrity number (RIN) and S28/S18 rRNA ratios were obtained using microchip electrophoresis. RNA extraction yielded 29.4 – 162 µg total RNA, with A260/A280 ratios of 2.05 – 2.18 and A260/A230 ratios of 1.79 – 2.37 across all euthanasia methods. RIN values ranged from 7.3 – 8.7 with the LN2 group being the lowest and E4 group the highest. The S28/S18-ratio varied between 1.14 – 1.76. RIN strongly correlated with the S28/S18-ratio ($r = 0.84$; $p < 0.001$), and moderately with total RNA yield ($r = 0.6$, $p < 0.001$). A260/A280 showed negative correlations with RIN ($r = -0.49$, $p < 0.001$) and A260/A280 ($r = -0.34$; $p < 0.05$). No significant differences were observed regarding RNA yield and sample purity (freedom from protein contamination, i.e. A260/A280 ratio). However, RNA from the E4 group had significantly lower A260/A230 ratios compared to E2 ($p < 0.01$), LN2 ($p < 0.005$) and P15 ($p < 0.01$) groups. RIN and S28/S18 rRNA ratios were significantly reduced ($p < 0.05$) in LN2 and MS10 groups, respectively. These results demonstrate that the euthanasia method used significantly influences RNA integrity in rainbow trout larvae, even when total RNA yield and general purity remain comparable. Liquid nitrogen shock resulted in consistently lower RIN values, whereas selected anesthetic treatments preserved RNA integrity more effectively. Lower RIN and 28S/18S ratios in LN2 and MS10 groups indicate that rapid physical inactivation or high anesthetic concentrations do not necessarily ensure optimal transcriptomic quality. Consequently, euthanasia protocols for early life stages should consider species-specific physiology, developmental stage, and downstream molecular applications. Selecting and optimizing anesthetic type and dosage is therefore essential to balance animal welfare with the reliability of molecular data generation.

Do stray currents impact the behavior, health and performance of dairy cattle? The farmer's perspective

C. Gazaix[2], F. Lascaze[2], P. Lemaire[1], T. Quemener[1], Y. Lecozler[1], V. Lollivier[1], A. Michaud[2], S. Brajon[1], L. Hervé[1]
[1] Insitut Agro Rennes, animal sciences, 65 rue Saint Brieuc, 35000 Rennes, France, [2] VetAgro Sup, animal sciences, 89 Avenue de l'Europe, 633370 LEMDPES, France

Dairy cow performance, health and behavior are influenced by animal characteristics, herd management practices, and environmental conditions. Among these, stray currents are frequently reported as contributing to the deterioration of dairy cows' condition. Stray currents can originate from nearby energy infrastructures (e.g., wind turbines, antennas, high-voltage power lines), on-farm installations (e.g., solar panels, milking robots, electronic feeders, grid-powered electric fences), or from grounding and wiring faults in farm facilities. Stray currents generate voltages perceivable by living organisms, with dairy cows considered approximately ten times more sensitive to electrical stimuli than humans. Such exposure may affect behavior, health and performance. This study aimed to provide an overview of French farmers' perspectives on the perceived effects of stray currents on dairy cattle. Surveys were conducted across France by MSc students. Farms experiencing or suspecting problems with stray currents were recruited via social media and advisory organizations supporting herds with performance issues. In total, 36 dairy farmers participated in semi-structured interviews. Topics addressed included problem characterization, the sequence of events, electrical and energy infrastructure on or near the farms, and the perceived impacts on animal behavior, health and performance. Data were analyzed using thematic analysis and multiple correspondence analysis (MCA) to explore relationships between reported problems and electrical or energy sources. Results showed that 18/36 farms were equipped with more than four electrical devices. 16 farms were located within one kilometer of an external energy infrastructure, while 20 were located more than one kilometer away. All farmers reported behavioral changes and 33 reported performance issues. The main behavioral changes reported were agitation (23), refusal to enter the milking parlor (27), reduced water intake (21), as well as kicking and signs of stress (28). Among the health problems reported, increases in somatic cell counts (31), mastitis (21) and higher mortality rates (14) were identified. A decrease in milk production was reported on 26 farms. MCA allowed the identification of three profiles: the first was mainly associated with internal sources and combined problems of agitation, abnormal milking behavior, decreased milk production and increased mortality; the second concerned internal and external sources presumed by farmers to have a predominant impact on performance; and the third was linked to nearby energy infrastructure, combined with internal sources, mainly associated with behavioral changes. Overall, the study highlights farmers' concerns regarding stray currents and their potential impacts on farm animal behavior, health and performance. This study emphasizes the need for further research to better characterize the effects of stray currents and develop practical mitigation strategies to support sustainable dairy farming systems.

Assessing the effect of trees on the welfare of dairy cows by limiting insect pressure

C. Bonnefous[1], A. L. Hochstrasser[2], N. O. Verhulst[2], Z. Amsler[1], V. Maurer[1]
[1] Research Institute of Organic Agriculture FiBL, Livestock, Ackerstrasse 113, 5070 Frick, Switzerland, [2] National Centre for Vector Entomology, Institute of Parasitology, One Health Institute, Vetsuisse and Medical Faculty, University of Zürich, Winterthurerstrasse 266a, 8057 Zürich, Switzerland

Insect pressure on grazing animals is increasing with global warming. However, using chemical products to protect grazing animals from this nuisance is not permitted on organic farms. Some trees have a natural repellent effect on insects and animals could benefit from these trees in agroforestry systems. In our trial, we assessed insect pressure on 6 herds of cows on pasture with/without trees insect traps (one H-trap in the meadow and sticky traps in various tree types per herd), observed defensive behaviours of cows for 5 minutes every week over 3 months and counted flies on the animals. Our results highlight that defensive behaviours of cows decrease in time for an individual on a specific pasture. This shows that cows get habituated by the insects around them and the defensive behaviours they express alone does not fully qualify the cows' welfare. To grasp which factors influence the total number of insects per cow, we modelled the number of insects at observation (reported from photography) depending on (1) the date, (2) the location on the pasture (close, under or no trees), the weather (sunny under shade or in the sun and cloudy), (3) the colour of the cow, (4) the air temperature (recorded ourselves for the temperature under trees and national database otherwise) and (5) at the lacrimal point of the cow (recorded with a infra-red camera). Only the weather variable and the date significantly influence the number of insects. The expected counts of insects on a cow are about 1.5× higher in sunny weather (regardless of whether the animals are in the shade or in the sun) than when the weather is cloudy. Additionally, the number of insects follows a quadratic formula with a negative value of the x^2 coefficient showing that the number of insects follows an inverted U form depending on the date between the beginning of June and the end of August. To further assess the dynamics of insects on pasture, we collected insects with sticky traps under a tree and with the H-traps in the meadow. First, we highlight that the number of biting insects under trees was close to inexistant while we collected a high number of biting insects, especially horseflies, with the H-traps. To discriminate influencing factors, we performed a mixed linear model per trap type and observed that while temperature and months when the traps were hanged influenced the number of insects on sticky traps, only the location by canton influenced the number of insects collected in H traps. Our result shows a significant increase of the total number of insects collected in sticky traps with increasing temperature, lower insect counts under Pinales compared to Sapindales, and finally higher numbers of insects in June and July compared to August therefore suggesting a similar curve as the one observed of insect on the cows. Regarding the number of insects (biting and non-biting) collected in H traps, the pastures located in the hilly canton of Jura showed significantly more insects (biting and non-biting) than in the alpine canton of Schwyz. The results in the lowland canton of Aargau showed no significant difference compared to both Jura and Schwyz. To conclude, in a follow up experiment, e-DNA, to quantify the number of insects that landed on a cow over a large period of time, and behavioural camera could contribute to fill the gap as this dataset, even though large, does not cover continuously either the cows' behaviour or the insects that were landing on a cow.

Analysis of the behavior of finisher pigs in the 24 hours before death on a commercial farm

M. Okayasu[1], Y. Sasaki[1]
[1] Meiji University, Graduate School of Agriculture, 1-1-1, Higashi-Mita, Tamaku, 214-8571 Kasawaki, Japan

Group housing systems where multiple pigs are reared together are common during the finisher period in commercial farms. In recent years, rising farm sizes have increased the number of pigs managed per worker. To improve productivity, it is essential to promptly detect and deal with problematic pigs at an early stage. However, under group housing conditions, it is difficult to monitor the behavioral features of individual pigs. This study aims to investigate the behavioral features of finisher pigs that died during the finisher period by analyzing video data from the 24 hours prior to death. This study included finisher pigs reared in a finisher barn on a Japanese commercial farm. Video data were recorded using ceiling-mounted cameras capable of capturing two pens simultaneously. We analyzed a total of 28 pigs, comprising 14 pigs that died during the observation period (death group) and 14 healthy pen-mates (control group). We analyzed the 24 hours prior to death, with each control pig assessed during the identical 24-hour time window as its paired deceased pig. We quantified the proportion of time spent in five postures (standing, sternal lying, lateral lying, sitting, and front-leg sitting), and the frequencies of feeding, drinking, and injurious behavior (being bitten). The chi-square test was used to compare the proportion of time spent in different postures between the groups. Temporal changes in feeding, drinking, and injurious behaviors were analyzed using Generalized Linear Mixed Models.The proportion of postures differed significantly between groups ($P < 0.05$). The death group showed lower proportions of standing and lateral lying, but higher sternal lying than controls. In the death group, the proportions of standing and sternal lying peaked 24–18 h before death and reached their lowest levels at 12–6 h, while lateral lying increased toward death. Feeding frequency was significantly lower in the death group ($P<0.01$), with a sharp decline starting 12 h before death ($P<0.05$). For injurious behavior, pigs in the death group were bitten significantly more often ($P<0.05$). A group-by-time interaction ($P<0.05$) revealed that being bitten intensified in the final 6 h ($P<0.05$). While overall drinking frequency did not differ between groups, it significantly declined within the death group during the final 12 h compared to the 24–18 h baseline ($P<0.05$). This study revealed distinct behavioral features in finisher pigs prior to death, identifying a higher proportion of sternal lying, a marked decline in eating and drinking behaviors starting 12 h before death, and a surge in injurious behavior as critical indicators of mortality. Regarding the shift in the proportion of postures, particularly the increase in sternal lying, this likely reflects energy conservation or respiratory distress in moribund pigs. Significant reductions in feeding and drinking 12 h prior to death are critical signs of impending mortality. Interestingly, the lack of a group difference in drinking might be due to compensatory water intake in febrile pigs, masking the decline. Furthermore, the surge in injurious behavior in the final 6 h suggests that debilitated pigs become targets for pen-mate aggression due to their inability to retreat or resist. Integrating these parameters into automated monitoring systems could facilitate early intervention, improving farm productivity and animal welfare. This research was supported by a grant (Smart Agriculture Demonstration Project by Ministry of Agriculture, Forestry and Fisheries of Japan; Project No. Livestock-5H3) from National Agriculture and Food Research Organization (NARO).

The restraint enclosure effects due to African Swine Fever on the reproductive parameters, ethology patterns and welfare of boars and sows of the free-range Greek autochthonous black breed.

C. Kalfopoulos[1], V. Tsartsianidou[2], A. Moulistanos[2], A. Triantafyllidis[2], G. Vatzias[1]
[1] Aristotle University of Thessaloniko, Animal Production, Panepistimioupoli, 54124 Thessaloniki, Greece, [2] Aristotle University of Thessaloniki, Genetics, Development & Molecular Biology, Panepistimioupoli, 54124 Thessaloniki, Greece

Pigs have been raised in Greece since the Homeric era. Following World War II, the introduction to farmers of genetically improved and high yield European breeds and the initiation of intensive pig production had a negative impact on the production of free-range black pigs. In the following years the remaining herds of the autochthonous black-breed pigs were raised in pastures and oak-tree forests, confined in "primitive" infrastructures. Due to African Swine Fever (ASF), the swine producers have been forced to comply with strict biosecurity measures during the last five years. The aim of this study was to record and determine differences in the reproductive ethology patterns, reproductive efficiency and welfare status between the breeding stock that was raised in free range (reproductive parameter's record keeping data of two consecutive years prior to enclosure -PE) vs the breeding stock's reproductive efficiency data (reproductive parameter's record keeping data) following the transition time (TT) from the pastures to a total confined setting for a period of two years. Data was collected from three farms, located in three different Greek regions (farm A: Central Macedonia, farm B: Thessaly and farm C: Epirus, respectively). The farms are located in mountainous regions. The breeding stock capacity – sows and boars – of the three farms prior to enclosure were 160 – 12, 120 – 10 and 80 – 6, respectively, while during the two – year transition time the farms' breeding stock capacity were 130 – 10, 100 – 8 and 60 – 5, respectively. Sows were bred with natural service twice a year. The boars' ethology patterns and the libido (Lsc-in a scale of 1 to 5, with 1.: not mounting, 2.: mounting but no protrusion, 3.: delayed mounting followed by protrusion but no penetration, 4.: multiple mountings, delayed penetration – ejaculation, 5.: aggressive mounting – penetration, ejaculation) was evaluated at the peri-copulatory time. Breeding records were evaluated for wean to estrus interval (WEI) and conception rate (CR) in sows. In addition, the pre-weaning mortality rate (PWMR) was determined while the sows' ethological patterns during the peri-parturient time were evaluated. A two – sided Student's t– test was used for the analysis of data. P–values ≤ 0.05 were considered statistically significant. The results showed that the majority of the PE boars exhibited a similar ethological reproductive pattern (Lsc:5, 21/28 boars, $P \leq 0.05$), while the TT boars' ethology varied from lethargic (Lsc:1) to highly aggressive (Lsc:5 $P \geq 0.05$). Similarly, the PE sows had a higher CR and a normal WEI compared to the TT sows ($P \leq 0.05$, 85% vs 55%, 6d vs 11d). The strict restraint measures had a detrimental effect on litter size with PWMR reaching 45% ($P \leq 0.05$) due to crushing and in some cases primiparous sows exhibited cannibalism. The above results indicate that the long-term enclosure had a negative effect on the reproductive parameters and the ethology of the TT breeding stock, while it had a major negative impact on the overall welfare status of the farms.

New house, stressed cows? Behavioural observations following relocation to a new barn

T. Rahmann[1], A. Langehennig-Peristenidou[1], N. Kemper[1], N. Volkmann[1]
[1] University of Veterinary Medicine Hannover, Foundation, Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, Bischofsholer Damm 15, 30173 Hannover, Germany

Regrouping is a common practice on dairy farms to adapt feeding and management cows' lactation status as well as milk yield, although changing the social environment might be stressful for the animals. In addition, the resulting social instability can have negative effects on their behaviour. This pilot study investigated if behavioural changes in dairy cows occurred after relocation to a new barn. Observations were conducted via video recordings in two compartments of a newly built free stall barn. Both recorded compartments kept a total of 24 animals and were identically designed (e.g. same drinking trough, cow brush) except for their different floors and lying areas (compartment A: deep straw; compartment B: slatted floor and cubicles). Beginning immediately after relocation, the behaviour of three focal animals (lactation 1-6) from each compartment was continuously observed for the first five days (milking times excluded). The observations focused on lying, eating and drinking behaviour as well as cow brush usage and agonistic interactions. For evaluation, it was examined if there were differences in the duration and frequency of the observed behaviours among animals kept on straw or slatted floor as well as among primiparous (pp) and multiparous (mp) cows. For all behaviours, the average duration as a percentage of the net observed time was calculated and their frequency was counted. The mean percentage of lying time across all observed animals was between 53.4 and 80.2% per day. No consistent trend in lying behaviour was found in the two different compartments. In compartment A, lying times first increased until the third day and then decreased (Mean: 70.5%), while in compartment B there were hardly any changes during the observation period (Mean: 68.6%). Contrary to expectations, the number of lying frequency also remained consistent over the observed period. Dairy cows in compartment A spent less time eating and drinking than those in compartment B. Regarding feeding behaviour, pp cows showed longer feeding times (Mean: 15.7%) than mp ones (Mean: 10.8%). Number of drinking frequency decreased after two days; this trend was observed in both compartments similarly. The cow brush was used more frequently in the straw compartment A than in compartment B, and the pp cows used it more frequently than the mp ones. Within the first 24 hours, 132 agonistic interactions with other cows were observed among the focal animals in compartment A. In contrast, there were 44 agonistic interactions in compartment B. After a decline on days 2 and 3, the total number of agonistic interactions in compartment A rose sharply until the end of the observation period. The longer lying times of cows in compartment A during the first three days indicated the high attractiveness of the comfortable deep straw bedding. The decline in drinking behaviour after the first two days might suggest that the initially increased exploratory behaviour reduced over time. The higher space allowance, respectively mobility, offered in compartment A led to a higher number of agonistic interactions on all observation days. Here, the particular increase on the fifth day after relocation was certainly because of one of the animals was in heat, which led to general unrest. To verify these first results, further investigations on the herd-synchronous behaviour of all cows in both compartments will follow. The project is funded by the Federal Ministry of Agriculture, Food and Regional Identity (BMLEH) based on a decision of the German Bundestag. The project is managed by the Federal Office for Agriculture and Food (BLE), FKZ: 28N1800003.

Does choice of calving location affect calving duration?

T. Tammen[1], A. Haeussermann[1], E. Hartung[1]
[1] Christian-Albrechts-University Kiel, Institute of Agricultural Engineering, Max-Eyth-Str. 6, 24098 Kiel, Germany

Previous research studies showed that cows, particular primiparous, increase their distance to their group in the hours prior to parturition and that some cows prefer calving behind a hide if provided. Cows in group calving pens equipped with a blind may show less position changes during parturition and receive less prior attraction from pen mates. However, the use of a blind or secluded area for parturition varies to a large extent and is influenced by pen design and, e.g., parity or health status of the cow. Group calving pens with blinds, stocking density and preferred dimensions of blinds were previously linked with calving duration, but the relationship between the use of secluded areas and calving duration is not that clear. Thus, the objective of the study was to evaluate how the individual cow's choice to calve in a secluded area within a group pen is related to her calving duration. For this purpose, calving duration was compared to cows calving in the group area of the calving pen and to cows giving birth in an individual calving pen. Data on calving location and duration were collected in a barn with three group calving pens and four individual pens for calving at the research farm Karkendamm from August 2024 to September 2025. Each group calving pen comprised two secluded areas (3.50 x 3.45 m) with a blind height of 1.5 m towards the group area, the neighboring pen and the walkway. Four cows were kept together in a group pen from 2-3 weeks before the expected calving date (all-in/all-out; 21 m² per cow at full stocking density). After each calving, the respective cow left the calving pen. For the evaluation here, only calving events with four cows in the group pen were considered. Cows which gave birth in the individual pens were moved into the pen about 2-3 days before calving. The calving location and start and end time of calving was analyzed by video observations. Thereby, the calving duration was defined as the time duration from the beginning of observable abdominal contractions until the calf's hips were fully expelled. Altogether, 24 calving events (8 primiparous, 16 multiparous cows) from 24 group pen cycles were included in the analysis, and 39 cows (15 primiparous, 24 multiparous) which gave birth in individual pens. Differences in calving duration between pen type or calving location in the group pens were tested pairwise by Mann-Whitney U Test. Cows in individual and group calving pens had an average calving duration of 122 min (56-188 min, n=39) and 131 min (62-198 min, n=24), respectively. No difference was found with regard to pen type ($p = 0.3539$). Of the 24 cows giving birth in group pens, seven did choose the secluded area as calving location, with an average calving duration of 100 min (62-149 min, n=7), and 17 gave birth in the group area. Average calving duration of the latter was 143 min (75-198 min, n=17). Calving duration between the group pen locations differed significantly ($p < 0.01$). The shorter calving duration in cows which did choose to give birth in the secluded area is in line with previous reports on shorter calving durations in pens with a blind and low stocking density. However, it also contradicts earlier studies which did link health issues and thereupon based preferences for larger blinds with prolonged calving durations. In conclusion, pen design and group dynamics might influence both calving duration and individual cow's choice for or against secluded areas. The ongoing analysis thus intents to get a deeper insight into the question whether the reduced calving duration is linked to the feasibility to distance or hide from the group, or rather results from other causations such as parity, health and calf's breed or sex.

Opinion of the FRCAW on the Effects of Transport on the Welfare of Calves under Five Weeks of Age

V. Colson[1], C. Bezançon[1], L. Kremer[1], Frcaw Panel Of Experts[1], G. Aubin-Houzelstein[1]
[1] INRAE, UAR CODIR, French Reference Centre for Animal Welfare (FRCAW-CNR BEA), 147, rue de l'Université, 75338 Paris, France

In 2023, the European Commission published a proposal for a regulation on the protection of animals during transport to replace Council Regulation (EC) No 1/2005. This new text proposes regulatory transport conditions based on the recommendations of the EFSA opinion on the welfare of cattle during transport, with specific recommendations concerning the transport of calves (EFSA AHAW Panel, 2022). The new regulatory proposal would increase the minimum age for the transport of calves to 5 weeks, whereas the minimum age is currently set from 10 days (for journeys over 100 km) to 14 days (for journeys lasting more than 8 hours). At the request of the Animal Welfare Office (BBEA) of the General Directorate for Food (DGAL) at the French Ministry of Agriculture, the FRCAW wrote a report addressing the main welfare issues encountered during the transport of calves under 5 weeks of age. The information reported by the EFSA has been supplemented by a comprehensive analysis of scientific literature not cited in the EFSA opinion, particularly studies that have been published since 2022. In Europe, calves are generally transported at the age of 2 to 4 weeks, a sensitive stage in their lives during which their own immune systems have not yet developed and their thermoregulatory capacities are limited. For such animals, transport conditions are likely to increase fatigue, stress, dehydration, the development of disease and mortality. This vulnerability decreases with age. Two-week-old calves are more vulnerable than four-week-old calves, who in turn are more vulnerable than six-month-old calves, whose immune systems have reached maturity. Furthermore, navel healing, which is a regulatory prerequisite for the transport of calves, is complete only at 3 to 4 weeks of age. Studies in the literature emphasise the need for good management of colostrum intake from birth to promote the transfer of passive immunity. They also stress that sufficient energy must be provided to calves by offering them milk replacer 4 hours before transport, and that the total journey duration should be limited to 8 hours. Altogether, current scientific literature recommends avoiding the transport of calves before four to four-and-a-half weeks of age. However, research on the impact of transport age on calf welfare remains limited. Future studies should systematically evaluate welfare indicators in calves aged 2 to 6 weeks – both transported and non-transported (control groups) – to fill this gap. Key research priorities include: nutritional and energetic needs of unweaned calves before, during, and after transport, as well as effective rehydration strategies; digestive impacts of consuming liquid or solid feed during transport; optimal rest periods during journeys for unloaded unweaned calves; development of an objective clinical scoring method to assess navel healing; effects of transport on calves' mental and emotional states.

Development of a research and demonstration barn to improve animal welfare in dairy husbandry and to regain societal acceptance

L. Bachmann[1,2], M. Zenk[2], R. Wulf[1]
[1] University of Applied Science, Faculty of Agriculture and Food Science, Brodaer Str. 2, 17033 Neubrandenburg, Germany, [2] Research Institute of Farm Animal Biology, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

A concept for a research and demonstration barn to improve animal welfare in dairy husbandry was developed, called "Future Dairy Barn" (FDB). Although the development and construction of the FDB were originally funded by the German government, the construction of the FDB could not be realized due to financial constraints and the FDB was built virtually. Housing conditions for dairy cattle have been improved in the last decades, for example leading to more loose than tethered housing. However, there is still a lot of room for improvement especially regarding animal welfare, societal acceptance and technical innovations, which do not compromise animal welfare but reduce the work load of the farmers and their employees. As animal welfare is a multidimensional concept that covers natural living and basic animal health and functioning, as well as the affective state, for the development of the FDB all three dimensions of animal welfare were taken into account. In the FDB, the cattle shall be able to (1) form a stable herd structure, (2) exhibit species-typical lying behavior, and (3) decide for themselves whether they stay indoors or outdoors. Referring to these three implications, the FDB concept integrates a family herd, which means that the calves can suckle their dams, heifers are reared within the herd and lactating as well as dry-off cows are kept together to avoid regrouping and to enable stable social relationships. A free lying area is included to allow species-typical lying behavior and pasture or paddock access is provided that the cattle can stay indoors or outdoors. A high degree of process automation is integrated in the FDB to reduce work load. Moreover, technical innovations like so-called "Smart Feeding Fences" and a "Smart Calf Sluice" are developed to realize the family herd concept. To meet the requirement of being a demonstration barn, a visitor corridor is included. Visitors can therefore look in detail into the FDB without compromising biosecurity. Future dairy production needs to be rethought. Society's demands on husbandry systems are increasing with respect to animal welfare of dairy cows. However, a higher workload of the farmers should be avoided. Therefore, investigations on long-term effects on animal welfare in a uniform social and housing environment with a high degree of automation techniques are needed. The FDB provides the opportunity to investigate holistic approaches on animal welfare in long-term studies and enables farmers and consumers to take a look into an alternative concept of dairy farming. The virtual application of the FDB available can be used to give an insight into the FDB and to transfer knowledge on animal welfare of dairy cows and their offspring.

Exploring the future of the European equine sector towards 2040: a participatory foresight approach

European Horse Network[1], 4Sing[2], A. Julien[3], L. Rosier[3], F. Gras[4], H. Blauw[5], M. Addes[6]
[1] EHN, B, 1930 Zaaventem, Belgium, [2] Foresight to Strategy for Security and Sustainability in Governance, Oesterleystraße 41, 22587 Hamburg, Germany, [3] IFCE, International and European affairs department, Rte de Troche BP6, 19231 Arnac-Pompadour, France, [4] World Tote Association, Washington street 40, 1050 Ixelles, Belgium, [5] FNRS (Dutch Federation of Professional Equestrian Centres), Kapweg 30, 3774 RD Kootwijkerbroek, Netherlands, [6] IFCE, pole DIR, Le-Pin-au-Haras, 61310 Exmes, France

A sector facing growing socio-environmental and economic pressuresThe European equine sector is facing increasing uncertainty driven by climate change, resource constraints, evolving societal expectations regarding animal welfare, and economic pressures. In this context, maintaining the sector's social acceptability and long-term sustainability has become a critical challenge. This study, developed by the European Horse Network (EHN), aims to explore how the European equine sector could evolve by 2040 under different socio-economic and environmental conditions. Its central research question is: How might the European equine sector evolve by 2040 under different economic, environmental, and social conditions, and what strategic actions are required to ensure its resilience and societal relevance? A participatory and matrix-based foresight methodologyA qualitative foresight methodology was applied, combining stakeholder workshops, expert interviews and a multi-country survey conducted across Europe. The study was structured using a matrix-based scenario approach, which consists in developing four contrasted scenarios based on the intersection of two key axes. In this case, the selected axes were (i) social acceptability of equine activities and (ii) sustainability, encompassing both environmental and economic dimensions. These two dimensions jointly reflect the sector's ability to maintain its "social licence to operate". The identified trends and drivers of change were then analysed and systematically projected across the four scenarios, allowing the exploration of coherent and plausible future pathways for the European equine sector. Four scenarios and the key conditions for the sector's futureThe main results highlight four potential futures: (1) strong societal integration of horses within sustainable rural development; (2) increasing competition for land and resources, requiring active defence of the sector's legitimacy; (3) marginalization of horses due to declining social acceptance and strict regulation; and (4) a contraction of the sector into an elite, exclusive activity. Across all scenarios, social legitimacy, environmental adaptation, and economic diversification emerge as decisive factors. The findings underline the growing importance of sustainability practices, welfare standards, innovation, and communication with the wider public. The study concludes that the future of the European equine sector is not predetermined but highly dependent on proactive adaptation. Strategic collaboration, improved policy engagement, investment in skills and research, and a clear demonstration of horses' societal value are essential to securing a resilient and socially accepted equine sector by 2040.

Professional Conceptions of Equine Wellbeing: Continuous Adjustment Grounded in Observation, Expertise, and a Human–Horse Moral Contract

M. Felga[1,3], C. Vial[1,2], B. Siadou-Martin[3]
[1] MoISA, Univ Montpellier, CIHEAM-IAMM, CIRAD, INRAE, Institut Agro, IRD, 2 place Pierre Viala, 34060, 2 place Pierre Viala, 34060 Montpellier, France, [2] IFCE, pôle DIR, Le-Pin-au-Haras, 61310 Exmes, France, [3] Université de Montpellier, Laboratoire MRM, Montpellier Management, 34000 Montpellier, France

Debates surrounding equine wellbeing (EW) are increasingly frequent, fostering the development of a body of knowledge, of a growing market and questioning existing practices. Professionals are primarily responsible for finding an economic and ethical balance in their daily activities, which involve both caring for horses and making use of them. This research in management sciences aims to better understand how professionals conceive the wellbeing of the horses they live and work with and the debates on this topic. Twelve semi-structured interviews were conducted with six riding instructors and six racehorse trainers in France, selected for their diversity. A thematic analysis identified more than 380 meaningful semantic units, which were then hierarchized and reorganized to describe three main thematic axes related to EW. 1) The definition of EW according to professionals Professionals define EW through a human-centered approach closely linked to the notion of welfare. EW is associated with proper management of horses' living conditions, satisfaction of their fundamental needs, a respectful human–animal relationship, professional expertise, and the ability to interpret horses' subtle signals. They also point out a constant uncertainty, due to horses' silence and individual variability. Differences appear between instructors and trainers regarding housing systems, the relationship to work, and perceptions of horses' specific needs. Overall, professionals struggle to provide a unified definition of EW, which they perceive as complex and multifactorial. 2) EW as experienced by professionals in their daily work EW is experienced daily through an ethic of reciprocity, in which good treatment represents fair compensation for the work provided by horses, moreover because in some cases the pursuit of performance may threaten EW. Competence and expertise play a central role and rely on observation, interpretation, adaptability, and the ability to engage horses' cooperation. However, professionals emphasize the impact of economic, sporting, and institutional constraints, which require horses to work and be profitable, while limiting professionals' capacity to provide optimal living conditions. 3) EW consequences and challenges for the profession Professionals perceive EW as a recent and major social issue shaping the future of their professions, with trainers expressing greater pessimism. They view it as a cultural and societal dynamic and as a challenge to professional legitimacy. They agree that public debates are excessive, multifaceted, and overly polemical. They believe that public perceptions would improve if people observed everyday professional practices. Both groups highlight the key role of institutions in regulating this phenomenon. To conclude, the absence of a formal definition of EW reflects not disinterest but a pragmatic, individualized approach centered on human action. EW refers not only to the horse's subjective state but also to professional skills and continuous trade-offs between care, use, unpredictability, and economic constraints. While the scientific approach aims to abstract from diverse individual cases in order to establish general laws, professionals appear to favor a "science of the singular," adaptable to each horse and situation. In doing so, they highlight their expertise and provide valuable insights for better adapting public policies and professional training to the realities of the field.

The INOSYS portal, open access equine references

G. Mathieu[1]
[1] *Institut de l'élevage, 149 rue de Bercy, 75012 Paris, France*

The INOSYS portal for herbivore sectors (https://portail.inosys-reseaux-elevage.fr/FR/) was developed to address a growing need for reliable, comparable references to support the sustainability of European herbivore farming systems. In a context of economic pressure, environmental transition, and generational renewal, farmers and advisers require comprehensive and up-to-date technical and economic benchmarks to guide decisions at farm and sector levels. The portal provides open-access references for seven herbivore sectors, including cattle, sheep, goats, and equines. It currently hosts around 250 "case-type" farms—model farms representing coherent, well-documented production systems that are both optimised and realistic within clearly defined economic conditions. Among them, three concern equine "riding school" systems, with two additional equine case-types ("competition rider livery" and "trotter training stable") under integration. For each case-type, approximately 500 downloadable indicators describe the system's multi-performance, including economic viability, environmental performance, and labour organisation. For instance, recent analyses show that equine riding schools combining diversified income sources (lessons, boarding, and training) achieve higher income stability while maintaining comparable workloads. Sectoral dashboards aggregate these results by farm type and present consolidated indicators to facilitate comparisons. The portal also centralises all related publications, serving as a single access point for teachers, students, researchers, and policy-makers. By offering annually updated references and synthetic tools, INOSYS contributes to the design, evaluation, and dissemination of resilient and sustainable herbivore farming systems.

Cost of production: a management tool for equine businesses

S. Boyer-Lafaurie[1]
[1] *Institut de l'Elevage, 149 rue de bercy, 75595 Paris, France*

In a context of high market variability and increasing pressure on farmers' incomes, having reliable and comparable indicators is essential for effectively managing production systems. Widely used in the dairy and beef sectors, the national method for calculating the cost of production is currently being adapted to the equine sector. This management tool aims to improve understanding of the farmers' income levels and to identify opportunities for technical and economic improvement. This method, which has been developed within the INOSYS livestock farming networks since 2010, is recognized at both the national and international levels and is now widely implemented in France. By the end of 2024, more than 28,000 cost-of-production analyses had been carried out in herbivore production systems. It also provides a structured framework for advisors, strengthening their expertise and their ability to support improved efficiency. Although still little developed in the equine sector, this approach nevertheless represents a relevant lever for equine businesses. It offers an analytical framework that helps farmers step back from the operation of their businesses, compare their results with Equine Network benchmarks, and identify levers to improve income. For the past two years, methodological work has been conducted in France to adapt this national cost-of-production method to the equine sector. The study is based on the analysis of 145 farms from the Equine Network over four accounting years (2020 to 2023). The approach, conducted at the activity level, relies on allocating production resources, costs, and certain outputs among the different activities. Costs are expressed in production units (€/hour for riding schools, tourism, and horse-drawn transport, and €/day for horse boarding) and are then compared with revenues in order to assess each activity's ability to generate income for the farmer. Initial cost-of-production calculations were carried out for six systems (riding schools and equestrian farms, sport boarding and livery stables, trotting trainers and horse-drawn transport and driving). Average income levels vary depending on the system: below 1 minimum wage per full-time farmer in working livery, between 1 and 2 minimum monthly wages in riding schools, boarding livery and equine transport services, and above 2 minimum monthly wage in equestrian farms and trotting trainers. In riding schools in 2023, the cost of production, before the farmer's own remuneration for work, amounted to €14.99 per hour, compared with revenues of €19.55 per hour, resulting in an average income level of 1.5 minimum monthly wages per full-time farmer. Analysis shows that farmers achieving an income level of 2 minimum monthly wages are characterized by better generation of revenue, optimized use of the horse herd, and good alignment between labor and production resources. These initial results are encouraging for the sector. They provide benchmarks for production costs per activity and improve understanding of the key factors influencing income in equine businesses. Aligning the farmer's objectives with the production resources used is essential for the efficient operation of the business.

Ecosystem restoration potential of equine farms – development of a practical and scalable framework supporting the EU Nature Restoration Law

L. Lovasz[1,2], I. Sereda[3], V. Milojevic[4], B. Robert[2], C. Zemp[1]
[1] University of Neuchâtel, Institute of Biology, Emile-Argand 11, 2000 Neuchâtel, Switzerland, [2] Aarhus University, Department of Biology, Ecoinformatics & Biodiversity, ECONOVO – Center for Ecological Dynamics in a Novel Biosphere, Ny Munkegade 114-116, 8000 Aarhus, Denmark, [3] Center for Ecological-Noosphere Studies, GIS and RS department, NAS RA, 0025 Yerevan, Armenia, [4] Sandgrueb-Stiftung, Sandgrueb 6, 8132 Egg b. Zürich, Switzerland

The EU Nature Restoration Law highlights the urgent need to scale up ecological restoration opportunities across Europe's human-dominated landscapes. Agricultural land covers more than 45% of the EU's territory, and thus agroecosystems strongly shapes the fate of biodiversity protection. Among agricultural systems, the equine sector represents a land-use system of considerable extent, for instance in Central Europe, with 2.3 million horses across 87,000 equine facilities in France and Germany alone. Moreover, large-scale equine farms stand out as potential areas for restoration and biodiversity enhancement: they are often exempt from intensive production pressures and may maintain semi-natural habitats. Identifying the strengths and weaknesses of equine facilities in contributing effectively ecosystem restoration and facilitating biodiversity protection, requires a systematic assessment framework. In this study, we developed a Restoration Potential Index (RPI) for equine facilities. The index integrates patch-scale habitat heterogeneity, connectivity, ecosystem quality and topographic variation together with indicator species richness, and the proximity and size of (semi-)natural areas into a single standardized measure, assessed at three spatial scales. The RPI was applied in four sample areas (Germany; Austria; Hungary, and France) which differ in terms of management, habitat mosaicity and naturalness, but are comparable in terms of climatic conditions. Applying the RPI in these four case study sites showed clear comparability of equine yards with the index. Among the facilities, the Hungarian site stood out for its within-site heterogeneity, habitat patch quality, connectivity and species richness (each scoring the maximum value: 5). The French site showed low topographic variability (1) but compensated this with high (5) inner habitat connectivity, showing the importance of using several indicators to assess the restoration potential of equine properties. In the German and especially the Austrian site, indicators showed intermediate to lower within-site scores, except site-scale topographic variation in the Austrian equine yards (5), indicating a basis for potential restoration measures. The surrounding areas of each facility (except the Hungarian site) revealed potentially lower possibilities for species flow and habitat connectivity on the macrohabitat scale, and, except at the French site, they also lacked the presence of near-natural areas. Such lower scores of the close surroundings, and the complete absence of designated protected areas in the 5 km buffer around the equine yards may represent a challenge in restoration, yet underscore the importance of the equine facilities as potential biodiversity hotspots in highly exploited surrounding areas. The RPI provides a novel, transparent and scalable tool for evaluating the restoration potential of equine facilities and, if adapted, potentially other agroecosystems across Europe. We propose the integration of the RPI into management strategies at equine facilities and in future agri-environmental subsidy schemes, to support the involvement of private land in ecosystem restoration and rewilding, thus increasing the size of areas targeted by the EU Nature Restoration Law.

An Economic Overview of Equestrian Tourism in France

C. Vial[1,2], A. Batouche[4], P. Heydemann[3], J. Laulhere[4], M. Primault[4], C. Drapeau[3]
[1] MoISA, Univ Montpellier, CIHEAM-IAMM, CIRAD, INRAE, Institut Agro, IRD, 2 place Pierre Viala, 34060 Montpellier, France, [2] IFCE, pôle DIR, Le-Pin-au-Haras, 61310 Exmes, France, [3] IFCE, pôle DIR, Route de Troche, 19230 Arnac-Pompadour, France, [4] IFCE, DT Ouest, L'Isle Briand, 49220 Le Lion d'Angers, France

Horse-related tourism activities contribute to the dynamism and attractiveness of French territories. These activities are diverse and widely dispersed, and there is limited data to objectively assess their economic impact. For this reason, the Economic and Social Observatory of the Horse (OESC) of the French Institute for Horse and Riding (IFCE), together with the IFCE Western Territorial Delegation, are conducting a national study, in collaboration with the French Equestrian Federation (FFE) and the National Federation of Horse Racing (FNCH), with the support of researchers in geography and economics. The objective is to identify and characterize horse-related tourism and leisure activities through key indicators (number of sites, attendance, turnover, full-time equivalent jobs, etc.). Data collection was carried out in late 2025 and early 2026 through internet research, online surveys, and interviews with site managers. The results are structured into two parts. Part 1: Horse-related tourism supply. This part includes sites and activities with tourism and leisure appeal, such as racecourses, competition venues, cultural and heritage sites, stud farms, private breeding or training facilities open to visitors or offering demonstrations, equestrian show venues, and sites hosting events such as fairs or exhibitions. Around 450 different activities have been identified as fully horse-related, including 214 activities related to culture, shows, festivals, fairs, and competitions, in addition to activities organized at the 231 racecourses. These activities generate around 5 million visits annually (1.7 million for culture/shows/festivals/fairs, 1.1 million for competitions, and 2.2 million for races) Ticket sale turnover is estimated at around €30 million for sites offering paid activities, including slightly less than €4 million for racecourses, for which ticket sales represent only a small share of total turnover. Part 2: Equestrian tourism in France. This part focuses on horseback tourism providers and tour operators. Around 1,000 FFE members hold an equestrian tourism label. Equestrian tourism constitutes the main activity for approximately half of them, that are of varying economic size, generating a combined turnover of €75 million and employing 1,450 staff. The other half mainly consists of riding schools offering diversified activities, in which equestrian tourism plays a more marginal role; their combined turnover of €135 million and 4,000 salaried jobs are therefore only partially linked to tourism. More than 3,300 riding tours organized by 750 certified clubs have been identified. In addition, around ten tour operators share the organized equestrian travel sector in France. The results highlight the economic importance of the sector and will help institutions better support these activities, their organization, and their impacts. The key figures that will be presented at the EAAP 2026 conference will also be used in regional exchanges with the equine sector, local authorities, and institutions, as well as in national economic publications and for international comparisons. Further work may be conducted at regional level (2026–2027), including methodological recommendations and additional field surveys to address remaining data gaps.

Relational practices in beef suckler systems: A literature review, holistic modelling, and emerging research questions

X. Boivin[1], G. Barbier[1,2], E. Delanoue[3], R. Lardy[1]
[1] Université Clermont Auvergne, INRAE, VetAgro Sup, UMRH, 63670 Saint Genès Champanelle, France, [2] AgroParisTech, Université Paris Saclay, 75005 Paris, France, [3] France Institut de l'Élevage – IFIP Institut du Porc – Itavi, Mon Voisin, 35652 Le Rheu, France

Beef suckler systems require farmers to coordinate long- and short-term tasks under variable climatic and organisational constraints. This complexity shapes work organisation and the human–animal relationship. Across animal science, management science, and rural sociology, farming practices are seen as a decision-making process in which farmers carry out coherent tasks based on their goals and resources. Within this framework, some farmers develop relational practices: intentional actions aimed at fostering positive interactions with cattle and improving working conditions. These practices are grounded in farmers' representations of working with animals and contribute to safety, efficiency, and work satisfaction. Yet empirical studies on relational practices in beef suckler systems remain scarce and fragmented. This review aims to synthesise existing knowledge on relational practices in beef suckler systems, integrate these insights into a holistic model of the human–cattle relationship, and identify key research gaps and questions for future work. We combined a review of interdisciplinary literature with a conceptual modelling approach integrating human, animal, and environmental factors, work organisation, and interactional dynamics. On this basis, four published on-farm surveys from France, Spain, and Canada were analysed to identify convergent and divergent patterns in farmers' representations and practices. These studies covered diverse contexts, including differences in seasonal housing, geographical environments, breeds, herd sizes, and production conditions ranging from intensive to extensive or rangeland systems. Survey results align with many elements of our holistic model. Farmers view cattle as sensitive beings that react fearfully to aversive stimuli. Their main objective is to keep animals calm during handling, which improves both safety and efficiency. Improved animal welfare is sometimes explicitly mentioned. Reported relational strategies include culling difficult animals, accustoming cattle to human contact when time allows, and relying on calm, consistent behaviour supported by adequate handling facilities. European farmers emphasise regular contact, early-life interactions, and temperament-based culling, although positive tactile interactions are less frequently mentioned. The Spanish study highlights that farmers consistently identify cattle responses to unfamiliar people as problematic. Substantial variation exists across stock people and contexts, shaping both the feasibility and perceived value of relational practices. These differences raise questions about whether farmers adopt strategic or opportunistic approaches when building relationships with cattle. The literature and surveys show that relational practices can be a key component of work organisation in beef suckler systems, but evidence remains limited. Farmers rarely describe animals as active agents in the relationship, even though some acknowledge having favourite individuals. The model developed here highlights the need for additional surveys in diverse contexts to understand how relational practices emerge, how they interact with system constraints and other farming tasks, to what extent they are recognised as genuine work activities, and how they can be designed most effectively for both farmers and animals. Such insights are essential for developing interventions, training programmes, and breeding strategies that support safer, more effective, and mutually adaptive human–cattle relationships.

Traffic noise exposure alters horse behaviour at pasture

J. Henke-Von Der Malsburg[1,2], U. König Von Borstel[1]
[1] Justus-Liebig-University of Giessen, Animal Welfare, Husbandry and Behaviour, Leihgesterner Weg 52, 35392 Giessen, Germany, [2] Research Institute for Farm Animal Biology (FBN), Working Group Animal Husbandry and Health, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

Horses are pastured to meet behavioural needs for movement. However, for various reasons, pastures are often located close to motorways or busy roads, which exposes horses to constant traffic noise. In humans, pronounced and constant traffic noise is a critical factor that promotes health risks, such as cardiovascular diseases and auditory impairments. Given the horse's evolutionary adaptation as a vigilant and noise-sensitive prey species, chronic anthropogenic noise may lead to similar health issues and, further, interfere with natural behaviour and stress regulation. We investigated how pastured horses are affected by continuous traffic noise and whether habituation to the noise exposure can occur. With portable loudspeakers, we exposed twenty noise-naïve horses from three facilities (four social groups) to controlled motorway playbacks. After an initial habituation day, we collected baseline behavioural data on a pre-exposure day. Then, horses were exposed to traffic noise from 54 to 71 dB, simulating distances of 500 to 10 m to a 3-lane motorway, across two exposure phases, intersected by an intermediate wash-out day. Exposure durations ranged from 4 to 11 hours per day, depending on pasture schedules and local regulations. The order in which the six sound levels were applied was pseudorandomized on a day-to-day basis. After the second exposure phase, we collected data on a final post-exposure control day. Throughout the whole sampling period, we continuously measured the heart rate to monitor the physiological stress response. Behavioural observations quantified foraging, social, comfort, resting, alert, and flight behaviour. Full-reduced model comparisons of linear mixed models confirmed our hypotheses that constant traffic noise exposure alters horse behaviour at pasture and provokes a stress response. Horses reduced foraging time from 81% of the observation time at baseline conditions before traffic noise exposure to 41% during noise exposure ($\chi^2(7, N=216)=43.96$, $p<0.001$). They increased vigilance behaviour from a maximum of nine instances per observation period at baseline conditions to a maximum of 54 instances during noise exposure ($\chi^2(7, N=217)=71.78$, $p<0.001$). Partial behavioural habituation was observed across repeated exposures, with vigilance decreasing over time, though not returning fully to baseline levels (second exposure period: max. 25 instances). Mean heart rate increased during noise exposure (median: +9.97 bpm; $\chi^2(7, N=35320)=1065.07$, $p<0.001$) but remained elevated during wash-out and post-exposure periods, suggesting anticipatory or avoidance-related arousal. Despite signs of behavioural habituation, constant traffic noise affected both activity budgets and physiological state. Importantly, the horses increased the distance to the sound source specifically during louder noise levels ($\chi^2(6, N =217)=18.97$, $p<0.001$), thus decreasing the actually experienced sound pressure. This avoidance behaviour may represent an active coping strategy, mitigating perceived threat. These first findings highlight that exposure to constant traffic noise can compromise welfare in pasture systems and underscore the importance of structural mitigation measures, such as noise barriers, to safeguard horse welfare.

Acoustic relationships between bovine vocalizations and traditional herding songs: implications for human–animal communication and cattle handling under grazing conditions

P. Betancourth-Chaves[1], J. Montoya-Zuluaga[2], N. Alvarez-Hernandez[2], B. Rodriguez[1], D. Vallejo-Timaran[3]
[1] Agrarian Sciences Faculty, School of Veterinary Medicine, University of Antioquia, Pathobiology Research Group – QUIRON, Ciudadela Universitaria Robledo - Universidad de Antioquia, 050036 Medellin, Colombia, [2] Institución Universitaria Visión de las Américas, Faculty of Veterinary Medicine and Animal Sciences, Agricultural Sciences Research Group – GIsCA, Circular 73 #35-04, Laureles, 050031 Medellin, Colombia, [3] Colombian Agricultural Research Corporation - AGROSAVIA, Obonuco Research Center, Km 5 Via Pasto - Obonuco, 520008 Pasto, Colombia

Communication between humans and animals plays a critical role in cattle management, particularly under grazing systems where auditory signals are commonly used to guide animal movement and behavior. Traditional herding songs represent culturally transmitted vocal signals used by farmers to interact with cattle; however, their acoustic relationship with bovine vocalizations under grazing conditions remains poorly understood. This study aimed to compare the acoustic characteristics of bovine vocalizations and traditional herding songs to identify sound patterns that may facilitate human–animal communication during grazing management. A descriptive comparative bioacoustic analysis was conducted using recordings of bovine vocalizations from Bos taurus and Bos indicus cows (n = 50) and traditional herding songs (n = 80) obtained from open-access sources and field recordings. Acoustic parameters were extracted using bioacoustic analysis and Music Information Retrieval (MIR) techniques, including spectral centroid, amplitude, dissonance, zero-crossing rate, and high-frequency content. Differences between vocalizations and songs were evaluated using ANOVA with Bonferroni post-hoc tests (statistical significance set at $P < 0.05$). Multivariate relationships among acoustic features were explored using principal component analysis (PCA). Herding songs exhibited longer durations (e.g., 4.2 ± 1.1 s vs. 1.3 ± 0.5 s; $P < 0.001$) and higher dominant frequencies (>2500 Hz; $\eta^2 = 0.42$; e.g., 2700 ± 350 Hz vs. 1450 ± 210 Hz; $P < 0.001$) with frequencies approximately 85% higher than those observed in bovine vocalizations, whereas bovine vocalizations showed shorter durations and frequencies ranging between 1115 and 1797 Hz. Multivariate analyses identified two distinct acoustic clusters separating bovine vocalizations from herding songs, with songs showing greater spectral variability and a higher proportion of high-frequency components (spectral centroid and high-frequency content, $P < 0.01$). These findings highlight structural differences between human vocal signals and bovine vocalizations while revealing acoustic characteristics that may influence cattle perception of human-generated sounds. The first two principal components explained 63.4% of the total variance. Understanding these relationships provides a quantitative framework for exploring how auditory stimuli used by farmers may affect cattle behavior and communication during grazing management. In addition, the acoustic patterns identified in both bovine vocalizations and herding songs provide a scientific basis for the development of species-adapted auditory stimuli. Such stimuli could be used as environmental enrichment tools to modulate animal behavior and improve welfare in grazing systems and holding areas, including pre-milking waiting pens or handling facilities.
Keywords: human–animal interaction; bioacoustics; herding songs; cattle communication; acoustic signals.

Behavioural indicators of the emotional state of outdoor managed pigs during an animal-human approach test

O. Menant[1], L. Frigerio[1], É. Peyrard[1], L. Boyle[1], K. O'Driscoll[1]
[1] Teagasc, Pig and Poultry Development Department, Animal and Grassland Research and Innovation Centre, P61 C996 Fermoy, Ireland

Evaluating behavioural responses during a human–animal approach test provides insight into the animal's underlying emotional state when confronted with this potentially ambiguous social stimulus. To investigate this, we carried out an Animal-Human Approach Test (AHAT) with an unfamiliar human on 181 pigs in 16 outdoor pig farms from February to May 2023. The AHAT was performed on female, castrated and uncastrated pigs, aged from 3 months to 6 years (~10 pure/mixed breeds across all farms). The test consisted of 3 phases: the 'pig approach' phase (the animal had 30 seconds to approach an unfamiliar human located 2m away); the 'human approach' phase (the human approached the pig slowly if there was no previous contact); the 'scratch phase' (the human attempted to scratch the pig's forehead if there was contact). Scores were applied from 0 (most avoidant, no contact) to 3 (least avoidant, scratch accepted). The tests were video recorded to enable analysis of the following behaviours: Tail position (not recorded when the tail was docked, n = 8), ear position, vocalisation, and locomotion behaviours related to avoidance (run away, turn away, walking backward). Tail position was categorised as up, horizontal or down, curly or straight, loose or wagging. Tucked tails were never observed. Ears could be forward, neutral, backward or asymmetrical. Grunts and screams were also counted. Based on these observations the frequencies of the position of each body area, and of the changes in position were calculated. Analyses were carried out using RStudio (2022.07.02 version). General linear mixed models (glmmTMB package) and type II Anova (car package) were used to investigate the relationship between the AHAT score and each of the behaviours recorded during the test. In general, the frequency of changes in body area position increased with the AHAT score (i.e. there were more changes in less avoidant pigs; $p<0.01$ for each behaviour). The frequency of the tail being up was lower for pigs scoring 3 than 2 ($p=0.035$), which could indicate that more avoidant pigs were more alert. A curled tail (often interpreted as a sign of a positive emotional state) was less frequently observed when pigs scored 1, compared with pigs scoring 2 ($p=0.02$) or 3 ($p=0.06$). A loose tail was more frequently observed in pigs scoring 1 than 0 ($p=0.011$) or 2 ($p=0.009$). The frequency of ears being in a neutral position, which could indicate they were not actively orienting towards a sound, was higher for pigs with a score of 3 than a score of 0 ($p=0.026$). Screams occurred rarely, but more often in pigs with a score of 1 than 0 ($p<0.001$), 2 ($p=0.02$) or 3 ($p=0.001$). The frequency of grunts was higher for pigs with a score of 3 than a score of 0 ($p=0.011$) or 2 ($p=0.026$). The frequency of avoidance locomotion decreased with the AHAT score ($P < 0.05$ for all). These results confirm that body posture, vocalisations, and locomotion behaviours can provide insight into pigs' emotional states during human–animal interactions in outdoor farming systems. Overall, pigs that were less avoidant of humans performed fewer behaviours that are indicative of a state of alertness.

Conflict behaviours and potential "positive" behaviours in horses ridden in a low level training situation in their home setting

I. Czycholl[1], J. Winther Christensen[2], L. Veje Johansen[1]
[1] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 8, 1870 Frederiksberg, Denmark, [2] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark

Recently, a number of studies have highlighted the high occurrence of conflict behaviours (e.g., mouth opening, tail swishing) in competition settings in equestrian sports. This study aimed to evaluate the occurrence of conflict behaviours in horses in a low-level training situation (dressage test of 10 min in all three gaits including circles and volts on both hands) in their home setting. This study further aimed to explore whether conflict behaviour was negatively associated with behaviours proposed to indicate a potential "positive" state in riding horses from the literature (ears pointing forward, snorting, low head-neck position). A convenience sample of 31 horses of different types (Wambloods, Trotters, PRE, Danish Sport Ponies, Welsh Ponies and Mixes), sex (17 geldings, 13 mares, 1 stallion) and age (ranging from 4 to 29 years) took part in the study. The riding sequences were filmed and behaviour observed based on a predefined ethogram (counts of each behaviour). State behaviours (ear positions and head-neck position) were recorded in bouts of 4 sec, i.e., the position should be present for at least 4 sec to be counted, and if the position remained for more than 4 sec, another bout was counted. Effects of sex, age, environment (indoor or outdoor) and gaits on behaviour were analysed using generalised linear mixed models and associations between behaviours using the Spearman rank correlation (ρ). Horses exhibited an average of 5.2 conflict behaviours per minute with open mouth (45.3%) and tail swishing (23.2%) accounting for the majority, aligning with previous findings. Conflict behaviour was not affected by sex, gait or environment. Age, however, was associated with a significant reduction in conflict behaviour ($P=0.01$), with an estimated 4% decrease per year. Horses exhibited an average of 1.5 potential "positive" behaviours per minute with ears forward being the most frequently observed, accounting for 71.3% of the total "positive" behaviour. Potential "positive" behaviours were significantly less frequent in canter compared to walk ($P<0.001$) and in trot ($P=0.04$), with no significant difference between walk and trot ($P=0.14$). Additionally, horses ridden outdoors showed significantly higher rate of "positive" behaviours compared to those ridden indoors, whereas there was no effect of sex or age. Total conflict behaviour was significantly ($P<0.05$) moderately negatively correlated with total "positive" behaviours ($\rho=-0.43$), indicating that horses displaying more positive behaviours tended to show fewer conflict behaviours. In interpretation of the single indicators, it is particularly noteworthy that snorts were often observed directly after a conflict behaviour which might indicate that they are rather seen as a release of tension, i.e. after a conflict occurred than a purely "positive" indicator. Likewise, for example ears forward and total ear movement depended on the context. Ridden behind the vertical was only observed in very low frequency in the present study and ridden above the vertical in the present study setting referred more to a loose frame than a conflict behaviour which should be borne in mind in the interpretation and underlines the effect of the study setting. Overall, the present study highlights the complexity of interpreting behavioural indicators of equine welfare in different settings. A combination of different indicators is likely preferable along with taking into account the specific settings.

Human perception of horses' facial expressions: implications for equine welfare assessment

C. Brunet Claret[1], I. Blanco-Penedo[1,2], S. Sund Hagelberg[3], A. Torra Burgués[1]
[1] University of Lleida, Department of Animal Sciences, Av. Alcalde Rovira Roure, 191, 25918 Lleida, Spain, [2] Swedish University of Agricultural Sciences, Department of Clinical Sciences, Ulls väg 26, 750 07 Uppsala, Sweden, [3] Proyecto Caballo, Más Ferran sn, 17648 Parets d Empordá, Spain

Accurate recognition of emotional states is essential for assessing horse welfare. Facial expressions are increasingly used as non-invasive indicators of animal emotions; however, the ability of humans to correctly interpret these expressions remains poorly understood. Emotional processing involves several brain structures, and facial muscle activation modulates observable expressions according to the internal emotional state. Humans often rely on facial expressions to assess animal welfare; however, misinterpretation may compromise welfare assessment. This study aimed to evaluate how accurately humans perceive horses' emotional states from facial expressions. An online survey based on 20 photographs of horses representing different emotional systems according to Panksepp's emotional framework (discomfort, fear, sadness, anger, pleasure, relaxation and curiosity) was conducted. Images were previously coded using EquiFACS to objectively identify facial action units associated with each emotional state. Participants were asked to identify the emotion displayed in each image and to provide information about their demographic characteristics, experience with horses and frequency of contact, in order to assess whether these factors influenced their ability to correctly interpret the expressions. A total of 250 individuals with diverse backgrounds participated in the survey, including equine professionals (e.g. veterinarians, caretakers, riders and breeders) as well as individuals with no prior experience in analysing facial expressions. The results indicate that some emotions, such as curiosity, were more easily recognised (58% correct responses), whereas frequent confusion occurred between other emotional states, including those of opposite valence. Several participant characteristics influenced recognition accuracy, including age, gender, professional background, prior experience with horses, frequency of observing horses' facial expressions and frequency of contact. Having a profession related to the equestrian sector (58% had equestrian-related professions, of whom 23% were veterinarians) and frequent contact with horses (72% of participants) significantly improved response accuracy ($p < 0.001$), although an overall limitation in emotion interpretation was observed. These findings highlight the limitations of relying solely on human perception to assess equine emotions and emphasise the need to develop more objective and standardised tools to complement human observation and improve the assessment of horse welfare.

Perceptions of equine welfare and the human–horse relationship within the equestrian community

C. Brunet Claret[1], A. Torra Burgués[1], S. Sund Hagelberg[2], I. Blanco-Penedo[1,3]
[1] University of Lleida, Department of Animal Sciences, Av. Alcalde Rovira Roure, 191, 25918 LLeida, Spain, [2] Proyecto Caballo, Más Ferran sn, 17648 Parets d Empordá, Spain, [3] Swedish University of Agricultural Sciences, Department of Clinical Sciences, Ulls väg, 26, 750 07 Uppsala, Sweden

Understanding how people involved with horses perceive equine welfare is essential for improving management practices and strengthening the human–horse relationship. This study analysed perceptions of equine welfare and daily interactions with horses among members of the equestrian community. An online self-report questionnaire was distributed between February and April 2025. The survey included 64 questions (closed questions, Likert-scale items and one open question) addressing perceptions of equine welfare, management practices and human–horse interactions. A total of 189 participants completed the survey, including horse owners, professionals and enthusiasts. Half of the respondents did not work in the equestrian sector, while the most represented professional groups were trainers (17%) and veterinarians (14%). Participants evaluated the importance of the five domains of animal welfare (nutrition, physical environment, health, behavioural interactions and mental state), and demographic variables such as gender, age, professional background and level of knowledge were analysed. Most participants (92%) considered horses to be companion animals or members of the family. Overall, aspects related to the absence of suffering—such as health, nutrition and adequate housing—were rated as highly important. In contrast, welfare dimensions associated with the presence of positive emotional states, including behavioural interactions and agency, were given comparatively lower priority. This suggests that horses' mental and emotional needs are not perceived as equally important as physiological or environmental needs. Gender emerged as the variable with the most marked differences (72% of respondents were women), with women tending to attribute greater importance to both physical and emotional aspects of welfare and reporting more empathetic and respectful practices. Younger participants, individuals not working in the equestrian sector, and those who considered horses as companion animals also tended to prioritise respectful interactions. Regarding the human–horse relationship, 63% of respondents reported that horses frequently initiate interactions with people (e.g., approaching during haltering or seeking tactile contact), and 71% reported regularly engaging in non-riding activities with their horses. Despite generally positive perceptions, respondents identified several barriers preventing welfare recommendations from being fully implemented in practice, including economic constraints, lack of owner knowledge, traditional management systems in equestrian facilities and logistical limitations such as space availability. These findings highlight a gap between recognising the importance of preventing suffering and promoting positive welfare states. Strengthening education and training initiatives that integrate emotional and cognitive aspects of equine welfare may help foster more comprehensive welfare practices and more positive human–horse relationships.

Young EAAP session - impact, career building and workshops

I. Adriaens[1], G. Gislon[2], F. Koch[3], J. Obsteter[4]
[1] CRV BV, Global Information Solutions, Rijksweg-West 2, 6842BD Arnhem, Netherlands, [2] University of Milan, Department of Agricultural and Environmental Sciences - Production, Territory, Agroenergy (DiSAA), Via Celoria 2, 20133 Milan, Italy, [3] Forschungsinstitut für Nutztierbiologie, Arbeitsgruppe Biochemie der Ernährung, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [4] Agricultural institute of Slovenia, Hacquetova ulica 17, 1000 Ljubljana, Slovenia

The Young EAAP session brings impactful topics and speakers to the early career people at EAAP. This year's session consists of 3 parts. In the first part, we handle how we can prepare ourselves and our CV for life after PhD. We will discuss with experienced people in a variety of roles what skills they needed and missed in their current careers. The second part of the session, we will discuss impact in all its facets. We will deal with what types of impact there are (e.g. on the sector/farmer, on people, on an academic audience, etc.), and how we can fit it into our work. Topics that will pass by are e.g. science communication, industry collaborations, etc. As many funding agencies also require to specify "impact" in a research proposal, we will discuss how we can address this during funding acquisition. In the final part of the session, we organize a series of workshops around a variety of topic, including artificial intelligence, large language models, animal welfare, agile working in science, reproducible science and code, talking about failure, how to sell sustainable animal production, leadership and work/life balance. In each, we will interactively and in small groups work around these topics together with other young scientists. Everyone is welcome to join and participate.

Productivity and behavioural monitoring of dairy goats under heat stress conditions

D. Mendez[1], D. R. Yanez-Ruiz[2], A. Gómez[2], B. Farjardo[1], M. Hassan[2], A. Sánchez-Garcia[2], F. Estelles[1], M. Romero-Huelva[2]
[1] Polytechnic University of Valencia, Institute of Technology and Animal Science, Camino de Vera s/n, 46022 Valencia, Spain, [2] CSIC, EEZ, Profesor Albareda, 1, 18008 Granada, Spain

Heat stress compromises dairy goat metabolic homeostasis, behavior and overall productivity. Modernization and production demands require shifting farmer-observation management toward technological approaches. However, digitalization poses challenges, including monitoring in high-density housing and developing robust algorithms that run on devices with limited battery life. Continuous monitoring is particularly critical under heat stress conditions, which severely impact animal welfare and productivity. This study aimed to validate an accelerometer-based behavioral monitoring system and apply it to identify activity patterns affecting milk production under heat stress. Following algorithm validation, a field study was conducted from June to October 2024. Fifty activity collars running the developed algorithm were deployed on multiparous dairy goats. Activity patterns were derived from the labelled behavioral states, specifically “Eating”, “Moving”, “Lying”, “Inactive”, and “Others”, and were recorded as a percentage of activity at an 11-minute temporal resolution. To quantify environmental stressors, meteorological data was retrieved from weather station installed in the farm. Furthermore, intrinsic individual traits, specifically the number of kids at birth and the genetic value of each animal, were collected as baseline predictive features. Intrinsic biological factors established the primary baseline for milk yield, with the animal’s Genetic Value emerging as the dominant predictor, followed by the number of kids at birth. This indicates that individual baseline potential is the strongest anchor for the predictive model. Environmental conditions showed to be a dynamic factor modulating this baseline. Notably, the THI recorded during the night ranked as the second most important feature overall. Furthermore, its historical lags dominated the top tier of predictors, suggesting that the physiological toll of poor nighttime recovery is a far more critical determinant of next-day production than daytime heat peaks. Random Forest analysis demonstrated that while intrinsic biological traits, specifically genetic value, are the primary drivers of milk yield, environmental conditions act as critical dynamic modulators. Notably, nighttime THI and its historical lags were stronger predictors than daytime heat peaks, emphasizing that inadequate nighttime physiological recovery severely impairs subsequent production. Although accelerometer-derived behavioral metrics provided useful predictive fine-tuning, they remained secondary to genetic and thermal factors. Ultimately, the model reliably tracked herd productivity trends, highlighting the potential of wearable sensors and machine learning to optimize dairy goat management under heat stress.

Feeding preferences of sheep grazing dryland pastures in Montado: influence of crude protein and neutral detergent fiber

E. Carreira[1], J. Serrano[1], F. G. Silva[1], N. Borges[1], E. Mata[1], M. Cruz[1], M. Braz[1], S. Travessa[1], A. Geraldo[1], R. Silva[2], R. Charneca[1], A. Pereira[1]

[2] ANCORME – Associação Nacional de Criadores de Ovinos de Raça Merina, Tv. João Rosa 1a, 7005-665 Évora, Portugal

Selective grazing behaviour in sheep not only affects animal performance but also has implications for animal welfare. Nutritional adequacy and access to preferred forage influence physiological and behavioural well-being. This study evaluated how crude protein (CP) and neutral detergent fiber (NDF) affect feeding preferences of sheep grazing Montado pastures under unrestricted biomass availability. The study was conducted at the ECO-SPAA experimental field, located at Herdade da Mitra (University of Évora, Portugal). A 4-ha area was subdivided into four experimental paddocks subjected to different treatments (with or without dolomitic limestone application × two stocking rates: 1 LU/ha and 2.5 LU/ha). In each paddock, 12 sampling points representing the existing botanical communities were previously identified, georeferenced, and physically marked. Field observations were carried out during four periods in 2024 (P1 – 20 March, P2 – 18 April, P3 – 13 May, and P4 – 20 June). On these dates, grazing locations of the animals were georeferenced and recorded by trained observers using binoculars at 10-minute intervals from sunrise to sunset. On the day preceding each observation period, pasture height was measured and samples were collected for laboratory determination of CP and NDF concentrations. Results showed that during P1 (CP > 14% at all sampling points) and P4 (CP < 10% and NDF > 59% at all sampling points), CP and NDF concentrations did not appear to influence grazing preferences, although selective grazing behaviour was observed across all treatments. However, during intermediate observation dates (P2 and P3), when CP showed high spatial variability (approximately 8–20%) and NDF variability was relatively low (45–56%), sheep exhibited selective grazing, preferentially grazing areas with higher CP and lower NDF concentrations. These results indicate that: (i) under conditions of high biomass availability, selective grazing occurred in all treatments, even at higher stocking rates; (ii) sheep preferentially selected areas with higher CP when spatial variability in CP was high within paddocks; and (iii) NDF concentration did not appear to significantly influence grazing preferences. These insights can guide pasture management strategies that promote both performance and animal well-being. Funding: This work is funded by National Funds through FCT – Foundation for Science and Technology under the Project UID/05183/2025.

Managing genetics of resistance to parasites in goats: Reviews at different scales of diversity to implement agroecological breeding systems in the tropics

C. De La Cruz[1], J. C. Bambou[1], N. Mandonnet[1]
[1] INRAE, ASSET UR0143, Domaine de Duclos, 97170 Petit-Bourg, Guadeloupe

In tropical and subtropical regions, agricultural economies are strongly supported by goat production. Ensuring the sustainability of farming households' incomes in such low-input systems requires achieving a balance between the environment and the animals. Livestock farming practices now emphasize the genetic adaptation of animals to their environment rather than environmental modification. In this context, gastrointestinal nematode (GIN) infections represent a major limitation to goat production in the tropics. The agroecological approach is to make use of the genetic variation that allows some goats to cope better with infection although this genetic resistance of goat to GIN is sometimes debated. We conducted Systematic reviews of exploitable genetic diversity at different levels, including the genome, the population, and the breeding system. Following PRISMA guidelines, we searched Web of Science, PubMed and Scopus (December 2025) and selected studies that either (1) identified genomic regions linked to resistance, (2) estimated genetic parameters for resistance or resilience traits and (3) studies conducted on ruminants that assessed GIN infection in multi-species or mixed grazing system, and reported the level of system resistance/resilience within agroecological, low-input, or locally adapted production systems. At the genomic scale, data were extracted from 26 selected studies including 29 breeds across nine countries, and identifying 52 candidate genes or genomic regions associated with resistance traits, including fecal egg count, packed cell volume, and immunoglobulin levels. At the population scale, 38 studies were included representing 30 breeds distributed across tropical, humid subtropical, temperate and hot semi-arid climates zones. At the system scale we reviewed x studies that examine how differences in GIN resistance between ruminant species can be used to design more resilient agroecological grazing systems. Gene prioritization analysis using ToppGene identified 8 high-confidence candidate genes. Functional enrichment analysis revealed significant enrichment of the immune-related biological processes, leukocyte activation, cytokine signaling, pathogen recognition, and immune receptor activity. A comprehensive and quantitative meta-analysis of genetic parameters for resistance to GIN in goats revealed a global heritability estimate for resistance of 0.25 ± 0.06 from 18 studies including 20 breeds. A meta-regression analysis was performed in order to test the influences of latitude, age, infection type, statistical method, or maternal effects on genetic parameters. The first conclusion of our analysis is that resistance to GINs in goats has a relatively stable genetic basis, consistent with that obtained for sheep. The approaches at the herd scale include mixed-species grazing, adaptive management strategies and the integration of resistant breeds to strengthen system robustness. Our study provides consolidated knowledge to integrate genetic diversity in resistance to GIN in goats across multiple scales (gene, population, herd) in tropical environments. These constitute key levers for sustainably improving the productivity of low-input goat production systems facing parasitism.

Evaluation of Haemonchus contortus-derived extracellular vesicles in modulating sheep immune response in vitro

Y. Dadi[1], M. Penati[1], S. Zanzani[1], L. De Matos[2,3], G. Salvi[1], R. I. Lazar[2], S. Cavallero[4], I. Bellini[4], F. Ceciliani[1], C. Lecchi[1,2], A. Gazzonis[1]

[1] University of Milan, Department of Veterinary Medicine and Animal Science, Via dell'Università 6, 26900 Lodi, Italy, [2] MOOVET DXC S.r.l., Precision Diagnostics LAB for Animal Health – Spin-off of the University of Milan, Department of Veterinary Medicine and Animal Science, Via dell'Università 6, 26900 Lodi, Italy, [3] Universidade Estadual de Campinas (UNICAMP), Department of Food Science and Nutrition, School of Food Engineering (FEA), Rua Monteiro Lobato, 80, SP, 13083-862 Campinas, Brazil, [4] University of Rome, Sapienza, Department of Public Health and Infectious Diseases, Piazzale Aldo Moro 5, 00185 Roma, Italy

Gastrointestinal helminths, particularly Haemonchus contortus, are major constraints to small ruminant health. Their survival is associated with excretory/secretory products, including extracellular vesicles (EVs), which act as key mediators in host-parasite communication. However, the interaction between H. contortus EVs and ovine innate immune cells remains poorly understood. This pilot study evaluated the ability of adult H. contortus EVs to modulate the in vitro immune response of sheep CD14+ monocytes. Adult parasites were recovered from the abomasum of sheep at slaughter. Following 24-h incubation in serum-free RPMI, EVs were isolated from the supernatant by sequential centrifugation, ultracentrifugation, and size-exclusion chromatography. Vesicles were characterized by nanoparticle tracking analysis and cryo-electron microscopy. CD14+ monocytes, isolated from ovine peripheral blood using Percoll gradients, were exposed to various EV concentrations. Assessment included MTT cytotoxicity assays, confocal microscopy for EV uptake, cytokine quantification (ELISA), gene abundance (qPCR), ROS production (cytochrome C assay), and apoptosis evaluation (Caspase 3/7). Data were analyzed using Shapiro-Wilk, ANOVA, or Kruskal–Wallis tests ($p<0.05$). Results showed that isolated EVs displayed typical EV-helminth morphology and were successfully internalized by monocytes. Exposure to non-cytotoxic concentrations induced measurable modulation of immune parameters. Significant variations in cytokine production, gene expression, ROS generation, and apoptosis were observed compared to controls. These findings indicate that H. contortus EVs interact with ovine monocytes to alter innate immune functions, providing a methodological basis for further mechanistic studies on parasite-driven immune modulation.

Genetic parameters for resistance to Small Ruminant Lentivirus (SRLV) in an experimental flock of dairy goats

R. Rupp[1], C. Roy[1], T. Fassier[2], G. Tosser-Klopp[1], I. Palhière[1]
[1] INRAE, GenPhySE, 24 chemin de Borde Rouge, 31326 Castanet-Tolosan, France, [2] INRAE, P3R - Domaine de la Sapinière, 18390 Osmoy, France

Lentiviral infections are responsible for chronic diseases that progress to severe clinical forms, such as arthritis in the case of caprine CAEV and lung disease in the case of ovine VISNA-MAEDI. There is currently no vaccine or cure for lentiviral infections, and eradication is impractical given their high prevalence. Literature from the last decade suggests that predisposition to lentiviral diseases in small ruminants has a genetic component. A major gene controlling seroprevalence has been identified in sheep. Knowledge of the genetic determinants of response to SRLV in goats is scarce. The objective of the present study was to estimate genetic parameters for SRLV-related phenotypes in a large-scale dairy goat herd. The data were collected from an INRAE experimental farm (P3R Bourges), where a herd of Alpine goats was observed over three years. Two complementary phenotypes of the goats' response to SRLV were measured once per year: i) seropositivity using a commercial ELISA test, and ii) presence of arthritis in the front carpal joints, reflecting the progression of the infection towards clinical signs (tolerance). To measure arthritis, we took circumference readings of the carpal and metacarpal bones using a tape measure. The Monicat score corresponds to the difference between the largest carpal bone circumference and the smallest metacarpal bone circumference. Arthritis is diagnosed if the Monicat score is 6 cm or greater (binary trait: presence/absence). Of a total of 1,106 individual measures from 578 goats, the seroprevalence was found to be 53.2%, and the prevalence of arthritis was found to be 34.6%. Both seroprevalence and arthritis increased with age, rising from 36% and 33%, respectively, in one-year-old goats to 94% and 59% in goats over four years old. Heritability was estimated by REML using a linear repeatability animal model with the wombat software. The pedigree comprised 1,841 animals. Heritability was equal to 0.10 (±0.06) for seroprevalence. Heritability for arthritis was 0.21 (±0.07) for the Monicat score and 0.13 (±0.05) for the binary outcome. The Pearson correlation of the estimated genetic values of seroprevalence with the two arthritis traits was then computed. The correlation ranged from 0.18 to 0.27, suggesting that the response to infection and the disease's clinical outcome (tolerance) are different genetic traits with different underlying mechanisms and genes. Taken together, these results suggest that there is a genetic component to the response to infection and the clinical form of SRLV, paving the way for future breeding control programmes.

Dairy goat welfare: Towards a welfare monitor with more animal-based welfare indicators

F. Marcato[1], K. Peterson[3], F. Neijenhuis[1], J. Roskam[2], J. Verkaik[1]
[1] Wageningen Livestock Research, De Elst 1, 6708 WD Wageningen, Netherlands, [2] Wageningen Economic Research, Droevendaalsesteeg 4, 6708 PB Wageningen, Netherlands, [3] Royal GD Animal Health, Arnsbergstraat 7, 7418 EZ Deventer, Netherlands

The Dutch dairy goat sector is currently working on ways to improve the sustainability. In this context, an animal welfare monitor included as part of the Sustainable Goat Dairy Chain has been developed in the past years. In the light of recent developments and new insights in the field of animal welfare, the sector needed an evaluation of the existing animal welfare monitor and advice on further development in the direction of an animal welfare monitor with more animal-based welfare indicators. Thus the aim of this project was, with the existing animal welfare monitor as a starting point, to develop a new animal welfare monitor for dairy goats with the inclusion of more animal-based indicators. The 13 indicators of the existing monitor were mainly focused on stable design and management factors. Despite their relevance, they are not animal-related and therefore do not provide a factual insight into the welfare of the dairy goats on a specific farm. The inclusion of animal-based welfare indicators in the current monitor was therefore desirable. A literature study and an analysis of existing well-being monitors have resulted in a longlist of well-being indicators. The animal-based indicators of the longlist have been classified and assessed for validity, feasibility and reliability. This review against the literature formed the basis for an expert selection of a list of ten animal-related indicators, consisting of 1) hair and skin condition, 2) thermal comfort (prevention of heat stress), 3) thermal comfort (prevention of cold stress), 4) healthy udder, 5) eye/nose discharge, 6) clean hindquarters, 7) smooth gait, 8) intact skin of the head, limbs and body, 9) alert and social animals and 10) mortality in goat kids and adult goats. In addition to the indicators on the longlist, the ten selected animal-based indicators have been classified according to the six guiding principles for animal-worthy livestock farming, drawn up by the Council for Animal Affairs in the Netherlands. A protocol has been developed to test the selected animal-based welfare indicators. The draft protocol has been tested on five Dutch dairy goat farms. Based on the findings, the protocol was evaluated after each visit and adjusted in the interim where necessary. In the development of the protocol, thermal comfort, social animals, and mortality were not measured for practical reasons. The final protocol was tested at two farms to obtain data for testing repeatability between and within observers. Goats were assessed in 3 ways: in a separation pen, during walk along, or via pictures. The walk-along scores of all indicators were low (intraclass correlations for intra- and inter-observer < 0.40). For the separation pen and pictures the degree of repeatability between observers was qualitatively divided into the categories poor, minimal, fair and good across all statistics used (percentage agreement, PABAK, Cohen's Kappa, or Gwet's AC1). Wounds abnormal gait, nasal discharge and coat condition have been identified as well-being indicators with both a high estimated well-being impact and good repeatability. Abnormal gait is an indicator easily repeatable on the basis of a limited number of observations in which abnormal gait has been observed at the front legs (this could not be estimated for the back legs). Reliability scores of lameness, signs of inflammation, diarrhoea, presence of swelling, and itching could not be estimated because the prevalence was too low (<2.5%), however these indicators need further attention as they have a high impact on well-being.

Effects of a higher colostrum intake on health and growth of goat kids in their first 12 weeks after birth

F. Marcato[1], A. Brinkman[1], T. Van Hattum[1], J. Verkaik[1]
[1] Wageningen Livestock Research, De Elst 1, 6708 WD Wageningen, Netherlands

Respiratory problems are the most common health issue in goats, and particularly in goat kids in the first weeks of their life. Respiratory diseases can be caused by various infectious agents, but they depend also on management strategies, including provision of a sufficient quality and quantity of colostrum. This study investigated the effects of higher colostrum intake on goat kid health and growth in the first 12 weeks after birth. It was hypothesized that a higher colostrum intake in the first 24 hours after birth would lead to fewer clinical signs and better growth in goat kids compared to a standard colostrum intake. A total of 5 Dutch goat farms with kidding season in May-June and September were selected for the study. A total of 678 goat kids (average birth weight: 3.56 kg ± 0.02) originating from these farms were included in the experiment and they were assigned to one of these two treatments: 1) control group (CON): received an amount of colostrum of 15% of body weight (BW), and 2) experimental group (EXP): received an amount of colostrum of 22.5% of BW. In each farm, the CON and EXP groups were housed separately in two different compartments with similar climate and management. The first colostrum feeding was provided as soon as possible after birth (with a maximum of 3 hours after birth). The other feedings had to be fed within 24 hours at the latest. Clinical health assessment and BWs were measured at birth and in week 2, 4, 6, 8, 10 and 12. Use of medications and mortality were recorded. Clinical health data were analyzed as binary variables (0= normal and 1= with a clinical problem) with a generalized linear mixed model (GLIMMIX), whereas average daily gain and BWs were analysed with a linear mixed model. Both models included fixed effects of treatment (CON vs. EXP), farm (1 to 5) and their interaction. Treatment did not affect absolute BW and overall growth, but there was a significant treatment × farm interaction ($P<0.05$). The prevalence of clinical problems was overall low (3.2%), and the number of goat kids with nasal discharge during the whole experiment was lower in the CON group than in the EXP group ($P=0.01$). The number of animals treated three (5.1% vs. 2.4%) or more times (2.6% vs. 0.3%) was higher in the EXP group, but the number of group treatments was higher for the CON group than for the EXP group (6 vs. 2). The results of the current study did not match expectations and the hypothesis over the beneficial effects of feeding more colostrum was not proven, with the exception of one farm. This was likely an effect due to the inclusion of farms with above-average management and the kidding season (not in winter), which also might have contributed to a lower prevalence of health problems. Additional research is recommended, especially to determine the effects of a higher colostrum amount in the longer term.

Examining the relationship between somatic cell score, test day milk, and milk composition in different stages of lactation in Cyprus Damascus goats

L. Koniali[1], G. Hadjipavlou[1]
[1] Agricultural Research Institute, Animal Production, P.O.Box 22016, 1516 Lefkosia, Cyprus

For several goat breeds, including Cyprus Damascus goats, the relevance of somatic cell count (SCC)-based selection and the establishment of specific threshold values to differentiate between healthy and pathological milk SCC have not been clearly defined. Therefore, the objective of this retrospective longitudinal study was to study SCC fluctuations during lactation and to examine the relationship between varying SCC levels, test day milk and milk composition at different stages of lactation in Cyprus Damascus goats. Data were obtained from the Cyprus Damascus goat research herd of the Agricultural Research Institute between November 2021 and March 2025 and included 513 lactations from 269 dams, with records collected during early (50-55 days), mid (81-86 days) and late (113-117 days) stages of lactation. For statistical analysis, the SCC distribution was normalized using a logarithmic transformation to somatic cell score (SCS). Mixed linear models were employed to analyze test-day milk and composition traits in relation to SCS levels, categorized into 6 classes based on their deviation from the mean. Separate analyses were conducted for primiparous and multiparous goats. Throughout lactation, multiparous goats exhibited significantly higher SCC and test-day milk than primiparous goats (mean SCC values of 1.48×10^6cells/mL in primiparous goats and 1.97×10^6cells/mL in multiparous goats ($p< 0.05$)). In primiparous goats, the mean SCC ranged from 1.29×10^6cells/ml in early lactation, 1.66×10^6cells/ml in mid-lactation, and 1.49×10^6cells/ml in late lactation, whereas in multiparous goats, mean SCC ranged from 2.27×10^6cells/ml, 1.57×10^6cells/ml, and 2.06×10^6cells/ml across the respective stages. In primiparous goats, test day milk ranged from 1.35 kg/day in early lactation, 1.34 kg/day in mid-lactation, and 1.24 kg/day in late lactation, whereas in multiparous goats, test day milk ranged from 2.12 kg/day, 1.80 kg/day, and 1.62 kg/day across the respective stages. SCS exhibited a significant negative correlation with test day milk in multiparous goats during both early ($r = -0.14$, $p< 0.01$) and mid-lactation ($r = -0.17$, $p< 0.001$), whereas no significant relationship was detected in primiparous goats. When comparing goats with low SCS (classes 1–2) to those with high SCS (classes 5–6), no significant relationship was observed in primiparous goats, while multiparous goats with elevated SCS produced significantly less milk compared to those with lower SCS, with daily milk losses reaching 0.46 kg/day in early lactation ($p<0.05$), 0.37 kg/day in mid-lactation ($p<0.05$), and 0.24 kg/day in late lactation. Similarly, SCS was negatively corelated with lactose concentration, with the relationship being significant throughout early ($r = -0.10$, $p< 0.05$), mid ($r = -0.25$, $p< 0.001$) and late lactation ($r = -0.26$, $p< 0.001$) in multiparous goats and only in mid-lactation in primiparous goats ($r = -0.19$, $p< 0.05$). Conversely, SCS was positively correlated with milk protein concentration, with significant associations observed in multiparous goats throughout early, mid, and late lactation ($r = 0.21–0.24$, $p< 0.001$) and only in late lactation in primiparous goats ($r = 0.20$, $p< 0.05$), indicating that higher SCS is associated with milk compositional changes, particularly in older goats.

Sheep Pox outbreaks in Bulgaria: Epidemiological spread and socio-economic impacts on the sheep farming sector

D. Dimov[1], P. Zhelyazkova[2], A. Vuchkov[1], K. Kolev[3]
[1] Agricultural University, Faculty of Agronomy, Trakia, bl."Mendeleev" 12, 4000 Plovdiv, Bulgaria, [2] Breeding Association of Maritza Sheep Breeds, 69 Konstantin Velichkov str., 4000 Plovdiv, Bulgaria, [3] Bulgarian Food Safety Agency, Sofia, Bulgaria, Directorate "Health, Identification and Animal Welfare", 15 A Pencho Slaveykov Blvd., 1606 Sofia, Bulgaria

In 2025, Bulgaria experienced a substantial wave of sheep pox outbreaks, posing serious challenges for disease control and the sustainability of the national sheep sector. The disease may have been introduced through neighboring Greece, where 1 539 outbreaks were reported during the same period. This study examines the epidemiological spread of sheep pox in Bulgaria and evaluates its socioeconomic consequences for the sheep and goat sector. Official data and field information from affected municipalities and regions for the period 01 January–31 December 2025 were used to assess both the geographical distribution of the disease and the impact of control measures on livestock production. Between 1 January and 31 December 2025, a total of 192 outbreaks were reported in 7 administrative regions, affecting 26 municipalities and 83 settlements in the country. According to the Animal Disease Information System (ADIS), 23 305 small ruminants were stamping out, including 21 968 sheep and 1 337 goats, as part of disease control measures. The Plovdiv region was the most severely affected, accounting for 143 outbreaks (75% of all cases). Public expenditures related to outbreak eradication, including veterinary interventions, carcass disposal and farmer compensation, reached approximately €15 million. Beyond these direct losses, significant economic and structural consequences were observed. Farmers experienced the loss of breeding animals, disruption of production cycles and reduced milk output in country, resulting in income losses and decreased farm viability. At sector level, field data indicate substantial reductions in valuable native sheep breeds, including population declines of approximately 30% in Patch-faced Maritza breed and 43% in White Maritza breed whose natural range is in the center of the sheep pox outbreak, increasing the risk of genetic erosion and potential breed extinction. Prolonged restrictions on the re-population of 192 affected holdings, lasting nearly one year—have further intensified these effects by limiting the recovery of production capacity of sheep farms and native sheep genetic resources, and by increasing the risk of sheep farm abandonment and transition to non-agricultural activities or beef cattle breeding. The management of the outbreaks also revealed competing policy priorities of the government, including the protection of export markets for sheep milk products and growing concerns regarding animal welfare and the preservation of sheep populations. In Bulgaria, control strategies were based on procedure of stamping-out and sheep and goat movement restrictions, without the use of vaccination, raising questions regarding the effectiveness of current control approaches under field conditions. Balancing effective sheep pox disease control with the long-term sustainability of the sheep sector therefore remains a key challenge for future livestock policy.

Cooperative handling strategies for group-housed sheep: Short-term training to improve welfare during routine procedures

J. Henke-Von Der Malsburg[1], A. Vernunft[1]
[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

Sheep are typically held in large groups and are consequently managed less at the individual level. In contrast, smaller flocks more often permit individual-based handling. Nevertheless, essential husbandry procedures—health checks, clipping, and claw trimming—require individual restraint. As prey animals, sheep are highly susceptible to stress, particularly when isolated or physically fixated. Although their relatively small size and light weight allow manual restraint (requiring manpower), such procedures remain markedly stressful for the individual. We evaluated an alternative, cooperative handling approach for group-housed sheep, emphasizing resilience, motivation, attention capacity, and tolerance of human contact, essential for a research environment. Special consideration was given to species-typical behavioural characteristics, including intense group cohesion, easily triggered flight responses (initiated by the focal or conspecifics), variable individual flight distances, differences in boldness and motivation, threatening behaviour, and learned aversion or blocking. Two structured training protocols were implemented consecutively in a group of eight sheep over a two-week period using repetitive short sessions of approx. 8 min per animal (5–15 min). Before the training phase, the sheep had not been subjected to any behavioural training. However, they were routinely handled for health checks, incl. clipping and claw trimming, and pasture change, which were described as stressful conditions with high arousal and the necessity of several people for individual fixation. Thus, the first training aimed at sheep-induced voluntary contact through an advance-and-retreat paradigm combined with pleasant tactile stimulation (e.g., tickling) as positive reinforcement to counteract previously experienced negative interactions. The second training focused on haltering to allow loose fixation and leading. All training sessions were videotaped, and the progress was scored based on achievements (e.g., approach, touching the nose). Initially, all sheep showed high arousal, flight behaviour, and partly threatening behaviour, resulting from previous negative and limited experiences with humans. After the two weeks, all eight sheep were reliably caught in a self-motivated way and haltered within 10–60 seconds. Two individuals accepted haltering within the first 2 days (min. training time: 1 h), whereas the most sceptical individual required 13 days (max. training time: 3.75 h). Based on the observations, progress likely depended on individual expectations, prior experience, and the degree of bidirectional communication established during training. Essential for the sheep's improved tolerance were respecting their individual capacity for cooperation and reliable human behaviour. After the two weeks, the training effects generalized to other handlers, particularly in less sceptical and bolder individuals. All eight sheep displayed reduced arousal during routine health checks, despite necessary group trapping. In conclusion, cooperative care in group-housed sheep can be time-effectively integrated into daily routines using structured, low-intensity sessions. Its potential to reduce stress responses, facilitate handling, and decrease manpower, equipment use, and restrictive fixation techniques is now further investigated by implementing it into daily routines by the animal caretakers. Cooperative flock management represents a practical, welfare-oriented strategy. It provides a future perspective for refining key management practices in sheep production systems and in other environments where sheep need to be handled individually, such as livestock shows.

Impact of dietary supplements, breed and lactation stage on milk somatic cells count in sheep and goats

M. Farina[1], A. Cesarani[1,2], A. Nudda[1]
[1] University of Sassari, Dipartimento di Agraria, Sezione di Scienze Zootecniche, Viale Italia, 39, 07100 Sassari, Italy, [2] University of Georgia, Department of Animal and Dairy Science, GA, 30602 Athens, United States

Somatic cell count (SCC) is a key indicator of udder health in dairy small ruminants and strongly influences milk yield, quality, coagulation properties, and cheese yield. Previous studies have examined the effects of breed, lactation stage, and nutritional strategies, particularly dietary supplementation with oils or agro-industrial by-products, on SCC. However, results are not univocal, and a comprehensive comparison across studies is lacking. The aim of this study was therefore to evaluate, through a literature-based analysis, the impact of some factors as dietary supplementation, breed, and lactation stage on milk SCC in sheep and goats. A literature review was conducted using following keywords: somatic cell count, SCC, sheep and goat nutrition, milk quality, by-products, and oils. Review papers and studies lacking milk analysis were excluded, resulting in 32 eligible publications. Log-transformed SCC values (LogSCC) were extracted from 14 sheep and 18 goat studies published between 2006 and 2022. Data were analysed separately for sheep and goats using mixed models including lactation stage and supplementation type (oil or by-product) as cross-classified fixed effects and article as a random effect. A reduced model was also run for the three sheep breeds represented in more than one study (Sarda, Chios, Comisana; 10 articles), with breed added as a fixed effect. Supplementation type did not significantly affect LogSCC in any analysis. Lactation stage was significant only for sheep, with early lactation showing higher LogSCC than mid or late lactation. Among breeds, Chios sheep had the highest LogSCC (6.33 ± 0.20), followed by Comisana (4.32 ± 0.17) and Sarda (3.91 ± 0.12). In conclusion, dietary supplementation with oils or agro-industrial by-products does not appear to be an effective strategy for reducing SCC in sheep and goat milk. Greater attention is particularly required during early lactation, when the mammary gland is exposed to increased physiological stress due to the natural modulation of immune defence mechanisms associated with the abrupt transition to machine milking. If not properly managed and cleaned, machine milking may also act as a vehicle for pathogen transmission. Breed effects were detected only in sheep, suggesting that genetic background, production level, and farming system may contribute to differences in SCC. CMT Scoring of ewe milk 15-70 days after lambing as an indicator for mastitis in commercial meat sheep flocks

J. H. Jakobsen[1], V. Tømmerberg[2], L. Hektoen[3], H. B. Olsen[1], M. O. Gløersen[1], I. A. Boman[1], S. Svendsen[2]
[1] Norwegian Association of Sheep and Goat Breeders, Moerveien 2A, 1430 Ås, Norway, [2] Norwegian Meat and Poultry Research Centre, Box 396, 0513 Oslo, Norway, [3] Norwegian University of Life Sciences, Box 64, 1431 Ås, Norway

Statistics from the Norwegian Sheep Recording System (SRS) indicate mastitis as the main culling reason for Norwegian White sheep (NWS). An average case is costly and includes deaths of both ewe and lambs, reduced weight gain of lambs, replacement costs, extra work and treatment costs. It is thus very important for the industry to improve resistance against mastitis. High milk somatic cell counts in the milk are an immune response to a bacterial infection. The California Mastitis Test (CMT) is a relatively easy field test to use for the categorization of milk somatic cell levels. The test is frequently used in dairy cattle, but less frequently in meat sheep. The aim of the current study was to investigate if CMT scoring of ewe milk 15-70 days after lambing can be used as an indicator for mastitis. CMT was performed by mixing CMT liquid with milk in a small testing plate and categorizing the milk somatic cell level on a leveraged scale from 0 to 4 depending on the reaction between the milk and the CMT liquid. The typical production cycle of Norwegian meat sheep includes indoor lambing in early spring, grazing cultivated pasture around the farm from around 2-3 weeks of age of lambs, outfield pasture during summer, gathering of sheep from outfields in early September and grazing cultivated pasture around the farm during the fall. Recording flocks in the Norwegian breeding system are required to weigh lambs at birth, during spring (15 – 70 days of age), and at weaning (90 – 180 days of age) as well as to record the reason and date of death/culling of the ewe. Registrations should be stored in the SRS. As a part of a field study, 34 of the recording flocks were asked to check ewes for scars on the udder and teats, udder lumps, and to perform CMT scoring of the milk of the ewes 15 – 70 days after lambing and prior to release on outfield pasture. Udder lumps were scored in three categories: no lumps, lumps smaller than 4 cm, and lumps larger than 4 cm. Recordings should be done separately from both mammary glands and the highest score kept for further analyses. Average daily gain (ADG) of the litter from birth to spring weighing was computed as the sum of ADG over lambs divided by litter size. Both biological lambs and fostering lambs were included. In total, 1865 NWS ewes participated in the study. The risk ratio showed an almost 4- and 7-times larger risk, respectively, of being culled due to mastitis if the ewe had CMT-scores of 3 and 4, respectively, in at least one of the mammary glands at CMT scoring during the spring, indicating CMT scores 3 and 4 as possible early indicators of culling due to mastitis prior to the next lambing season. Also, a larger proportion of CMT scores of 3 and 4 were associated with udder lumps larger than 4 cm compared to lower CMT-scores. Least square means of average daily gain of the litter from birth to spring weighing corrected for herd, age at spring weighing, age of dam, litter size at spring weighing, and average gender of the litter show reduced ADG of lambs of higher CMT-scores, with a difference of 49 gram between CMT-score 0 and CMT-score 4. Despite the fact that field responses indicated challenges in milking the ewes, and in some cases in performing of the CMT scoring, we conclude that CMT score performed 15-70 days after lambing can be used to identify elevated milk somatic cell counts (mastitis), leading to reduced daily gain of lambs from birth to spring weighing as well as a larger risk of the ewe being culled due to mastitis prior to next lambing season.

Blood Transcriptome and Immune Cell Profiling Highlights Host Defence Variations in Naïve and Immune Goats infected with Gastrointestinal Nematodes

C. De La Cruz[3], H. Aboshady[1], M. Rashid[2], X. Godard[4], D. Romil-Granvilled[4], N. Mandonnet[3], Y. Felicite[3], J. C. Bambou[3]

[1] Faculty of Agriculture, Cairo University, Animal production department, 2696+J87, Inside Cairo Uni, Oula, Al Giza, 12619 Giza, Egypt, [2] Agricultural Research Center, Regional Center for Food and Feed, 9 El Gamma Street, 12619 Giza, Egypt, [3] INRAE, ASSET UR0143, Domaine de Duclos, 97170 Petit-Bourg, Guadeloupe, [4] INRAE, PTEA UE1294, Domaine de Duclos, 97170 Petit-Bourg, Guadeloupe

A major economic and health concern in small ruminant production is gastrointestinal nematode (GIN) infection. The aim of this study was to compare the blood transcriptome of naïve and immune goats at different time points after Haemonchus contortus, as well as the abomasal mucosa and lymph node transcriptomes at late infection. Besides, identify the immune cell profiling variation between naïve and immune kids from transcriptome data, in order to identify different pathways and immune cell variation involved in the host defence. Naïve and immune Creole kids were orally infected with 10,000 H. contortus infective larvae (L3), and blood was sampled at 0, 3, 8,15, 21, 35 and 49 days post-infection (dpi). At 49 dpi, all the animals were slaughtered and abomasum and lymphe node tissues were collected. RNA-seq analysis showed that the highest number of different expressed genes (DEGs) was recorded when comparing immune versus naïve at 35 dpi, while the wider range for log2 fold change was recorded at 21 dpi. Results for canonical pathways showed that inhibition of matrix metalloproteases, leukocyte extravasation signalling, oncostatin M signalling and glioma invasiveness signalling pathways were significantly different between naïve and immune kids at early infection time in blood. Meanwhile, at 49 dpi, there was no identified different pathways when compare immune versus naïve kids at abomasum tissues level. In the other side, at lymph node level, several immune and cell healing pathways were significantly different between immune and naïve kids. Principal components analysis explained 74%, 66% and 71% of the variance in immune and naïve animals based on immune cell types identified from differentially expressed genes (using CIBERSORTx) at 49 dpi in blood, abomasum and lymph nodes tissues, respectively. Deconvoluted transcriptomic data showed that blood B cells were significantly higher in immune kids at different time points post infection compared with naïve kids. Meanwhile, CD4 and CD8 T cells proportions depend on the tissue examined and the time post-infection reflecting the development of the immune response. In conclusion immune cells proportion could serve as a reliable indicator of a developed immune response against GIN.

Bioclimatic profile of the rearing areas of local sheep breeds in Montenegro defined by multivariate analysis

B. Markovic[1], M. Djokic[1], M. Zorc[2], I. Curik[3], S. Mirecki[1]
[1] University of Montenegro, Biotechnical Faculty, Mihaila Lalica 15, 81000 Podgorica, Montenegro, [2] University Ljubljana, Biotechnical Faculty, Jamnikarjevi 101, 1000 Ljubljana, Slovenia, [3] University of Zagreb, Faculty of Agriculture, Svetošimunska cesta 25, 10000 Zagreb, Croatia

Montenegro possesses a significant diversity of autochthonous sheep breeds adapted to unique and contrasting geographical landscapes, ranging from Mediterranean coastlines to high alpine massifs. Understanding the bioclimatic specificities of these breeding areas is crucial for defining the adaptive capacities of local populations. Autochthonous sheep breeds in Montenegro represent a key component of national livestock biodiversity, developed through long-term adaptation to specific agro-ecological conditions. This study aimed to precisely define the bioclimatic profile of the rearing areas of seven local populations: Pivska pramenka, Bardoka, Zetska žuja, Sora, Sjenička ovca, Piperska žuja, and Ljaba, using multivariate statistical methods. Such characterization is essential for developing sustainable conservation strategies for animal genetic resources under ongoing climate change. The research covered 24 primary rearing locations across Montenegro. A historical climate dataset (1979–2018) including precipitation, minimum and maximum temperatures, wind speed, and altitude was utilized. Thirteen bioclimatic variables were derived, focusing on annual mean temperature (BIO1), annual precipitation (BIO12), and precipitation seasonality (BIO15). Data were processed using Principal Component Analysis (PCA) and Hierarchical Clustering on Principal Components (HCPC) to perform ecological classification of the areas and identify patterns of seasonal animal movement. The multivariate analysis revealed three distinct bioclimatic profiles corresponding to the major geographical and ecological zones of Montenegro. Cluster 1 (high-altitude) is characterized by rearing areas located at elevations above 1400 m, with low annual mean temperatures (BIO1 ≈ 5°C) and pronounced wind variability. Pivska pramenka and Sora are the predominant representatives of this climatic zone. While Pivska pramenka shows a high degree of year-round stationarity, Sora exhibits a mixed pattern, with part of the population remaining in the harsh conditions of Cluster 1 and another part moving seasonally towards more temperate zones. Cluster 2 (mid-altitude) comprises transitional areas at elevations between 800 and 1100 m, characterized by a moderate temperature regime. Sjenička ovca and Piperska žuja are consistently associated with this cluster, indicating predominantly sedentary management in climatically more stable environments without pronounced vertical migration. Cluster 3 (lowland–Mediterranean) includes areas with the highest temperatures (BIO1 > 15°C) and the lowest annual precipitation, but with the most pronounced precipitation seasonality (BIO15 > 50). Zetska žuja is well adapted to stationary production systems within this warm climatic zone. Results confirm that the bioclimatic profile of the rearing areas for breeds such as Bardoka and Ljaba changes seasonally due to vertical transhumance, where animals stay in the warmer Cluster 3 during winter and move to Cluster 1 or 2 during summer to avoid heat stress and utilize mountain pastures. Overall, the findings confirm a high degree of bioclimatic specialization among Montenegrin local sheep populations. The identified clusters indicate that traditional rearing systems, including transhumance, are key adaptive mechanisms to specific climatic regimes. These findings provide a scientific basis for long-term management and in-situ protection of indigenous populations in the context of increasing climate instability.

Within-day dynamics of milk components in intensively managed Saanen dairy goats.

J. Kirkham[1], F. Zamuner[1], A. Cameron[2], B. Leury[1], K. Digiacomo[1]
[1] The University of Melbourne, School of Agricultureal, Food and Ecosystems Sciences, Royal Parade, 3010 Parkville, Australia, [2] Metedith Dairy Pty Ltd, 106 Camerons Rd, 3333 Meredith, Australia

Understanding variation between morning (AM) and afternoon (PM) milk components is essential for accurate estimation of milk quality and composition. In dairy cattle, milk yield is typically greater in the AM while fat, protein and total solids are greater in the PM. Evidence in dairy goats is limited. Published data is based on small and regionally concentrated populations (12-40 goats) but suggests that milk yield and lactose may be greater in the AM, protein greater in the PM, and fat similar between AM and PM milkings. However, data from larger, intensive systems and from high-producing Saanen goats are lacking. We compared AM and PM milk components in high (HP) and low (LP) producing early lactation Saanen goats (n = 52) to quantify within-day differences and their interaction with production group. Individual milk samples (20mL) from HP (n = 28) or LP (n = 24) producing dairy goats were collected once in the PM and again the following AM for 7 weeks as part of a larger experiment. Samples were subject to milk component analysis using a Foss MilkScan Mars milk analyser (Foss Analytics, Hillerød, Denmark) that was specifically calibrated for goat milk to determine fat, protein, lactose, and total solids. Daily milk yield was recorded automatically using in-line electronic milk meters (MidiLine SG Parlor, DeLaval Inc., Australia). This was a retrospective experiment, and yield was automatically recorded daily rather than by AM or PM volumes. Thus, AM or PM yields were determined on only 5 occasions throughout the 7 weeks of sampling. Data was log10 transformed and analysed using REML in Genstat (22nd ed.), and presented means have been back-transformed and presented ± standard error of difference (SED). Milk yield was greater in the AM compared to the PM (2.0 L vs. 1.2 L; ±0.05; $P < 0.001$) on the 5 occasions this was compared. Overall, the HP goats had greater quantities of all components compared to the LP goats including fat (4.0% vs 3.5%; ±0.01; $P < 0.001$) and protein (3.3% vs 3.2%; ±0.001; $P = 0.008$). For both HP and LP goats, PM milk samples had greater proportions of fat (4.4% vs. 3.2%; ±0.001; $P < 0.001$), protein (3.3% vs. 3.2%; ±0.001; $P < 0.001$), lactose (4.7% vs 4.6%; ±0.001; $P < 0.001$), and total solids (12.8% vs. 11.5%; ±0.002; $P < 0.001$). These findings indicate clear and consistent differences between AM and PM milk quality and quantity. The PM milk was richer in fat, protein and total solids, and HP goats exceeded LP goats for all components. For the most accurate estimate of 24hr milk quality, averaging AM and PM component values or, if only one milking is used, standardising to AM or PM sampling is recommended. The findings partially agree with current literature, but lactose was greater in PM samples (a pattern commonly reported in dairy cattle), which may reflect differences in milking interval, feeding timing or circadian regulation of mammary metabolism. Variation can affect cheese yield estimates and payment systems based on fat and protein. Further work on the metabolic and lipidomic bases of variation and on economic consequences is warranted.

Farmer attitude to ovine lameness - Where do they seek information when a problem occurs?

F. Campion[1], E. Kelly[2], J. Angel[3], J. Delaney[1,2]
[1] Teagasc, Animal & Bioscience Department, Mellows Campus, Athenry, H65 R718 Galway, Ireland, [2] University College Dublin, School of Veterinary Medicine, Belfield, Dublin 4 Dublin, Ireland, [3] Wern Veterinary Surgeons, Department of Research and Innovation, Lon Parcwr Industrial Estate, LL15 1NJ Ruthin, United Kingdom

Ovine lameness impacts production efficiency, animal welfare and coupled with the associated treatment and preventative costs reduces farm profitability. Information on how to control and manage lameness is widely available but is sometimes conflicting or limited in its effectiveness. There is a paucity of information on where Irish sheep farmers go for information on ovine lameness treatment and control strategies. A survey of Irish sheep farmers on ovine lameness identification, control and treatment was conducted opportunistically and non-randomly between January 2023 and May 2024. Online respondents were gathered through promotion on Teagasc social media platforms. In-person respondents were collected at livestock sales and attendance at Teagasc sheep events with responses subsequently collated via 'Survey Monkey'. Following collation a combination of SAS Version 9.4 and R studio 4.5 were used for data screening and analysis. Results from this survey showed farmer reported median ovine flock-level lameness prevalence of 6.0%, with 47.0% of farms reporting that Contagious Ovine Digital Dermatitis (CODD) was present in their flock. As past of this survey participants were asked where they sourced information on ovine lameness. The most frequently chosen source of information on lameness was 'My Vet', reported by 30.0% (n = 92 [95% CI 25.0–35.5]) of farmers, followed by 'Own knowledge' (n = 38 [12.3%, 95% CI 8.8–15.8]), a combination of 'Farming media and veterinary advice' (n = 35 [11.4%, 95% CI 8.2–15.6]) and 'Farming media' (n = 24 [7.8%, 95% CI 5.2–11.6]), while other combinations such as advisors, farm knowledge transfer events, or other farmers were reported by smaller proportions respectfully. These results, particularly the high percentage that rely on 'Own knowledge' for the control and treatment of ovine lameness demonstrates the need for having consistent and effective KT messages presented to farmers and industry personnel in order to reduce the impact of lameness on production and welfare.

Substrate pH: A Critically Overlooked Microenvironmental Factor in Black Soldier Fly Larvae Performance and Systematic Reporting

E. Parand[1], A. Reazei Far[1], D. G. A. B. Oonincx[2], R. Hao[2], S. Naser El Deen[1], T. Veldkamp[1]
[1] Wageningen Livestock Research, Animal Nutrition, De Elst, 6708 WD Wageningen, Netherlands, [2] Wageningen University, Animal Science, De Elst, 6708 WD Wageningen, Netherlands

pH is a fundamental physicochemical parameter that affects microbial community structure, enzyme activity, and nutrient solubility. In black soldier fly (Hermetia illucens) (BSF) production, the substrate forms both the primary nutritional source and physical habitat for the larvae. Despite this biological relevance, quantitative relationships between pH and larval performance are poorly understood because pH is inconsistently reported. This exploratory study utilized a multi-study dataset (N = 635 observations) to highlight the importance of pH and advocate more systematic reporting. Analysis revealed reporting is exceptionally sparse: initial pH (Initial_pH) was recorded for only 15.3% of observations (n = 97), and final pH (End_pH) for only 10.2% (n = 65), limiting the paired subset to 65 observations. For these, the average initial pH was 5.67 ± 1.13 (range 3.61–8.40) and the average end pH was 7.25 ± 1.35 (range 4.03–9.11), with a mean change (Delta_pH) of 1.58 units (range −1.90 to 4.82). The Pearson correlation between Initial and End pH was weak ($r = 0.211$, $P = 0.092$), suggesting that other factors, potentially such as larval activity (feeding, excretion, bioturbation) and microbial processes, influence the chemical environment, diluting the impact of initial substrate conditions. Four modelling specifications, including ordinary least squares (OLS) and mixed-effects models (REML estimation) with study as a random intercept, were used to evaluate associations. Single-predictor OLS models demonstrated a negative association between Initial pH and performance outcomes; larval growth rate decreased by 3.14 ± 0.54 mg/d ($R^2 = 0.370$, $P < 0.0001$) and larval final wet mass decreased by 22.82 ± 4.32 mg ($R^2 = 0.279$, $P < 0.0001$) per unit increase in pH. In contrast, End pH associations were weaker and outcome-specific ($R^2 = 0.105$, $P = 0.034$ for larval growth rate; $R^2 = 0.012$, $P = 0.420$ for larval final wet mass). Accounting for study-level clustering in mixed models attenuated these coefficients but confirmed the negative relationship of Initial pH with larval growth rate ($\beta = -2.26 \pm 0.63$, $P = 0.0007$) and larval final wet mass ($\beta = -15.67 \pm 4.97$, $P = 0.0024$). In these models, End pH was no longer a significant predictor of larval final wet mass ($P = 0.267$). Neither the interaction between Initial and End pH nor the absolute change in pH (Delta_pH) meaningfully explained variance ($P > 0.15$). The analysis also revealed high intraclass correlation coefficients (ICC), ranging from 0.448 to 0.591, indicating that 45–59% of total variance was attributable to between-study heterogeneity, likely reflecting differences in substrate composition, larval density, and climate. While this dataset is observational and limited in size, precluding definitive causal inference, the persistent negative association between initial pH and performance supports the hypothesis that substrate pH may influence larval performance. Controlled experimental studies are needed to determine whether moderate acidification improves larval growth rate. Further studies should examine whether changes in microbial activity or nutrient accessibility explain any growth response to pH manipulation. This study serves as a vital call to the BSFL research community to systematically monitor and report initial and end substrate pH to support future optimization of rearing conditions and determine relevant interactions.

Bugs in the System: Have the economic and environmental benefits of insect farming been overstated?

C. Biteau[1]
[1] *Observatoire national de l'élevage d'insectes, 20B rue de l'avenir, 78400 Chatou, France*

Insect farming has attracted over $1.5 billion in investment in Europe, with the sector positioned as a promising route to reducing dependence on fishmeal and soy in animal feed. Yet several leading companies have gone bankrupt, and investment fell sharply between 2022 and 2026. This presentation examines whether the assumptions underlying the research literature hold up against commercial realities. The scientific literature has broadly supported the environmental and economic case for insect farming. However, much of this evidence appears to rest on fragile foundations. Most life cycle assessments have been conducted at small or pilot scale, often in tropical or semi-tropical settings whose conditions may not be transferable to Western industrial production. Cost projections have relied on theoretical parameters that diverge from actual farm operations, and a pervasive assumption persists that insect farms will utilise food waste at an industrial scale, despite persistent regulatory, logistical, and safety barriers. These gaps between published research and commercial realities may have contributed to overly optimistic expectations among investors, policymakers, and feed industry stakeholders. Based on a series of peer-reviewed studies by the author, this presentation provides a comprehensive assessment of the challenges facing the insect farming sector. When more realistic inputs are used, the conclusions drawn from the literature appear to change substantially. In the feed market, insect meal appears to generate higher greenhouse gas emissions than soybean meal and fishmeal in most scenarios relevant to Western production, and the circular economy narrative central to the sector's value proposition remains largely aspirational at this stage. The economic outlook appears equally challenging: insect meal currently costs several times more than conventional alternatives, a gap that available modelling suggests is unlikely to close under realistic near-term conditions. In the human food market, these environmental and economic limitations are compounded by market dynamics, as insect-based products appear to overwhelmingly displace plant-based foods with already low environmental footprints rather than meat, thereby further undermining the sustainability case for entomophagy as a dietary shift strategy. These findings may be directly relevant to stakeholders in the feed industry and policymakers. They help identify the critical barriers that would need to be addressed for insect farming to deliver on its promises, while also flagging strategies that appear unlikely to succeed. While niche applications may still offer genuine benefits, for the sector to build a credible future at scale, research and investment decisions should be grounded in evidence that reflects actual industrial conditions rather than theoretical projections. Bridging the gap between theoretical promises and industrial realities will require a collective effort from researchers, industry actors, and policymakers to produce and rely on data that accurately reflects the conditions under which insect farming operates today.

Eclosion and mating postponement, how it influences oviposition in black soldier fly (Hermetia illucens)

C. Coudron[1], J. Claeys[1], D. Deruytter[1]
[1] Inagro vzw, Insect Research Centre, Ieperseweg 87, 8800 Roeselare, Belgium

Egg production is a key indicator in black soldier fly (Hermetia illucens, BSF) breeding systems, as it determines both the supply of progeny and the proportion of larvae that can be allocated to biomass production. For commercial breeders, the ability to manipulate the insect's life cycle is valuable for aligning emergence, mating, and oviposition with operational schedules. Two potential interventions are cooling pupae to delay development and keeping adults in darkness to postpone mating and subsequent egg laying. However, these measures have biological limits: excessive cooling reduces emergence and egg output, and prolonged darkness may disrupt mating success. Earlier work showed that long-term cold storage (>10 days at 15 °C) is detrimental, yet unexpectedly, short-term cooling (2 days) increased egg production by 28% compared with non-cooled pupae. This raised the question of whether brief cold exposure during the pupal stage could reliably enhance egg production. In addition, we examined whether delaying mating by storing newly emerged flies in darkness affects total egg output. To address these questions, four trials were performed. Each trial consisted of 24 reproduction cages (60 × 60 × 90 cm), each containing a single batch of 250 g of pupae (≈2000 flies), maintained under uniform conditions (30 °C, 80% RH) with controlled lighting, water access, lures, and standardized oviposition traps. Treatments included short-term cold storage of pupae (up to 2 days at 15 °C) and delayed mating through dark storage of adults (up to 7 days). Eggs were collected at fixed two-day intervals until production ceased, and total egg yield (g) per cage served as the primary response variable. Results show that dark storage is a viable way to reduce the number of egg harvests without significantly affecting total egg production, provided the delay does not exceed four days after the first flies emerge. Flies kept under a normal day–night cycle required five harvests to produce an average of 23.2 g of eggs, whereas flies stored in darkness for up to four days required only three harvests and still reached 22.3 g. The results for cold-stored pupae are preliminary, as the third trial is still ongoing at the time of writing. However, the first two trials already showed increased egg outputs of +28% and +12.7% compared with non-stored pupae. These findings demonstrate that interventions at different life stages can improve both operational efficiency, by enabling better alignment with production schedules and reducing the number of egg harvests and, in some cases, even enhance overall egg output. Short-term pupal cooling and controlled dark storage thus offer practical tools for optimizing BSF reproductive performance.

Ammonia emissions during BSFL rearing: initial continuous measurements and the impact of feed protein/carbohydrate ratio

D. Deruytter[1], J. Claeys[1], C. L. Coudron[1]
[1] Inagro, Insect Research Centre, Ieperseweg 87, 8800 Rumbeke-Beitem, Belgium

All animals produce emissions. Hence, there are emissions generated during the rearing of black soldier fly larvae (BSFL). Most notably carbon dioxide and ammonia result both from the microbial activity in the feed for the larvae as well as the larvae themselves. Especially in western Europe the emissions released due to animal husbandry are a hotly debated item. However, for mini livestock, such as the BSF, the available information is very scarce. Within the HiGa project we attempted to start filling this knowledge gap. In the first phase three measurement devices were built and tested to ensure accurate and continuous (every 30s) readings for temperature, humidity, CO2 and ammonia in both the incoming and outgoing air. Currently three devices are operational, and each can measure the emissions of one 60*40cm crate with a variable ventilation speed between 0.1 and 9 m^3/h. In a second stage, and as proof of concept, we investigated how altering the dietary protein-to-carbohydrate (P/C) ratio influences CO_2 and NH□ emissions during BSFL rearing. The control diets consisted of wheat bran and maize flour. In the experimental diets, the maize flour was replaced with soybean meal to change the P/C ratio. All experiments were performed at room temperature of 27 °C and relative humidity of 55 % with 5-day old BSFL (15 000 per 60*40 crate). The initial data clearly indicates that there is a clear positive correlation between the ammonia production and increase in protein in the feed mixture. Even with very small additions. This strengthens the prevailing theory that more proteins in the feed result in more nitrogen losses through volatilization and highlights the importance of optimizing feed P/C ratios to minimize environmental emissions and improve nitrogen utilization efficiency in BSFL production systems. However, further research is needed if this correlation also holds when using other sources of protein such as egg or milk protein.

Computer vision for weight estimation and activity levels in Tenebrio molitor: Improving production and welfare

E. Osei[1], M. Wutke[2], I. Traulsen[2], J. Tetens[1], E. Werner[3], R. H. Mateus-Vargas[1]
[1] University of Goettingen, Functional Breeding Division, Animal Science, Burckhardtweg 2, 37077 Goettingen, Germany, [2] Christian-Albrechts-University Kiel, Behavioural Informatics in Livestock Husbandry, Hermann-Rodewald-Straße 6, 24118 Kiel, Germany, [3] Alpha-Protein GmbH, Werner-von-Siemens-Straße 2-6, 76646 Bruchsal, Germany

Edible insects have emerged as an alternative protein source. They require less land and water, emit fewer greenhouse gases, and are rich in protein and healthy fats. Despite its growing acceptance in Europe, industrial challenges, including regulations, safety, and public perception, remain. A major bottleneck is standardising monitoring systems, especially the accurate measurement and tracking of production and welfare traits. Monitoring weights and assessing movement activity is important because they are key indicators of welfare in animal production. However, current assessments of these traits are mostly manual, requiring time-consuming tasks such as weighing, counting, and manual human observations due to their small size, large numbers, and fragility. Although vital for safety and productivity, manual data collection is labour-intensive, error-prone, and hampers scalability. This study aims to develop a non-invasive computer-vision-based approach using the object detection model YOLO and the foundation model Segment Anything (SAM) to detect, segment, and subsequently estimate the weight and activity levels of yellow mealworms. Larvae were reared under standard conditions (27°C, 65% RH, 0:24 light: dark). For model training and analysis, 226 single-larval and 98 group-larval videos were recorded with 5 larvae per group using a dome IP camera. For both single- and group-larvae videos, segmentation masks were generated for each larva, and the median of the estimated segmentation area was computed. Additionally, for the group videos, larval activity was determined by calculating the displacement of the bounding box centres between frames. After feature extraction, Pearson correlation was used to estimate the linear association between the median of the estimated segmentation areas and the actual larval weight in the single-larva dataset. Subsequently, a linear regression model was fitted using the ground-truth weights and segmentation data to quantify this relationship and generate weight predictions for the larvae in the group videos. Preliminary results show a strong, positive linear relationship between the estimated segmentation masks and ground truth larval weights. Median pixel values correlated with the actual weights at $r = 0.9750$. The median-pixel values explained about 95.1% of the variance with a residual error of 13.91 mg. Our study offers a promising framework for automated assessment of larval weight and activity, which could aid in monitoring key welfare and production traits, such as disease incidence and growth rate. Thus, also a scalable alternative to manual data collection that could minimise human error and facilitate breeding strategies. Further validation is, however, needed for continuous monitoring in enclosed production systems, especially regarding how changes in lighting affect stress and welfare detection. Future research on group monitoring under various lighting conditions could improve non-invasive assessment of yellow mealworms.

Waste Valorization Through Insects: Larval Growth Evaluation of Hermetia illucens on Olive Pomace Diets

C. I. Rumbos[1], P. Soulioti[2], G. V. Baliota[2], M. T. Capucchio[3], C. G. Athanassiou[2]
[1] International Hellenic University, Department of Agriculture, Alexander Campus, 57400 Sindos, Thessaloniki, Greece, [2] University of Thessaly, Department of Agriculture, Crop Production and Rural Environment, Phytokou Str., 38446 Volos, Greece, [3] University of Turin, Department of Veterinary Sciences, Via Verdi, 8, 10124 Turin, Italy

Two-phase olive pomace (TPOP) is the main byproduct of olive-oil extraction process, accounting for more than 80% of the raw material. Finding effective ways to convert this residue is important, as its uncontrolled disposal leads to soil and water pollution, increased phytotoxicity, and reduced water infiltration. Black soldier fly (BSF) larvae are known for their ability to process a wide range of organic byproducts, making them a promising option for TPOP valorization. This study examined the impact of diets consisting of chicken feed and TPOP on BSF larval growth and performance. Eleven diets were prepared using both dry and wet TPOP. Dry TPOP was included at 10, 15, 25, 50 and 75%, while the wet form was included at 5%, 10, 15, 25, 50 and 75%. Chicken feed served as the control diet. Larval survival and weight were recorded every three days, whereas the experiment was completed when 10% of the larvae reached the prepupal stage. In addition, bioconversion efficiency corrected for residue (BER), feed conversion ratio (FCR), waste reduction rate (WRR) and specific growth rate (SGR) were also calculated. According to the results, the highest final individual larval weight was recorded in the control diet (144.0 mg), followed closely by the 25% wet TPOP diet (139.6 mg). The lowest weight was documented in the 75% dry TPOP diet (84.4 mg). Survival remained consistently high across all treatments, exceeding 94% at the end of the trial. According to feed indicators, the 25% wet TPOP diet performed best, showing the highest BER (13.2%) and the lowest FCR (7.6), followed by the 25% dry TPOP diet (11.4% and 8.8, respectively). Overall, these results show that TPOP can be incorporated into BSF diets at moderate levels, supporting its potential use in circular bioeconomy strategies. This research is supported by the EU-PRIMA program – project OLIWA- Repurposing OLIve WAste in circular economy solutions for feeds, additives, packaging, and biogas – GA 2432, Call 2024 Section 1 Food Value Chain in Nexus.

Farming insects: evaluation of safety and legal framework

N. Meijer[1], K. Niermans[1], L. Tromp[1], S. Naser El Deen[2], T. Veldkamp[2], C. J. De Vos-De Jong[3], M. J. Appel[1], E. F. Hoek-Van Den Hil[1]
[1] Wageningen food Safety Research, Akkermaalsbos 2, 6708 WB Wageningen, Netherlands, [2] Wageningen Livestock Research, De Elst 1, 6700 AH Wageningen, Netherlands, [3] Wageningen Bioveterinary Research, Houtribweg 39, 8221 RA Lelystad, Netherlands

Dipteran insects such as black soldier fly larvae (BSFL; Hermetia illucens) are known for their ability to convert a wide range of organic residual streams, including materials that are currently not allowed under EU feed legislation, into valuable biomass. These streams are often excluded because of elevated contaminant levels or the presence of animal by products, which may pose risks of transmitting diseases to humans or animals. However, these residual streams represent valuable opportunities for circularity and valorization. Over the past years, we have conducted multiple experimental studies to evaluate BSFL performance and safety outcomes on a variety of non-authorized, or otherwise unsuitable substrates. This contribution provides an elaborate overview of our research on chemical and microbiological hazards across several projects investigating residual streams contaminated with: packaging materials, microplastics, mycotoxins, pesticide residues, heavy metals, dioxins, food pathogens, parasites, viruses, and antimicrobial resistant genes. Results from these studies are linked to the current regulatory framework for farmed insects and potential changes are discussed. This knowledge will contribute to necessary legal reforms required to permit insect rearing on organic residual streams.

Telomere Length as a Biomarker of Health in Apis mellifera

R. Pistucci[1], A. Bonfante[2], G. Di Prisco[3], A. Iannuzzi[1]
[1] National Research Council- Institute for Animal Production System in Mediterranean Environment, P.le Enrico fermi 1, 80055 Portici, Italy, [2] National Research Council- Institute for Agricultural and Forest Systems in the Mediterranean, Institute for Agricultural and Forest Systems in the Mediterranean, P.le Enrico fermi 1, 80055 Portici, Italy, [3] National Research Council- Institute for Sustainable Plant Protection, P.le Enrico fermi 1, 80055 Portici, Italy

Honey bees (Apis mellifera, L.) are indispensable for global agriculture due to their critical role as pollinators, ensuring crop productivity and ecosystem stability. Despite their importance, honey bee populations are increasingly threatened by multiple stressors, including habitat degradation, pesticide exposure, pathogens, and climate change, resulting in significant colony losses worldwide. Recent advancements in molecular biology have introduced biomarkers as valuable tools in agricultural and ecological research, offering innovative approaches to monitor the health and well-being of pollinators. In honey bees, genomic biomarkers are particularly promising due to their capacity to reflect complex environmental interactions and physiological states. Among these, telomere length has emerged as a potential biomarker of health, as demonstrated in other species, including mammals. Telomeres, the repetitive DNA sequences located at the ends of chromosomes, play a vital role in maintaining genomic stability and have been associated with aging, stress response, and overall health. Although telomere sequences are evolutionarily conserved, species-specific methodologies and primers are necessary for accurate measurement. At present, no standardized protocols exist for assessing telomere length in honey bees. This study aims to establish a reliable qPCR-based protocol to quantify telomere length in honey bees, using GAPDH as an internal reference gene to ensure consistent and accurate results across variable conditions. By applying this protocol, we aim to evaluate telomere dynamics in response to environmental stressors, providing new insights into the health and resilience of these essential pollinators. This research is supported by the project "Studio trans-disciplinare per la valutazione della salute dell'ecosistema e degli impatti sulle api in ottica di planetary health" – izs me 02/24 rc.

House cricket (Acheta domesticus) powder as an alternative protein source in the development of protein energy bars

E. Semedo[1], E. Pereira[1,2], B. Carbas[1,2], J. Sá Morais[1], D. Cabral[1], E. Ramalhosa[1,2]
[1] Instituto Politécnico de Bragança, Campus de Santa Apolónia, 5300-253 Bragança, Portugal, [2] CIMO, LA SusTEC, Campus de Santa Apolónia, 5300-253 Bragança, Portugal

Edible insects are an alternative source of protein whose production promotes greater environmental sustainability, requiring less space for domestication and fewer resources for production, and causing less environmental pollution than conventional animal production. Therefore, the development of insect-based products with desirable nutritional and sensory properties is necessary to increase animal and human consumption of this products. This study evaluated the potential use of house cricket (Acheta domesticus) powder as an alternative in the production of protein energy bars for human consumption. Three cereal bars were formulated with cricket powder (CP): 0% (without CP – control), 5%, and 10%, incorporating fig paste, puffed rice, sesame seeds, sliced almonds, almond butter, and honey. After being baked (180 °C for 15 to 20 minutes), the bars were cooled and stored for later analysis of the following parameters: water activity (aw), minerals, protein, total fat, fatty acid profile, and total dietary fiber, as well as microbiological analysis. The aw values were always below 0.6, suggesting microbiological stability. The addition of 10% CP increased the ash content. However, the levels of potassium and magnesium did not change significantly with the addition of CP. On the contrary, sodium levels increased. The control formulation (0% CP) had a protein content of 15.1%, f.w., which increased to 17.6% and 20.9% after the addition of 5% and 10% CP, respectively, these latter being considered a source of protein, as well as of fiber (>3 g of fiber/100 g of product (f.w.)). The bars developed in this study exhibited high MUFA and PUFA values (>80%), with oleic (C18:1n9c) and linoleic (C18:2n6c) fatty acids being the most predominant. The developed products presented satisfactory microbiological quality. This study demonstrated the potential of incorporating cricket powder into foods, such as snacks, as a sustainable and nutritious alternative, rich in protein and fiber.

Improving genomic prediction of juvenile mortality through causal variant inclusion in the Normande dairy cattle breed

L. Chapard[1,2], F. Besnard[1,3], T. Tribout[1], S. Aguerre[1,2], C. Escouflaire[1,3], H. Leclerc[1,3], S. Fritz[1,3], S. Mattalia[1,2], A. Capitan[1], P. Croiseau[1]

[1] Université Paris-Saclay, INRAE, AgroParisTech, GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [2] IDELE, 149 rue de Bercy, 75012 Paris, France, [3] ELIANCE, 149 rue de Bercy, 75012 Paris, France

Juvenile mortality is partly driven by recessive genetic defects, making it a relevant target for genomic selection. However, standard single-step GBLUP (ssGBLUP) models do not explicitly account for causal variants or their non-additive effects. Therefore, this study consisted of, first, the development of three ssGBLUP models for juvenile mortality that explicitly included a causal variant. These models either assigned (i) a higher proportion of genetic variance explained a priori by the causal variant or (ii) estimated and incorporated its additive or (iii) both additive and dominance effects as covariates. Second, a comparative analysis was performed to identify the most accurate model between the latter and a standard ssGBLUP model, used as a reference. This methodology was applied to the Normande dairy cattle breed where cases of Alopecia of the body extremities have been reported. This recessive genetic defect is caused by an inframe deletion of the replication factor C subunit 5. Homozygous mutant calves exhibit stunted growth, chronic diarrhea, a noticeably thin hair coat, and alopecia affecting the extremities, resulting in a higher incidence of late juvenile mortality (up to 3 years of age). 497,010 female juvenile mortality records were included in a training set (born in 2009-2015), of which 28,150 were genotyped (27,078 live, 1072 dead). A value of 100 was given to animals that died between days 3-1095, and 0 to those alive after day 1095. The validation set consisted of records of 333,476 daughters (born in 2016-2022) of 346 genotyped bulls (13 heterozygous HT and 333 homozygous wildtype WT for the causal variant) considered as candidate bulls in the training set (e.g. bulls without daughters' records). The estimated breeding values (EBVs) of the candidate bulls were estimated with the four models using HSSGBLUP program. The moderate correlations between the bulls' EBVs and the observed mortality rates of their daughters in the validation set indicated similar predictive abilities across the models (R=0.41-0.44). However, EBVs obtained from models that included the causal variant showed a greater difference between homozygous WT and HT compared with the reference model (ranging from +0.51 to +0.57 genetic standard deviation vs +0.32 for the reference model), resulting in an improved ability to differentiate carriers from homozygous WT bulls. Accordingly, integrating causal variants into routine genomic evaluations may offer a valuable strategy for reducing juvenile mortality. Moreover, expanding genotyping efforts to include more dead animals could further improve model performance. Finally, additional research is required to identify the most effective approach for including causal variants into ssGBLUP models.

Insights into the genetic basis of emerging health and vitality related traits in Holstein Friesian calves

L. Stahmer[1], L. Schwarz[1], L. Engel[1], K. Voß[1], G. Thaller[1]
[1] Kiel University, Institute of Animal Breeding and Husbandry, Olshausenstraße 40, 24098 Kiel, Germany

Functional traits including health and vitality are of utmost interest in modern dairy cattle breeding as they ensure vital animals and offspring, leading to genetic merit, reduced cost for treatment and improved animal welfare. Diseases occurring during the early live stages increase veterinary costs, require additional management efforts and may negatively affect performance later in life. In recent years, calf housing and welfare have received increased attention and are ongoing part of scientific and public discussions, focusing on the potential for transformations within the sector. A national prevalence study (PraeRi) conducted by the University of Veterinary Medicine Hannover assessed calf health from 2016 to 2019 on 765 German dairy farms and found an average mortality rate of 5.4 % (retrospective for one year). The most common health issues in calves were navel infection, diarrhea, pneumonia as well as multimorbidity. Although the importance of successful calf rearing has attracted attention in dairy farming practice, traits directly addressing calf health and vitality are not yet adequately considered in breeding programmes and the genetic background of these traits remains largely unknown. The aim of this study is to analyse the genetic architecture of different calf traits and to evaluate their potential for the integration of these traits into future breeding goals through the development of a new trait complex defined as “calf vitality”. The dataset contains more than 3,800 female Holstein Friesian calves which were raised on a large dairy farm in eastern Germany. Phenotypic information of all animals is routinely recorded on the farm and contain birth weight, maternal calving ease, serum total protein as well as repeated records for weight development (6 measurements, between day 30 and 310) from birth to first insemination. Additionally, disease events (pneumonia, navel infection and diarrhea) affecting calf health as well as animal losses and its cause are documented. All animals were genotyped using a 50K bovine SNP Chip. Genetic analyses combining the genetic and phenotypic information were conducted, including the estimation of genetic parameters, followed by genome wide association studies. In initial genetic analyses, SNP-based heritability estimates for the traits birth weight (BW), average daily weight gain from birth to day 120 (ADG120) as well as serum total protein (STP) were $h^2 = 0.52$ (SE 0.038), 0.37 (SE 0.058) and 0.29 (SE 0.037), respectively. The results of this study provide valuable insights into the genetic basis of calf health and vitality traits. A profound understanding of the genetic background enables their consideration in future breeding goals and breeding selection decisions. Combining relevant calf traits into a trait complex referred to as “calf vitality” represents a promising possibility to address the increasing importance of genetic improvement focusing on enhancing calf health and robustness. Ultimately, this may contribute to improved animal health and welfare while at the same time improving sustainability and efficiency in dairy farming systems. This work is funded by the German Federal Ministry of Food and Agriculture (BMEL) based on a decision of the Parliament of the Federal Republic of Germany, granted by the Federal Office for Agriculture and Food (BLE; grant number 281C809A21).

Optimizing lesion phenotypes to enable breeding against psoroptic mange susceptibility in Belgian Blue cattle

I. Patteet[1], L. Wirix[1], N. De Wilde[2], L. De Veerman[2], S. Janssens[1], E. Claerebout[2], C. Charlier[3], N. Buys[1], R. Meyermans[1]

[1] KU Leuven, Center for Animal Breeding and Genetics, Department of Biosystems, Kasteelpark Arenberg 30, 3001 Leuven, Belgium, [2] Universiteit Gent, Laboratory for Parasitology, Salisburylaan 133, 9820 Merelbeke-Melle, Belgium, [3] ULiège, GIGA Institute, Avenue de l'Hôpital 11, 4000 Liège, Belgium

The Belgian Blue (BB) breed forms a cornerstone of Belgium's cattle production because of its valuable beef qualities. However, the breed exhibits high susceptibility to psoroptic mange, a skin disease caused by Psoroptes ovis mites, leading to severe dermatitis and major welfare concerns. Notably, substantial individual variation in lesion development is observed under similar environmental conditions, suggesting a genetic component underlying disease susceptibility. A recent large-scale study evaluated ±2,000 animals across more than 100 management groups, using standardized phenotypes (lesion extent and severity scoring). They reported low but non-zero heritabilities for these traits (h^2 = 0.07-0.09) and identified 3 candidate genes possibly linked to disease susceptibility. Building on this work, we have continued sampling for an independent dataset of approximately 650 animals to validate and refine our previous findings. However, practical experience has shown that the detailed lesion mapping and severity scoring are labour-intensive, time-consuming, and difficult to standardize across farms, which limits their scalability for routine implementation in breeding programs. Therefore, we evaluated whether lesion phenotyping can be simplified without compromising the ability to perform genetic analyses and to develop an effective breeding programme. Specifically, this study aimed to determine whether a lesion phenotype based on assessing lesion extent within defined various anatomical regions (head, neck, topline, flank, belly, hindquarters, tail and legs) can distinguish susceptible from resistant animals and capture most of the biologically relevant variation in disease expression. Lesion distribution per severity score was compared between cases (n = 139) and controls (n = 139). Within each management group, cases were defined as the 10% most severely affected animals and controls as the 10% least affected, based on severe lesion extent. Across all scores, cases showed a broader and more severe lesion distribution. The topline, hind quarter, flank, and tail were most frequently affected, consistent with clinical descriptions of psoroptic mange. Severe lesions (scores 3–4) were particularly concentrated on the topline and hind quarter. The flank showed strong discriminatory power, with severe lesions present in up to 50% of cases versus 12.5% of controls. Each dual-trait animal model included total lesion extent as trait 1, while trait 2 was alternated across the different regional lesion measures. Genetic correlations between total lesion extent and the specific regions ranged from −0.12 to 0.87, indicating that some regions (topline, hind quarter and flank) capture a substantial proportion of the genetic variation underlying overall lesion extent. Predictive tree-based modelling further identified the topline, hind quarter, and flank as the most informative regions for classifying case/control status. These findings indicate that region-specific lesion assessment, particularly focusing on topline, hind quarter, and flank, may capture a substantial proportion of meaningful phenotypic variation. A reduced, region-based scoring system could therefore improve feasibility and standardization while maintaining biological relevance for genetic evaluation.

Variance components for number of oocytes and number of embryos in Austrian Fleckvieh cattle

H. Schwarzenbacher[1], C. Fuerst[1], J. Miesenberger[2]
[1] ZuchtData GmbH, Dresdner Straße 89/B1/18, 1200 Vienna, Austria, [2] Oö. Besamungsstation GmbH, Dr. Otmar Föger Straße 1, 4921 Hohenzell, Austria

The total number of oocytes (NoO) and embryos (NoE) was recorded in Austrian Fleckvieh cattle from multiple ovulation and embryo transfer (MOET) sessions conducted between 1991 and 2025. In total, approximately 2,200 records for NoO and 3,100 records for NoE were available from sessions performed on 579 farms. NoO ranged from 0 to 65 oozytes with a mean of 12.2, while NoE ranged from 0 to 50 with an average of 7.6 embryos. Variance components were estimated using the software WOMBAT. The statistical model included age within lactation number and season within year of MOET session as fixed effects, and farm, permanent environmental, and additive genetic effects as random effects. Heritability estimates were 0.35 for NoO and 0.21 for NoE. A high genetic correlation of 0.96 was observed between NoO and NoE, indicating a largely shared genetic background. A genome-wide association study (GWAS) was conducted using GCTA with the MLMA-LOCO approach, in which a genomic relationship matrix constructed from SNPs on all chromosomes except the one under analysis was used to control for population stratification. Significant associations for NoE were identified on chromosome 22. Correlations between estimated breeding values (EBV) for NoO and NoE and EBV for the fertility index, were close to zero (+0.06), suggesting that superovulatory response traits are genetically independent from traditional fertility traits. These results indicate that NoO and NoE show substantial heritability and that both traits could be considered in breeding programs aimed at improving embryo production without adversely affecting fertility.

Revealing inheritance patterns and genomic regions associated with embryonic loss in Holstein Friesian embryos

L. Rienesl[1], L. Hoffmann[2], M. Diederich[3], S. Meier[3], H. Grothmann[3], E. Tholen[2], E. Held-Hoelker[1], M. Hoelker[1], C. Große-Brinkhaus[1]

[1] University of Goettingen, Department of Animal Sciences, Albrecht-Thaer-Weg 3, 37075 Göttingen, Germany, [2] University of Bonn, Institute of Animal Science, Endenicher Allee 15, 53115 Bonn, Germany, [3] SYNETICS Germany GmbH, Osterkrug 20, 27283 Verden, Germany

Hereditary defects contribute to impaired embryonic development in dairy cattle and represent an important concern for animal welfare and economic losses. While previous studies have inferred embryonic lethality indirectly from adult populations, direct analyses at the embryo level remain limited. In our initial study, single-nucleotide polymorphism (SNP) genotyping data (~50K) from biopsied Holstein Friesian embryos collected between 2018-2023 and derived from elite matings were examined. A total of 865 literature-based candidate markers previously reported to be associated with fertility and fetal viability were pre-selected for analyses. After quality control and application of predefined genotype filtering criteria, 65 autosomal SNP markers were retained; requiring homozygous Q-genotype (aa) frequencies ≤10% in parents, presence of Q-genotypes (>0%) in embryos, and minor allele frequency (MAF) >5% in parents, thereby minimizing potential biases from allele dropout and ensuring robust detection of genotype frequency distortions. The dataset for analysis included 1674 embryos and 715 parental animals. Statistical analyses focused on genotype frequency distributions and deviations from Hardy-Weinberg equilibrium (HWE) in embryonic and parental generations. Among the 65 markers, 55 showed significant deviations from HWE ($p<0.05$) in embryos, whereas their parents remained largely in HWE. Homozygous Q-genotypes were more frequent in embryos (1.9%) than in parents (0.7%). This over-representation of homozygous Q-genotypes in embryos relative to parental expectations indicates recessive inheritance effects on embryo and/or fetal developmental competence to term. The present study aims to validate previously observed genotype distortions on an expanded dataset including embryos collected until January 2025. More importantly, it seeks to expand the genomic scope beyond the literature-based candidate markers to elucidate further the genetic mechanisms underlying embryonic loss and developmental competence to term. The updated dataset comprised 2633 genotyped embryos and 797 genotyped parents. In a first step, same quality control and genotype filtering steps were applied, resulting in the same marker set (N=65). Comparisons of genotype frequency distributions and deviations from HWE in embryonic and parental generations were re-evaluated for these markers. Preliminary results indicate consistent patterns of genotype distortion, with significant deviations from HWE persisting in embryos, whereas parental generations remained largely in HWE. Homozygous Q-genotypes remained overrepresented in embryos relative to parental expectations. These findings support the hypothesis that recessive genotype distortions can already be detected at embryonic stage. Within the analysed marker set, individual SNPs exhibited particularly pronounced genotype distortions. In some cases, homozygous Q-genotypes were observed exclusively in embryos despite their absence in the parental generation. Notably, several of these markers were located on BTA12. Analyses expanding the evaluation to additional genomic regions, to be presented, aim to further refine our understanding of inheritance patterns associated with embryonic loss and developmental competence to term. These resulting findings will contribute to a more comprehensive characterisation of genetic factors affecting embryonic viability and may inform improved genomic management strategies in cattle breeding.

Inferring the genetic background of immunity and associated Vitamin D pathway gene polymorphisms in Holstein cattle

M. Aïbouki[1], S. Vanvanhossou[1], I. Giambra[1], D. Gessner[2], K. Eder[2], S. König[1]
[1] Justus-Liebig-University Giessen, Institute of Animal Breeding and Genetics, Ludwigstr. 21b, 35390 Giessen, Germany, [2] Justus-Liebig-University Giessen, Department of Animal Nutrition and Nutrition Physiology, Heinrich-Buff-Ring 26-32, 35392 Giessen, Germany

Advancing genomic selection towards enhanced animal health and immune resilience suggested approaches simultaneously considering phenotypic data from multiple diseases rather than treating them separately. Moreover, specific integration of vitamin D (VitD) pathway genes due to their key roles in innate immunity into targeted selection might contribute to improve the overall animal health status. The aim of this study was to construct an immunity index (IMI) integrating four major diseases across three lactations and to associate signals from genome-wide association studies (GWAS) for the IMI with polymorphisms identified in 16 sequenced genes functionally related to vitamin D metabolism and signaling, with potential relevance for immune regulation. Phenotypes included health records for mastitis (MAST), metabolic disorders (MET), claw disorders (CD) and reproductive pathologies (RP) from 17,437 German Holstein cows kept in 29 large-scale contract herds. Genomic estimated breeding values (EBVs) for the specific diseases were computed using a multiple-trait animal repeatability model. De-regressed proofs (DRP) were calculated for animal i with phenotypic disease records via DRPi = EBVi / ri_2, with ri_2 denoting the EBV reliability. We created an IMI by weighing the DRP according to the health selection index definition as currently applied in official German national genetic evaluations, i.e., IMIi = 0.4DRP(MAST)i + 0.25DRP(MET)i + 0.2DRP(CD)i +0.15DRP(RP)i. The IMI served as dependent variable in GWAS on 50k genotypes applying the leave-one-chromosome-out approach. SNPs with a false discovery rate adjusted P-value below 0.01 were considered as significant, and potential candidate genes located within ±25kb segments surrounding these SNPs were subsequently functionally annotated. The computed IMI ranged from -3.9 (low immune potential) to 1.6 (high immune potential). The GWAS identified 18 significant SNPs linked to genes across seven BTA, playing pivotal roles in VitD-dependent signalling, like CAMK4 which is involved in immune-related transcriptional regulation. Additionally, sequencing of all exons, introns, flanking 5′ upstream and 3'- downstream regions was conducted for the 16 VitD pathway genes ABCB1, CUBN, CYP24A1, CYP27A1, CYP27B1, CYP2J30, CYP2R1, CYP3A28, DHCR7, FGF23, GC, LRP2, NADSYN1, PIM1, SNAI2 and VDR. For this purpose, for a subset including 96 cows, shotgun sequencing was performed with target enrichment on an Illumina NextSeq 2000 platform. The identified variants were mapped to ARS-UCD1.2 and annotated with the Ensembl Variant Effect Predictor tools. The analysis revealed 7,556 SNPs and 766 InDels across the 16 VitD pathway genes. A total of 4,653 detected polymorphisms (60.6%) were previously referenced in the Ensembl variant table, while 3,022 variants were novel. 1.5% of the variants are missense SNPs, e.g.rs447850593 in CYP3A28, leading to p.Arg105Trp which is already linked to milk production and drug residues, and rs109876475 in CYP2R1 leading to p.Val11Ala which is already associated with increased somatic cell count. In conclusion, the developed IMI enabled a comprehensive evaluation of dairy cow immunity. The significant genomic regions for IMI were associated with immune resilience, highlighting the role of annotated VitD pathway genes with functions in VitD-dependent signalling. Targeted sequencing of 16 VitD genes uncovered several functional variants, further supporting the predominant effects of these genes on the overall immune status.

Phenotypic Responses of Milk β-Hydroxybutyrate and Somatic Cell Score to Heat Stress in Dairy Cattle

V. Storing[1], C. Baes[1], F. Schenkel[1], G. Dodd[1], C. Machefert[1], F. Malchiodi[1,2], C. Richardson[3], F. Miglior[1,4]
[1] University of Guelph, Center for Genetic Improvement of Livestock, 50 Stone Road East, N1G 2W1 Guelph, Canada, [2] Semex, 5653 Highway 6, N1H 6J2 Guelph, Canada, [3] Abacusbio International Ltd, Roslin Innovation Centre, Easter Bush Campus, University of Edinburgh, EH25 9RG Edinburgh, United Kingdom, [4] Lactanet Canada, 660 Speedvale Avenue West Unit 101, N1K 1E5 Guelph, Canada

Rising temperatures driven by greenhouse gas emissions continue to impact dairy cattle health and productivity. Under heat stress, cows shift priorities toward thermoregulation over essential psychological functions, increasing their susceptibility to metabolic and inflammatory disorders such as ketosis and mastitis. These conditions can be monitored using milk beta-hydroxybutyrate (BHB) and somatic cell score (SCS), respectively. However, Temperature-Humidity Index (THI) thresholds associated with their heat stress responses remain insufficiently characterized. Thus, evaluating BHB and SCS together may provide a more integrated understanding of cattle health under heat stress. The objectives of the study were to: (1) identify THI thresholds at which BHB and SCS begin to respond to heat stress, and (2) quantify their phenotypic changes across several exposure windows. After editing, the dataset provided by Lactanet (collected between 2015 and 2025) included 1,851,881 BHB records and 5,450,830 SCS records from 1,501,009 and 1,753,254 first-parity Canadian Holstein cows, respectively. BHB values were loge transformed (loge (x + 1)) and SCS was calculated based on somatic cell count (SCC cells/mL), as follows: SCS = log2(SCC/100,000) + 3. Outdoor temperature and relative humidity were obtained from the NASA POWER database (https://power.larc.nasa.gov/; accessed 2026-02-05) using herd geographic coordinates. Hourly THI values were calculated and averaged to obtain daily THI values. For each trait, daily THI was aligned with milk test-day records and averaged across seven exposure windows: the day of testing (d0) and cumulative averages from d0 through the preceding six days (d0-d1, d0-d2, …, d0-d6). Single-trait repeatability animal models were fit with fixed effects for herd, year-season of test day, and age-season of calving for both traits. For BHB, days in milk class was also included. Random effects for both models included herd-year of calving, animal, and permanent environment. Residuals of this model were subsequently paired with corresponding THI averages, and a segmented linear polynomial regression was used to estimate THI breakpoints. Coefficient of determination (R_2) was used to identify the most predictive exposure window for each trait by indicating the proportion of variation explained by each model. Mean transformed BHB value was 0.09 ± 0.05 and mean SCS was 2.02 ± 1.60. For both traits, 73% of records originated from Ontario and Quebec. Estimated THI breakpoints differed by exposure window, ranging from 63 to 69 for BHB and 40 to 75 for SCS. The most predictive exposure window for BHB and SCS were d0-d2 and d0-d1 with THI thresholds of 69 (R_2 = 0.93) and 74 (R_2 = 0.84), respectively. These results suggest that short-term heat exposure preceding sampling is associated with changes in BHB and SCS. Across provinces, average summer (June to August) THI was 64. Only 12% of summer days across all provinces exceeded the identified BHB threshold, and 3% exceeded the SCS threshold, suggesting that broader environmental and management factors may play a stronger role on the phenotype than heat stress alone. Establishing robust THI thresholds for BHB and SCS in Canadian Holsteins can help support earlier and more targeted heat-stress mitigation on farm, especially during transition period when cows are most vulnerable.

Characterization of WC1+ porcine γδ T cell subpopulations using transcriptomic data

A. Chofre[1], T. Jové-Juncà[1], C. Hernández-Banqué[1], O. González-Rodriguez[1], R. Quintanilla[1], M. Ballester[1]
[1] Institute of Agrifood Research and Technology (IRTA), Animal Breeding and Genetics, Torre Marimon, 08140 Caldes de Montbui, Spain

Emerging infectious diseases and environmental pressures threaten livestock systems, emphasizing the need to improve animal robustness and to understand the mechanisms underlying disease resistance. γδ T cells represent a substantial proportion of peripheral blood lymphocytes in livestock species and play an important role bridging innate and adaptive immunity. In ruminants and swine, most blood γδ T cells express receptors from the WC1 family. WC1+ γδ T cells can be divided into two main subpopulations (WC1.1 and WC1.2) based on their WC1 gene expression, which correlates with their ability to respond to specific pathogens. However, γδ T cells and their functional segregation in pigs remain poorly understood. Previous studies from our group identified a genomic region in SSCX associated with γδ T cell abundance in blood, and the most significantly associated genetic variant was also associated with higher survival after PRRSV infection. This study aims to investigate the transcriptional profiles and co-expression networks involved in the genetic regulation of γδ T cell abundance in pig peripheral blood. Blood γδ T cell abundance was quantified in 255 healthy piglets by flow cytometry. Genomic DNA was extracted for genotyping using a commercial GGPSNP70 chip and imputed to whole-genome level, resulting in over 8 million variants. Total RNA from whole blood was sequenced and a differential expression analysis between two groups of animals (15 pigs by group) with extreme γδ T cell abundance was conducted. WC1 genes were identified based on bovine orthologues using Ensembl BioMart. A total of 396 genes were differentially expressed, including 253 upregulated and 143 downregulated in animals with high γδ T cell abundance. Functional enrichment of differentially expressed genes revealed strong overrepresentation of immune-related processes and cytokine signaling pathways. Correlation and network analyses of differentially expressed genes across all animals revealed two tightly co-expressed transcriptional modules and identified several genes whose expression was associated with γδ T cell abundance. Genes upregulated in the group with high γδ T cell abundance included, among others, SOX13, WC1 orthologues, GATA3 and MAF, suggesting a WC1.2 Th17-oriented transcriptional program. In contrast, the module downregulated in high-abundance animals comprised key genes including IFNG, TBX21 and CCL5, consistent with a WC1.1 Th1-like cytotoxic program. Furthermore, an expression genome-wide association study detected eQTLs for 74 differentially expressed genes, with strong signals for WC1 orthologues on SSC5 (61–65 Mb), suggesting that local genetic variation may regulate expression within the Th17-like module. These results reveal distinct transcriptional networks underlying blood γδ T cell abundance and highlight WC1-linked gene modules as regulators of Th1 and Th17-like responses, providing potential targets to enhance immunocompetence and disease resistance in swine populations.

Genetic relationship between cardiorespiratory traits assessed via CT imaging with production traits in pigs

M. Londoño-Gil[1], Ø. Nordbø[1], N. G. Leite[1], J. Dunkelberger[1], E. Grindflek[1]
[1] Topigs Norsvin, Meerendonkweg 25, 5216 TZ 's-Hertogenbosch, Netherlands

Heart and lung (H&L) traits in pigs are recognized as indicators of overall physiological capacity. Advances in CT imaging technology now enable accurate, large-scale phenotyping of internal organs, offering new opportunities to better understand organ development and the biological relationship between H&L traits with production traits. As breeding goals evolve toward more sustainable, resilient animals, monitoring internal organ development becomes increasingly relevant to ensure that selection decisions maintain optimal physiological capacity in modern production systems. Therefore, the aim of this study was to estimate genetic parameters for H&L traits measured via CT imaging and to evaluate their genetic relationships with production traits in four purebred pig genetic lines. For this purpose, records for H&L volume and weight (n = 52,926) from animals born between 2010 and 2025 were analyzed. Production traits included: wean-to-rear (n = 49,171), and rear-to-finish mortality (n = 92,991), feed intake variation (n = 47,127), stress indicators such as stress score (n = 54,459) and blotchy score (n = 48,075), test daily gain (n = 84,856), percentage of belly (n = 40,267), and number of teats (n = 57,534). The (co) variance components and genetic parameters were estimated using single- and multi-trait animal models using ASREML-R. All H&L traits showed moderate-to-high heritability (h^2 = 0.41 – 0.54). Heart volume and heart weight were perfectly genetically correlated (rg = 1.00), while lung volume and lung weight were also highly correlated (rg = 0.86), suggesting that weight and volume represent the same biological trait for each organ. Genetic correlations between heart and lung traits were close to zero, indicating genetic independence. Heart traits showed small, positive correlations with growth (rg ~ 0.18-0.19) and slightly positive associations with stress- and mortality-related traits (rg ~ 0.9 – 0.14). In contrast, lung traits showed modest negative correlations with robustness-related traits (rg down to -0.36), suggesting improved stress resilience in animals with larger lungs, although they were slightly negatively correlated with growth and belly percentage. Overall, H&L traits are moderately-to-highly heritable, indicating sufficient genetic variation for selection and providing biologically important insights into physiological capacity. The genetic relationships observed with growth, stress, and mortality-related traits highlight the relevance of maintaining an appropriate balance between production efficiency and functional robustness. Although organ size is not considered a primary selection criteria, routine phenotyping using CT technology enables effective monitoring of genetic trends and, if needed, data to facilitate within-line selection for optimal organ development. This approach allows us to continuously monitor physiological capacity while continuing to make genetic improvement in production and robustness traits.

Co-occurrence and genetics of feed intake perturbations and drug treatments in pigs

W. Gorssen[1], C. Winters[2], N. K. Kadri[1], N. Khayatzadeh[3], H. Pausch[1]
[1] ETH Zürich, Animal Genomics, Universitätsstrasse 2, 8092 Zürich, Switzerland, [2] ETH Zürich, Universitätsstrasse 2, 8092 Zürich, Switzerland, [3] SUISAG, Allmend 10, 6204 Sempach, Switzerland

Breeding pigs that are resilient to environmental stressors is gaining importance. Recent studies have quantified resilience using deviations from predicted feed intake patterns obtained via automated feeding stations, demonstrating that these feeding perturbation patterns are heritable and genetically correlated with health-related traits, such as treatment incidence. However, the temporal relationship between feed intake perturbations and drug treatments, as well as the underlying genetic architecture of these traits, remains poorly understood. This study used feeding station data recorded at the performance testing station of SUISAG from 2019 to 2025. Daily records of feed intake were available for 7,802 Swiss Large White dam line (SLW) and 2,657 Swiss Landrace (SLR) finishing pigs, as well as medical treatment records and pedigree data. A subset of the phenotyped cohort consisting of 2,717 SLW and 2,052 SLR pigs had microarray-derived genotypes, which were imputed to the sequence-level. Periods with individual perturbations in feed intake were estimated via the R-package UpDown, while correcting for age and breed. Resilience was estimated as the ln-transformed variance of differences in observed versus predicted trait values via linear regression for feed intake (lnvarFI). The total number of medical treatments was summed per pig, discarding group treatments and prophylactic treatments. Co-occurrence of feed intake perturbations and drug treatments was analysed using individual-level binomial mixed-effects models, including a discrete-time hazard framework with daily lead–lag exposure terms. Genetic parameters were estimated per breed using gibbsf90+ software accounting for pen (random), sex and farm of origin (fixed) and the arrival weight and number of daily records (covariate) using single-step GBLUP. Genome-wide association studies (GWAS) between imputed sequence variant genotypes and resilience indicators were performed using GCTA-software. Co-occurrence analysis showed that pigs experiencing a feed intake perturbation had 3.1-fold higher odds of receiving a drug treatment compared with non-perturbed pigs ($p < 0.0001$). Discrete-time hazard modelling revealed a pronounced temporal association, with treatment initiation strongly increased only in the days following feeding perturbation onset, peaking one day after perturbation start (odds ratio = 9.2). Breed effects were not significant, while younger pigs had higher odds of treatment initiation. Heritability estimates for lnvarFI were moderate (SLR: 19.7%; SLW: 19.1%), while heritability for medical treatments was lower (SLR: 5.2%; SLW: 7.7%). The genetic correlation between lnvarFI and medical treatments was only positive with 95% highest posterior density (HPD) estimates larger than zero in SLW (rg=0.42; HPD=0.15 to 0.62), but not in SLR (rg= -0.03; HPD=-0.58 to 0.46). GWAS for the number of medical treatments did only identify several loci reaching the suggestive threshold (1×10^{-5}). For SLW, the most significant association was found on SSC14 (14:124,703,050, $p=3.0\times10^{-7}$). For SLR, the most promising association was detected on SSC7 (7:21,333,895, $p=1.6\times10^{-6}$) near the PRSS16 gene, which is involved in thymic T-cell development. These findings show that feed intake perturbations strongly predict subsequent medical treatments in SLW and SLR pigs, highlighting their value as resilience indicators. Low to moderate heritability and identified genomic regions suggest a genetic basis for these traits that could be leveraged in breeding for robustness, although further validation is needed due to uncertain genetic correlations.

Genomic background of bone-related traits considering a genotype-by-environmental interaction in Landrace boars

C. Große-Brinkhaus[1], M. F. Bellersen[1], E. Jonas[2], R. Lohmayer[3], D. A. Brüggemann[3], E. Tholen[4]
[1] University of Goettingen, Department of Animal Sciences, Albrecht-Thear-Weg 3, 37075 Göttingen, Germany, [2] Association for Bioeconomy Research (FBF e.V.), Adenauerallee 174, 53113 Bonn, Germany, [3] Federal Research Institute for Nutrition and Food, Max Rubner Institute, E.-C.-Baumann-Straße 20, 95326 Kulmbach, Germany, [4] University of Bonn, Institute of Animal Science, Endenicher Allee 15, 53115 Bonn, Germany

The reduction of nitrogen (N) and phosphorus (P) in animal feed aims to minimise environmental pollution, such as excess nutrients in water bodies and the impairment of soil quality, without impairing the growth and health of the animals. The aim of this work was to investigate the effects of N/P-restricted diets on the morphological bone structure, chemical bone composition, bone density, as well as fundament conformation in pigs. In total 1’082 purebred landrace (LR) boars were split into two feeding groups. The diet of the control group (CON) contained, depending on the live weight, crude protein and P in a range of 187 to 171g/ kg DM (CP) and 6 to 5.5 g/kg DM (P), respectively. The N/P-reduced diet (LPP) contained ~10% less CP and ~7% less P following the recommendations by DLG. Before slaughtering leg and body conformation of 835 boars was evaluated subjectively by a routinely applied linear scoring system. After slaughtering, the right front foot from all animals was collected, and the metacarpal bones 3 (Mc3) and 4 (Mc4) were extracted. Length, weight, and diameter of Mc3 and Mc4 were measured, and the bone density of Mc3 was determined by computer tomography (CT). Afterwards, the content of ash, calcium, phosphorus, magnesium, and sodium of Mc3 was analysed. There was no significant impact of the diet group on bone density. The chemical analyses showed significant differences for the magnesium content only. Four conformation traits were significantly affected by the diet group. Skin or muscle tissue samples were routinely collected post mortem. Genomic DNA was isolated from the collected samples. Single Nucleotide Polymorphisms (SNPs) of all boars were genotyped on the Porcine 70k ggp porcine Illumina© HD array. Quality control was performed using PLINK, accounting for low call rate >0.95 and low minor allele frequency (MAF) >0.01, leading to 55’378 SNP for further analyses. The Genome-Wide Association Study was performed using the rrBLUP. First, these data were analysed by considering the feeding group as a fixed effect in the model. This was followed by an analysis within each feeding group, where the data were divided by feeding group. To correct for multiple testing, chromosome-wide Bonferroni significance levels ($p<0.05$) were calculated based on the number of tag SNPs representing the different chromosomes. A total of 102 SNPs located on 7 autosomes were significantly chromosome-wide associated with at least one bone-related trait. In particular, two regions located on Sus scrofa chromosome (SSC) 14 and one region on SSC 16 were identified as being associated with six bone morphological traits, three chemical composition traits, and two CT-related bone traits. This suggests potential pleiotropic effects. The analyses within the feeding groups revealed 24 and 21 significantly associated SNPs for the CON and the LPP, respectively. Interestingly, the region on SSC16 was only detected in the CON, whereas the region on SSC14 was only significantly associated with bone-related traits in the LLP. This could indicate genotype × environment interactions, whereby a different set of genes is responsible for the expression of bone-related traits depending on the feeding strategy. The next step is to investigate the identified regions for any candidate genes and functionally relevant variants.

A deterministic epidemiological model of flavobacteriosis in rainbow trout farming: implications for farm management and genetic improvement

A. Caen[1], F. Phocas[1], T. Rochat[2], E. Duchaud[2]
[1] Université Paris-Saclay, INRAE, GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [2] Université Paris-Saclay, INRAE, UVSQ, VIM, Domaine de Vilvert, 78350 Jouy-en-Josas, France

The objective of this study was to develop a modelling framework describing the transmission dynamics of flavobacteriosis in aquaculture systems and to identify practical levers for disease control through farm management and genetic improvement. Flavobacteriosis, caused by Flavobacterium psychrophilum, is a major health challenge in rainbow trout (Oncorhynchus mykiss) aquaculture and can lead to severe mortality during outbreaks, resulting in significant economic losses. Effective control remains difficult because the epidemiological mechanisms governing pathogen transmission within aquaculture systems are still insufficiently understood. Current knowledge on flavobacteriosis largely relies on experimental infection studies and challenge tests that investigate host resistance and pathogen virulence (Nematollahi et al., 2003). While these studies provide valuable information on infection processes, quantitative epidemiological approaches remain limited. In particular, modelling frameworks capable of linking disease transmission dynamics with aquaculture management practices and host genetic variability are still scarce (Brenden et al., 2023). We developed a deterministic compartmental epidemiological model describing disease transmission in farmed rainbow trout populations. Fish are represented by epidemiological states (susceptible, exposed, infected, recovered and dead), coupled with the dynamics of pathogen concentration in the aquatic environment. The model incorporates key processes relevant to aquaculture systems, including pathogen excretion by infected and dead fish, pathogen removal through water exchange, and removal of dead fish from tanks. Genetic heterogeneity within the fish population is explicitly represented through variability in epidemiological traits related to infection, recovery and pathogen excretion. Model parameters were compiled and calibrated using experimental results and epidemiological information reported in the literature in order to generate biologically realistic simulations of outbreak dynamics. Model analyses identify conditions under which epidemics can spread within a farm and highlight the influence of management-related parameters such as water renewal rate and carcass removal frequency, as well as epidemiological traits including pathogen excretion and host recovery rates. By linking disease dynamics with both farm management practices and host genetic variability, this modelling framework provides useful guidance for farmers, health managers and breeding programs aiming to improve disease resilience in rainbow trout aquaculture.

Mating strategies to increase the polled phenotype in organic dairy cattle production: potential and consequences

A. Bouquet[1]
[1] *Aarhus Univeristy, Center for Quantitative Genetics and Genomics, C.F. Møllers Allé 3, 8000 Aarhus C, Denmark*

Following a revision of its branch guidelines, the Danish organic cattle industry has committed to banning dehorning by 2031. Consequently, farmers who wish to avoid horned animals must rapidly increase the proportion of polled (naturally hornless) cattle. This simulation study evaluated the impact, both in terms of genetic gain and genetic diversity, of different mating strategies aimed to increase the frequency of polled animals in organic herds. Simulations started from real haplotype data, including 47 599 autosomal SNPs, from Danish Holstein animals born in 2024. About 65% of animals were horned, 32% polled single carriers and 3% homozygous polled based on genotypes at the polled locus. A dairy cattle breeding program was simulated in which 10 000 cows were mated to 50 bulls each year resulting in 8 000 viable calves. Selection was performed on a single trait, resembling the total merit index, simulated by designating 10% of SNP as QTL whose additive effects were sampled from a normal distribution. Genetic effects were scaled in the founders so that genetic variance was equal to 1. All 8 000 newborn calves were genotyped. Each year, the best 30 1-year-old males were selected to become AI sires with fixed genotype distribution (best 18 horned, 9 heterozygous polled, 3 homozygous polled bulls). Selection was performed using genomic breeding values (GEBVs) sampled to achieve a reliability of 0.50 for candidates without own phenotypes. Twenty additional bulls aged 2-3 years were selected independently of polled genotype. The best 10 000 females were also selected on GEBVs and the top 400 were flushed annually to produce 4 viable calves. All matings were performed at random in the breeding population. An organic population of 5 000 cows was also simulated in which five mating strategies were tested: 1) Baseline with random mating considering all 50 AI bulls; 2) S1: mating include at least one polled parent; 3) S2: all horned bulls excluded from mating; 4) S3: all horned females mated to polled homozygous bulls and polled females to any polled bulls; and 5) S4: identical to S3 but doubling the number of matings allowed for homozygous polled bulls. Simulations ran for 20 years with 20 replicates per scenario. Mating strategies were compared based on the proportion of polled calves born in organic herds, achieved genetic gain and inbreeding trends, and extended haplotype homozygosity (EHH) around the polled locus. The proportion of polled calves born remained stable in the baseline scenario (0.30-0.45) but increased sharply in strategies S3 and S4. About 90% of calves were polled within 5 years in S4 and 20 years in S3. Compared with the baseline, mating strategies S1-S4 reduced genetic gain by 11.8 to 13.1%, because the use of high merit horned bulls was restricted or excluded. Differences in genetic gain were not statistically significant as gain depended largely on the group of heterozygous bulls. Due to low recombination rate around the polled locus, EHH remained high across all mating strategies and was highest for S4. Genome-wide inbreeding trends did not differ significantly among scenarios. Notably, homozygous polled animals remained slightly more inbred than horned and polled single carrier animals over 20 years in all scenarios. In conclusion, rapid adoption of polled genetics in organic dairy herds requires the availability and intensive use of homozygous polled bulls. While targeted mating strategies accelerate polledness, they slightly reduce genetic gain and maintain a strong selection signature at the polled locus. Adjustments to selection and mating decisions, including increased selection of polled bulls and optimization of matings, may help mitigate impacts on genetic diversity.

Establishment of breeding lines for organic dairy production

M. Kargo[1,2], J. R. Thomasen[2], R. Zaalberg[1], M. Hansen[1], L. P. Sørensen[2], T. Christensen[3], S. Denver[3], H. M. Nielsen[1]
[1] Aarhus University, QGG, C.F. Møllers Allé 3, 8000 Aarhus, Denmark, [2] VikingGenetics, Ebeltoftvej 16, 8961 Randers SØ, Denmark, [3] University of Copenhagen, Department of Food and Resource Economics (IFRO), Rolighedsvej 28, 1958 Frrb. C, Denmark

Organic farming plays a vital role in agricultural production. The European Union considers organic farming to be a key element in promoting sustainable agriculture; consequently, the EU has set a target of 25% organic agricultural land by 2030. While the management practices and labeling of organic products have been clearly regulated, the origin of animals in organic farms has, to date, been sourced from conventional breeding programs despite existing EU regulations (Regulation (EU) 2018/848). In the future we expect that animals used for organic production need to be sourced from organic farms. Also, we assume that organic dairy producers as well as other organic stakeholders want to differentiate from conventional production with respect to both management procedures and their genetic material used in organic dairy productions. The Danish project "Breeding dairy cows adapted for organic production" aims to demonstrate methods for practical implementation of organic dairy breeding schemes. Consumer (organic and conventional) surveys have been carried out among German, Swedish and Danish consumers. The consumers were asked how much they were willing to pay for organic dairy products. The results showed that consumers were willing to pay most when welfare-traits were included in the breeding goal. Traits related to climate impact were considered less important, while there was nearly no willingness-to-pay for increased milk yield. Furthermore, the survey revealed that consumers knew little about "modern" reproduction techniques. In addition to consumer preferences, we will also derive economic values based on farmer profit using a bio-economic farm model. Economic values are derived for three organic production systems defined by dairy farmers with focus on: 1) Efficiency Improvement within current organic regulations (ECO), 2) Biodiversity with high self-sufficiency and minimal transport and (ECO+) 3) Biodiversity, minimal transport, home grown feed, "naturalness" and "max" animal welfare (ECO++). Economic values and consumer preferences will be combined to weigh traits in the breeding goal with more weight on welfare, climate and product quality traits and less on production. Finally, these breeding goals will be used for designing optimal breeding schemes using the simulation program ADAM, followed by cost-benefit analysis of running breeding schemes for organic dairy production.

Genomic evaluation of a lactation persistency indicator in French dairy cattle breeds

Q. Berger[1], M. Barbat[1], S. Fritz[3], E. Dugas[1], C. Moulin[1], D. Boichard[2], A. Ben Abdelkrim[1], R. Rostellato[1]
[1] GENEVAL, 3 rue du petit Robinson, 78350 Jouy-en-Josas, France, [2] INRAE, GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [3] Eliance, 149 rue de Bercy, 75595 Paris, France

Today, lactation persistency in dairy cattle is mainly estimated via random regression models on test-day records, providing accurate genetic values for post-peak slope or late-lactation yield. Yet a simple indicator remains valuable: easy to compute and interpret while being low-cost. Better persistency supports longer lactations, delivering economic savings (lower replacement/rearing/vet costs, stable profitability), ecological benefits (reduced Green House gas emissions per kg milk, fewer surplus animals), and welfare gains (less metabolic stress, better longevity and health). To provide references and evaluate genetic potential for extended lactations, we investigated persistency of milk protein yield (PY) in six French breeds: Abondance, Tarentaise, Brown Swiss, Simmental, Montbéliarde, and Vosgienne. Data originated from official milk recording, spanning up to ten lactations. Persistency was defined as the ratio (in %) of PY from days 101 to 200 to PY from days 6 to 100. Genetic parameters including heritability and repeatability coefficients were estimated using the AI-REML algorithm in WOMBAT software. A univariate repeatability animal model included fixed effects of herd-year, age class, calving month, and drying-off status, plus permanent environment, additive genetic, and residual random effects. Correlations of persistency genomic predictions with national genomic estimated breeding values (GEBVs) for other traits were also computed. Persistency ranged from 0% to 195%, mostly between 50–130%, indicating strong phenotypic variation. Phenotypic mean varied between breeds, from 82.1% for Vosgienne to 93% for Brown Swiss, suggesting different improvement potential across breeds. Persistency performances increased over time in five breeds reflecting long-term phenotypic improvement likely driven by selection on correlated traits. In contrast, the Vosgienne breed remained stable, suggesting distinct underlying dynamics. Permanent environment exceeded genetic variance. Heritability estimates were low but significant (0.05–0.12 across breeds) and the genetic standard deviation ranged from 4.8 to 9.5, implying potential of improvement. Repeatability was moderate to high (0.30–0.50, lowest in Brown Swiss), indicating consistent individual differences across lactations. Genetic trends were positive in all breeds, accelerating from the 1980s in parallel with intensified multi-trait selection on production and functional traits. Despite the absence of direct inclusion of persistency in the current breeding objectives, these favourable trends demonstrate indirect genetic progress via correlated responses to selection on milk yield and functional traits. Genetic correlations with national GEBVs for other traits were mostly favourable: strongly positive with milk production (0.85-0.90), positive with udder health traits (0.20–0.80), neutral to positive with fertility and calving ease (0.00-0.60), variable for non-return rate. However, its correlation with individual genomic relationship with the rest of the population is negative, (−0.30 to −0.45), showing that genetically original individuals have a lower persistency. These findings indicate that direct selection on this lactation persistency indicator offers interesting potential, given significant heritability and favourable correlations with key production and functional traits. Owing to its simplicity and the indirect progress already observed, the indicator is useful to incorporate into breeding goals to promote more resilient cows, extended lactations, and enhanced sustainability in French dairy breeds.

Prediction of GEBVs for health traits in Australian and German Holstein cattle using Bayesian methods

A. M. Križanac[1,2,3], C. Schmidtmann[4], J. Bennewitz[5], G. Thaller[6], R. Xiang[7,8,9], A. J. Chamberlain[7,8], I. M. Macleod[7,8], J. Tetens[1,2], M. E. Goddard[7,9]

Genomic estimated breeding values (GEBVs) are commonly calculated using one of the two main approaches: (i) Genomic Best Linear Unbiased Predictor (GBLUP), and (ii) Bayesian methods. Even though GBLUP is still the most commonly used approach in national evaluations, recently Bayesian approaches have gained more attention. This is especially the case for traits controlled by a few major QTLs in addition to a polygenic effect, and traits with lower heritability, such as health traits. In Germany, health traits have been incorporated as a part of a balanced breeding goal in 2021, and their GEBVs are calculated using a single-step breeding value estimation model (ssGBLUP). However, to our knowledge, Bayesian methods haven't been commonly applied to calculate GEBVs on these traits or to evaluate the performance of the two approaches. By the end of 2025 the German national evaluation dataset contained 460,000 genotyped female cows with phenotypes for various health traits. Cow genotype data was collected during the KuhVision project, the purpose of which was to build a female reference population for the calculation of GEBVs. Part of this dataset was imputed to whole genome sequence, and SNP effects were calculated for various complex traits using a mixed linear model approach. To utilize the availability of large-scale WGS dataset in the prediction of EBVs using Bayesian methods, we first estimated the SNP effects of more than 2 million markers from ~100,000 to 180,000 German Holstein cows in 11 health traits using BayesR3–Bayesian MCMC mixed-effects genetic model. Health traits included six feet and leg related diseases; claw ulcers, digital phlegmon, digital dermatitis, interdigital hyperplasia, laminitis and white line disease, three metabolic diseases; milk fever, displaced abomasum, ketosis, and mastitis and somatic cell score. SNP effects calculated here will be correlated with EBV for some health-related metabolic traits in Australian genotype data.

Early Good Is Not Late Good: Why Early Performers Are Not Necessarily Finishing-Phase Winners

S. Götz[1], H. Geffert[2], D. Debiasi[2], U. Höne[2], I. Traulsen[2], I. Reker[3], N. Kemper[1], J. Probst[1]
[1] Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour (ITTN), University of Veterinary Medicine Hannover, Bischofsholer Damm 15, 30173 Hannover, Germany, [2] Institute of Animal Breeding and Husbandry, Christian-Albrechts-University Kiel, Hermann-Rodewald Straße 6, 24118 Kiel, Germany, [3] Chamber of Agriculture Lower Saxony, Herrmann-Ehlers-Straße 15, 26160 Bad Zwischenahn, Germany

Growth impairments in pigs are economically and clinically relevant but often detected late. Although growth curve models such as the Gompertz function can more accurately capture growth trajectories and health-related deviations, they require multiple measurements per animal and are therefore rarely feasible under routine farm conditions. This study examined whether a consistent performance ranking can be derived from few weighing events across the nursery and finishing phases, or whether phase-specific rank shifts occur that necessitate separate evaluation of both production stages. Individual body weights were collected in a commercial herd. The first weighing (W1) was conducted shortly before weaning, the second (W2) at the end of the nursery period, and the third (W3) was based on the calculated gross live weight of the animal at slaughter (421 pigs; 1263 weight records). The nursery phase (P1) was defined as W1→W2 and the finishing phase (P2) as W2→W3. To quantify phase-specific performance independently of starting level and time, expected end-of-phase weights were derived from batch-referenced linear models accounting for initial weight, time and batch structure (P1: $\hat{W}2$ from W2 ~ W1 + dt12 + batch; P2: $\hat{W}3$ from W3 ~ W2 + mast_days + batch). Performance deviations were then expressed as residuals, defined as observed minus expected weight (rP1 = W2 − $\hat{W}2$; rP2 = W3 − $\hat{W}3$), enabling identification of under- and overperforming animals within a batch. Residual distributions were centered close to zero (medians: rP1 +0.04 kg; rP2 −0.14 kg), supporting their interpretation as relative, within-batch performance deviations. No animal exceeded the plausibility threshold in either phase; maximum deviations corresponded to approximately −197 g/day (nursery) and +176 g/day (finishing). Only a weak association was observed between nursery and finishing deviations ($r = -0.06$; $p = 0.22$), indicating pronounced phase-specific re-ranking and compensatory growth patterns. Consistently, pigs in the lowest rP1 decile required a median of approximately seven additional days to reach slaughter (W2→slaughter). These findings demonstrate that a small number of weighings enables practical, phase-specific monitoring of performance development, but a stable ranking across nursery and finishing cannot be assumed. The approach supports within-batch prioritization (identification of outlier animals) and phase-specific interpretation of performance patterns ("lost early," "lost late," "caught up"). Future work will validate the method in additional batches and evaluate predictive performance in true within-batch train/test setups. In the longer term, deviations can be contextualized by integrating routinely available process indicators (e.g., barn climate, feed intake, health events) to support identification of potential drivers of phase-specific performance loss.
The project is supported by funds of the Federal Ministry of Agriculture, Food and Regional Identity (BMLEH) based on a decision of the Parliament of the Federal Republic of Germany via the Federal Office for Agriculture and Food (BLE) under the strategy for digitalization in agriculture.

Identification of candidate genes and key QTL associated with anogenital distance in Holstein cattle

S. K. Ashar[1], G. R. Dodd[1], S. M. F. Cunha[1], F. Miglior[1,2], F. S. Schenkel[1], C. F. Baes[1]
[1] University of Guelph, Centre for Genetic Improvement of Livestock, 50 Stone Road East, N1G 2W1 Guelph, Canada, [2] Lactanet, 660 Speedvale Ave W Unit 101, N1K 1E5 Guelph, Canada

Anogenital distance (AGD) is the distance from the centre of the anus to the base of the clitoris in dairy cows and has been proposed as an early-in-life indicator of fertility. Shorter AGD has been phenotypically associated with earlier return to cyclicity, shorter calving-to-conception intervals, and higher pregnancy rates. Because prenatal androgen exposure lengthens AGD, the trait may capture variation in fetal androgen signaling. Given its moderate heritability (0.37±0.08), AGD is a promising phenotype to improve selection for female fertility. However, its genomic architecture in dairy cattle remains uncharacterized. The objective of this study was to identify genomic regions, candidate genes and functional pathways associated with AGD in Canadian Holsteins using a single-step genome-wide association study (ssGWAS). Phenotypic records were available for 5,541 heifers and cows from 20 herds. After data editing, 4,988 animals remained for analysis. Genotypes from 6,631 animals in the pedigree and 40,274 single nucleotide polymorphisms (SNP) located on autosomal chromosomes passed quality control. A single-trait animal model was implemented in the BLUPF90 family of programs, integrating both pedigree and genomic information via the hybrid H matrix. The model included fixed effects of technician, quadratic regression on age at measurement, linear regression on days since calving at measurement, and herd-year-season of birth. Significant markers were identified using a chromosome-wise Bonferroni threshold based on the number of independently segregating genomic regions. Additionally, sliding windows of 10 adjacent SNP were used to estimate the proportion of additive genetic variance explained, applying an empirical threshold of ≥0.2%. Gene and QTL annotation were performed within ±50 kb of each significant SNP. A total of 34 significant SNP were identified, with 7 of those located within 6 genomic windows explaining ≥0.2% of the additive genetic variance. A total of 40 unique protein-coding genes were annotated within ±50 kb of each significant SNP that surpassed the chromosome-wise Bonferroni threshold. Among these, STOX2 and STOX1 genes have been implicated in preeclampsia, a pregnancy-associated hypertensive disorder in which elevated androgens may play a role; the CCAR1 gene is a known co-activator of the androgen receptor, which may influence androgen signalling during fetal development; and the NR2C1 gene, one of the genes found to be significant as per consensus of the two analyses, functions as a nuclear receptor that modulates androgen receptor activity and suppresses estrogen-mediated transcription, supporting a potential role in sex steroid signaling. Additionally, 106 nearby QTL previously associated with fertility, puberty, growth, carcass traits, and lactation persistency were also identified. Consensus analysis highlighted 6 genes and 19 QTL supported by both single-marker and window-based approaches. Thus, this study provides novel insights into the genomic architecture of anogenital distance in Canadian Holsteins, identifying significant genomic regions, potential candidate genes, and QTL associated with steroid hormone signalling and reproductive physiology, improving our understanding of the biological mechanisms underlying variation in AGD.

Genomic Diversity and a Haplotype Imputation Reference Panel for Pikeperch (Sander lucioperca)

Z. Cai[1], Z. Bai[1], J. Overton[2], T. Boutrup[2], H. M. Nielsen[1], G. Sahana[1]
[1] Aarhus University, Center for Quantitative Genetics and Genomics, C. F. Møllers Alle 3, 8000 Aarhus, Denmark, [2] Aquapri ApS, Skomagervej 4L, 7100 Vejle, Denmark

Pikeperch (zander; Sander lucioperca Linnaeus, 1758) is an economically important freshwater and brackish-water fish native to the Black, Caspian, and Baltic Sea basins. Its aquaculture has progressed from reliance on wild spawners to reliable controlled reproduction with improved larviculture and recirculating aquaculture systems (RAS) grow-out. However, the breeding of pikeperch lacks genomic resources required to accelerate genetic gain and support broodstock management. To facilitate the development and usage of genomic tools for pikeperch selective breeding, we aimed to 1) characterize genomic diversity in the breeding stock; 2) construct the first species-specific haplotype reference panel that enables imputation from low-density SNP arrays or low-pass sequencing (LPS) to whole-genome sequencing (WGS) resolution by integrating in-house and public datasets. We generated de novo WGS data for 60 samples, including 48 individuals from four breeding cohorts and 22 founders from the base population at Aquapri Innovation (Vejle, Denmark). These were combined with 365 publicly available WGS samples from Germany. Variants calling was performed using GATK best- practices pipelines. Population structure was assessed using principal component analysis (PCA), admixture analysis, and phylogenetic inference. A species-specific reference panel was constructed. We identified approximately 7.4 million bi-allelic variants segregating across 425 samples. PCA revealed clear genetic separation between Danish and German populations. Both the admixture and phylogenetic analysis supported population differentiation between Danish and German samples while indicating shared ancestral origin. Within the Danish samples, the founder individuals (22 individuals) were genetically interspersed with breeding cohorts (48 individuals), indicating genetic contribution of the base population across all cohorts. Based on this variant dataset, we constructed the first haplotype reference panel for pikeperch providing genomic resources for whole genome imputation and downstream breeding applications. This study establishes a foundational genomic diversity framework and delivers the first imputation resource for pikeperch, enabling genome-wide association studies (GWAS), genomic selection, and broodstock management. Ongoing validation using ~2,000 LPS samples will support scalable, cost-efficient selective breeding and long-term genetic improvement in pikeperch aquaculture.

Sequence-level genome-wide analysis of hoof disease traits in Swiss dairy cattle populations reveals a polygenic and breed-specific architecture

S. Vasiljevic[1], F. R. Seefried[2], S. Widmer[2], N. K. Kadri[3], A. S. Leonard[3], H. Pausch[3], A. Steiner[4], C. Drögemüller[1], J. Jacinto[1,4]

Background: Hoof diseases pose a significant health and welfare challenge to dairy cattle, negatively impacting their productivity and longevity. However, their genomic architecture is not fully understood. Objectives: We aimed to identify possible quantitative trait loci (QTL), candidate genes, and candidate variants associated with infectious and non-infectious hoof diseases in Swiss Holstein (HO) and Brown Swiss (BS) cattle using standardized hoof health phenotypes from routine professional hoof health recording and imputed whole-genome sequence (WGS) single- nucleotide variant (SNV) data. Materials & Methods: Genotypes were quality controlled and imputed to WGS level. After breed assignment and filtering, 87,806 HO and 52,202 BS animals were retained (36.3 and 24.1 million biallelic SNVs, respectively) for further analyses. Phenotypic data comprised standardized hoof health records from professional hoof trimmers. The considered traits included: digital dermatitis (DD), white line disease (WLD), other infectious diseases (INF), and claw horn lesions/diseases (CHL). Yield deviations (YD) were calculated by correcting phenotypes for fixed and random effects. Only YD from the first lactation were then retained and averaged per animal to serve as proxy phenotypes in in genome-wide association studies (GWAS). SNV-based additive heritabilities (h^2) were estimated using GCTA software. Recessive, but also additive GWAS were performed separately using GCTA with breed-specific significance thresholds based on PLINK software pruning and Bonferroni correction. Significant regions were refined using joint analysis and Bayesian fine mapping with PAINTOR software. Candidate variants were prioritized based on statistical significance, PAINTOR credible-set inclusion, linkage disequilibrium with lead SNVs, and biological plausibility of nearby genes. Results: Additive h^2 were generally low across traits and breeds, with the highest estimate for DD in Holstein ($h^2 = 0.086 \pm 0.023$). Additive and recessive GWAS identified multiple breed- and model-specific QTL for the four hoof disease traits. For DD in HO, we identified one single additive QTL on chromosome (chr) 21 but also a recessive QTL on chr 23. In BS, DD was associated with one additive QTL on chr 23 and two recessive QTL on chr 10 and chr 23. For CHL, one additive QTL was detected in HO on chr 16 and one additive QTL in BS on chr 14. Conclusion: This study is the first to analyse the genetic architecture of hoof disease traits in Swiss dairy cattle, revealing a low h^2. Additive and recessive GWAS results using proxy phenotypes suggest a polygenic basis and identify several QTL. One of these QTL was previously found in a different HO cattle population. Our findings require further functional and clinicopathological validation and demonstrated that precise phenotypic data and extensive WGS data are essential for the analysis of health traits with low h^2.

Understanding dairy producer's perspective and experience with reporting gestational and developmental dairy calf conditions

[1] University of Guelph, Centre for Genetic Improvement of Livestock, 50 Stone Rd East, N1G 2W1 Guelph, Canada, [2] Ontario Veterinary College, 50 Stone Rd East, N1G 2W1 Guelph, Canada, [3] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, Postboks 50 Tjele, Denmark, [4] Lactanet, 660 Speedvale Ave. West, N1K 1E5 Guelph, Canada, [5] Holstein Association of Canada, 20 Corporate Place, N3T 5R4 Brantford, Canada, [6] Council on Dairy Cattle Breeding, 4201 Northview Dr., 20716 Bowie, United States, [7] University of Florida, Department of Animal Sciences and the Genetics Institute, 2250 Shealy Dr., 32611 Gainesville, United States, [8] North Carolina State University, Department of Animal Science, 120 W Broughton Dr, 27695 Raleigh, United States

Genomic selection has accelerated genetic progress in the dairy industry by enabling earlier selection decisions and increasing evaluation accuracy. At the same time, it has contributed to higher rates of inbreeding and reduced genetic diversity. Higher homozygosity increases the likelihood that an individual will inherit two identical-by-descent copies of deleterious or lethal recessive alleles, raising the risk of affected gestational and early calf development, including embryonic loss, stillbirth, congenital deformities, and early-life disorders. As many of these conditions are caused by recessive inherited haplotypes, early identification is essential to limit their frequency in the population. Canada currently lacks a centralized system for reporting and coordinating information on gestational or developmental conditions for downstream analysis. Producers may report to veterinarians, semen distributors, or breed associations, or may not report at all, resulting in a fragmented approach that hinders early detection of emerging genetic issues. To inform the design of an effective national reporting system, an online questionnaire was distributed across Canada through industry sector magazines and producers' meetings. The objective of this study was to characterize producer perspectives on reporting conditions and genetic testing. The questionnaire, available in English and French, included 32 questions organized in three sections: 1) demographics; 2) awareness and comfort with reporting systems; and 3) experience with gestational and calf developmental conditions and reporting behaviour. A total of 130 respondents consented to analysis. Overall, 81.6% of respondents indicated being comfortable with reporting conditions; those who were uncomfortable cited time constraints and uncertainty about where to report. Respondents indicated that a simple electronic format and clear educational resources would improve participation. If the reporting system were improved, 93% of respondents said they would be likely or very likely to use it, highlighting the need to create a reporting system that satisfies producers. Although 87% of respondents had experienced conditions within their herds, 70% of this group did not report these events, and cases were not investigated to prevent recurrence. These findings identify modifiable barriers to reporting and highlight key features required for a practical, producer-centred system. While the responses represent a relatively small, engaged group, they emphasize the need for a centralized database to support genetic monitoring, reduce stigma surrounding conditions, and improve industry-wide learning. Ultimately, the results provide direction for how a system should be structured to enhance coordinated data collection, enable continued genetic discovery, and strengthen long-term management strategies.

Integrating Long-Read Sequencing and SNP Genotyping to Uncover Genetic Determinants of Stillbirth in Holstein Cattle

Y. Zheng[1], C. Reimer[1], F. Fischer[1], C. Schmidtmann[2], L. Hüneke[2], C. Klein[1], C. Kühn[3,4], J. Geibel[1]
[1] Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Höltystr. 10, 31535 Neustadt, Germany, [2] IT Solutions for Animal Production (vit), Heinrich-Schröder-Weg 1, 27283 Verden, Germany, [3] Friedrich-Loeffler-Institut, Südufer 10, 17493 Greifswald, Germany, [4] University of Rostock, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany

Stillbirth in dairy cattle represents not only a significant economic burden but also a key animal welfare concern, with a demonstrable genetic component that remains incompletely resolved. Large-scale genomic studies in multiple cattle populations have mapped quantitative trait loci (QTL), haplotypes, and chromosomal regions associated with stillbirth and related reproductive outcomes, while also highlighting the complex and multifactorial nature of this phenotype. However, previous studies have largely relied on short-read sequencing, which has limited power in detection of large structural variants (SVs), or array-based genotyping, which often misses deleterious variants with low frequencies due to them being poorly tagged by nearby array SNPs. Additionally, without observing the genotypes of stillborn calves directly, candidate causal alleles cannot be pinpointed. To overcome these challenges, we implement a strategy that combines long-read whole-genome sequencing and SNP array data. Our study uses Nanopore long-read sequences from more than 60 Holstein individuals in addition to 50K-SNP-genotypes from hundreds of stillborn calves and their parents and live-born half-sibs. The sample collection is linked to the development and implementation of a stillbirth monitoring system within the project "Monitoring of Genetic and Phenotypic Trends" (MGPT), which collects extensive phenotypic data to accompany these genotypes. Variant discovery begins with extensive analysis of long-read genomes using both reference mapping and a de novo assembly pangenome graph framework, allowing us to capture a broad spectrum of potentially deleterious variants — especially large SVs and sequences absent from the reference genome that are typically missed by short-read approaches. Using annotated regulatory and functional genome resources, we assess the potential phenotypic impact of these variants, with particular attention to rare alleles of high effect. We then define haplotype blocks from the SNP genotypes and impute the long-read-derived variants into the larger stillbirth and adult cohorts. This imputation-enhanced genotype dataset enables the direct identification of rare recessive variants that are homozygous only in stillbirth cases while appearing in heterozygous form in healthy adults — a pattern indicative of deleterious effects. By including actual genotypes from stillborn calves, we observe deleterious haplotypes directly rather than inferring them solely from missing homozygotes in adult populations. Preliminary results already enabled the first description of an inverted repeat with substantial copy number variation underlying a previously identified QTL on BTA18. Through this comprehensive framework, we aim to refine current understanding of Holstein genomic trends, uncover previously unknown genetic contributors to stillbirth and developmental failure, and ultimately design a risk monitoring system based on parental genotypes. Such a system would support breeding decisions that reduce the transmission of defective alleles and improve reproductive performance in dairy cattle populations.

Identification of novel shared loci across purebred boar lines influencing the onset of puberty

P. Sá[1], C. A. Sevillano[1], J. M. Tabet[1], J. Dekkers[2], R. Fernando[2], H. Yu[3], R. M. Godinho[1], E. Grindflek[1,4]
[1] Topigs Norsvin Research Center B.V., Meerendonkweg 25, 5216 TZ 's-Hertogenbosch, Netherlands, [2] Iowa State University, Department of Animal Science, Kildee Hall, 1221, IA 50011 Ames, United States, [3] University of Florida, Department of Animal Sciences, 2250 Shealy Dr,, FL 32608 Gainesville, United States, [4] Norsvin S.A., Storhamargata 44, 2317 Hamar, Norway

The onset of puberty (OP) is a valuable trait for pig breeding programs, especially for optimizing reproduction management in boars and gilts. Accurately determining the OP can greatly influence farm reproductive management, productivity, and profitability. However, detecting the OP is tedious and typically involves observing sexual behavior and confirming the presence of viable sperm after ejaculate collection. Alternatively, the OP can be estimated indirectly by identifying the inflection point of sigmoidal growth curves, such as the Gompertz curve. In practice, this last approach is advantageous because pig breeding companies routinely collect large phenotypic datasets on growth and development. A Bayesian hierarchical model was previously developed in our group to integrate a whole-genome prediction model using a 25K SNP panel and a pig growth model that fits a Gompertz curve, incorporating a recursive relationship between daily body weight and daily feed intake records. This model was applied to predict key OP traits, including age at OP (AOP) and weight at OP (WOP). These predicted values showed positive correlations with male reproductive performance, i.e., sperm motility, age at first ejaculate, and trainability, supporting their biological relevance. To further elucidate the genetic architecture underlying these novel phenotypes, we conducted a genome-wide association study to identify genomic regions and candidate genes involved in OP variation. Data were available for 25,686 purebred boars from four lines (Duroc, Landrace, Large White, and Synthetic), including 594,095 imputed SNPs obtained through routine imputation procedures. The set of 25K original SNP were used to construct genomic relationship matrices. Association testing was performed for each line separately on autosomal SNPs with a minor allele frequency greater than 0.05. Quantitative trait loci (QTL) were detected using a Bonferroni-adjusted significance threshold (−log10(P-value) > 6.9–7.0), and candidate regions were defined by grouping at least three consecutive significant SNPs located within 1 Mb of each other. The AOP ranged between 110 and 210 days across different lines, with line-specific averages ranging from 146 to 165 days (SD = 8-10 days). The WOP ranged between 75 and 190 kg, with line-specific averages ranging from 91 to 134 kg (SD = 7-11 kg). In total, eight QTL were identified (1 in Duroc, 2 in Landrace, 5 in Large White, and 4 in the Synthetic line). One QTL was shared between Large White, Landrace, and Synthetic lines, and three QTL were shared between the Large White and Synthetic lines, consistent with their shared genetic background. Notably, one shared QTL on chromosome SSC1 (150.0 Mb) exhibited dominance/recessive effects and was located in the CYB5A gene, which encodes a key enzyme involved in steroidogenesis pathways and has been associated with testosterone levels in multiple human GWASes. Further downstream analyses are required to validate these QTL and to identify potential causal variants influencing the onset of puberty in boars.

Single-step genomic predictions considering QTLs with large effects

R. Bonifazi[1], D. Jamieson[2], M. Bink[2], K. Janssen[2], J. Vandenplas[1]
[1] Wageningen University & Research, Animal Breeding and Genomics, PO Box 338, 6700 AH Wageningen, Netherlands, [2] Hendrix Genetics, PO Box 114, 5831 AC Boxmeer, Netherlands

Genomic selection has been implemented in many livestock and aquaculture species. Traditional genomic prediction models such as single-step single nucleotide polymorphism (SNP) BLUP (ssSNPBLUP) assume a priori homogenous SNP (co)variances. Hence, all markers are assumed to explain the same proportion of the trait's genetic variance. However, this assumption is violated in the presence of loci with large effects, such as for traits with large QTL effects. In the presence of loci with large effects, SNPs in linkage disequilibrium with such loci are expected to have a larger impact on the phenotypes than others. Different approaches to model these markers in single-step evaluations have been proposed, but usually, limited benefits are observed. Moreover, it is not clear what the impact of different marker weighting in multi-trait evaluations could be when only some traits are associated with a few QTLs with large effects. Therefore, the aim of this study was to implement and validate several single-step genomic prediction models that account for SNPs linked with QTL with large, trait-specific effects. A commercial rainbow trout (Oncorhynchus mykiss) dataset was available, consisting of ~178,000 individuals in the pedigree, ~8,300 individual genotypes at ~4,500 SNPs density, and ~117,000 phenotypes recorded on nine traits across three different environments (nucleus, challenge, and sentinel). Variance components were estimated using a multi-trait pedigree REML approach (heritabilities ranged between 0.02 and 0.69). A univariate single-step GWAS (ssGWAS) was used to identify SNPs significantly associated with each trait ($p \leq 1 \square 10^{-8}$). Four traits showed significant SNPs. Three single-step models were compared: i) ssSNPBLUP: an unweighted single-step SNPBLUP evaluation, assuming homogenous SNP (co)variances (ssSNPBLUP). ii) w_ssSNPBLUP: a weighted ssSNPBLUP weighing SNP (co)variances based on their posterior probability obtained from the univariate ssGWAS. Weights were defined based on a moving average across five SNPs. Only the four traits with significant SNPs were weighted, while the rest were unweighted. iii) LV_ssSNPBLUP: an unweighted single-step SNPBLUP in which SNP(s) associated with QTL(s) are modelled as a different but correlated trait. All models were validated using a forward-in-time cross-validation approach (LR method), comparing two evaluations: a "whole" evaluation using all data, and a "partial" evaluation in which phenotypes of individuals born after 2019 were masked. Validation individuals were genotyped parents born in 2019 (74 males and 122 females). Within each model, genomic estimated breeding values (GEBVs) from the partial and whole evaluations were compared to estimate dispersion and accuracy. Compared to unweighted ssSNPBLUP, the w_ssSNPBLUP approach improved the accuracy (from 0.56 to 0.69 in males, and from 0.48 to 0.60 in females) and reduced dispersion (from 0.89 to 1.00 in males, and from 0.76 to 0.94 in females) of GEBVs for bacterial cold water disease (BCWD), a trait associated with highly significant QTL effects. For other traits, w_ssSNPBLUP showed no advantage or had a slightly negative impact compared to ssSNPBLUP, likely due to overemphasizing weight on only a few SNPs or genetic correlations between traits. Finally, modelling QTLs as separate correlated phenotypes in LV_ssSNPBLUP showed no significant advantage over ssSNPBLUP. Our results show that for traits with large QTL effects, such as for BCWD in this study, the weighted ssSNPBLUP model yields more accurate genomic predictions.

Evaluation of targeted sequencing as a flexible alternative to SNP arrays for routine cattle genotyping

K. Huijben[1], E. Francis[1], P. Doran[2]
[1] VHLGenetics, Agro business Park 100, 6708 PW Wageningen, Netherlands, [2] Twist Bioscience, 681 Gateway BLVD, CA944080 San Francisco, United States

High-density SNP arrays are the current standard for cattle genotyping in genomic selection and breeding programmes. While robust and widely adopted, array-based platforms rely on fixed marker content, limiting rapid incorporation of newly discovered variants and reducing flexibility as breeding objectives evolve. Targeted sequencing panels offer the potential to overcome these limitations by enabling dynamic marker selection while maintaining compatibility with established genomic evaluation pipelines. However, evidence for their feasibility, operational scalability, and cost-effectiveness under routine commercial genotyping conditions remains limited. The objective of this study is to evaluate whether targeted sequencing can provide a technically reliable, operationally scalable, and economically viable alternative to SNP arrays for routine cattle genotyping in commercial breeding programmes. Commercial cattle DNA samples (initial dataset n = 96, with ongoing expansion) are analysed using both array genotyping and a bovine targeted sequencing panel developed in collaboration with Twist Bioscience. Sequencing is performed on an in-house Element Biosciences Aviti platform to assess implementation within a practical laboratory workflow. Comparative evaluation includes genotype concordance, call rate, coverage uniformity, data completeness, turnaround time and estimated cost per sample. This study provides an applied framework for transitioning from fixed array-based genotyping towards flexible, scalable sequencing-based strategies, supporting adoption in commercial cattle breeding programmes. Demonstrating comparable data quality combined with improved flexibility and competitive costs would enable faster integration of novel traits and accelerate genetic improvement.

Pangenome construction enables detailed investigation of the IGH locus in alpacas

B. Schmitt[1], N. Khaveh[1], A. K. Struck[1], D. Höltig[2], J. Metzger[1]
[1] University of Veterinary Medicine Hannover, Institute of Animal Genomics, Bünteweg 17p, 30559 Hannover, Germany, [2] University of Veterinary Medicine Hannover, Clinical Centre for Farm Animals, Bischofsholer Damm 15, 30173 Hannover, Germany

Camelid single-domain antibodies, derived from natural occurring heavy-chain-only antibodies (HCAbs), represent a unique class of antigen-binding molecules. Due to their exceptional stability and small size, they have become increasingly important in diagnostics, research, and therapeutic development. While conventional IgG molecules consist of two light and two heavy chains, these specialized IgG subclasses are composed solely of heavy chains and are, therefore, referred to as HCAbs. The ability to produce HCAbs is encoded within the immunoglobulin heavy chain (IGH) locus, where HCAb-associated γ constant genes harbor characteristic structural features that prevent light-chain association. However, the genomic organization, allelic diversity, and regulatory architecture of the IGH locus in camelids, particularly in alpacas, remain incompletely annotated and poorly resolved at the haplotype level. In this study, we generate haplotype-resolved long-read assemblies of the IGH locus across alpacas to characterize structural variation across individuals that are currently not represented in the reference genome. For this purpose, we used blood samples from 10 unrelated alpacas, 5 females and 5 males. To create a pangenome, we performed long-read sequencing using PacBio HiFi to examine the individual differences between the animals in the IGH locus in more detail. We then compared the IGH locus of the alpaca with that of dromedary, for which some variants responsible for the development of HCAbs have already been described, to assess whether these variants are also present in alpacas. Although the IGH locus of alpaca and dromedary show high similarity, not all HCAb-associated variants occur in alpacas. Instead, we identified novel variants that may contribute to HCAb development in this species. Long-read sequencing was essential for pangenome construction because antibodies loci are highly repetitive and rapidly exceed the resolving power of short-read technologies. By spanning the full IGH region, long reads enable accurate assembly and variant detection, resulting in more complete and reliable representation than short-read sequencing. This finding provides an important basis for targeted selection and breeding strategies for HCAbs production.

GENIUS: Genotype-Informed Unbiased Selection of Individuals for Efficient Phenotyping

M. Neuditschko[1]
[1] *Agroscope, Animal GenoPhenomics, Route de la Tioleyre 4, 1725 Posieux, Switzerland*

The rapid decline in genotyping costs over the past two decades has resulted in an unprecedented increase in the number of genotyped animals across all livestock species. In contrast, phenotyping complex traits, such as health, behavior, resilience, and efficiency, remains expensive and labor-intensive. Consequently, the limited availability of high-quality phenotypic records has become a major constraint for exploring the genetic architecture of these traits. However, the abundance of genomic data creates new opportunities to strategically select the most informative individuals for phenotyping based on their genotype information, an approach we term GENIUS (Genotype-Informed Unbiased Selection). Using a simulated dataset comprising 2,326 individuals genotyped for 10,031 SNPs and segregating three additive quantitative trait loci (QTL), we evaluated the utility of two strategies for identifying informative individuals for phenotyping: (i) a principal component analysis (PCA) based approach and (ii) a redundancy-reduction (RR) approach aimed at maximizing genetic diversity. The performance of these strategies was compared with random sampling. Both approaches achieved higher QTL detection rates than random selection across reduced subsets of 1,000, 500, and 250 individuals. Notably, the RR strategy outperformed the PCA based method and successfully detected all three QTL using phenotypic information from only 250 individuals, approximately 10% of the dataset. These results demonstrate that GENIUS enables efficient identification of phenotyping candidates and provides a feasible and highly effective strategy to substantially reduce phenotyping costs while maintaining strong power to detect QTL in complex populations.

Discovery of methylated regions from nanopore sequence data of pigs

C. Reimer[1], J. Geibel[1], L. Vollmer[1], A. Weigend[1], D. Hinrichs[2], S. Weigend[1], C. Klein[1]
[1] Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Höltystraße 10, 31535 Neustadt, Germany, [2] University of Kassel-Witzenhausen, Faculty of Organic Agriculture, Nordbahnhofstraße 1a, 37213 Witzenhausen, Ghana

Epigenetic variation is an important regulatory layer influencing complex traits in livestock. DNA methylation plays a central role in gene regulation, development, and environmental responses. In pigs, breeding traits such as growth, fertility, health, and robustness are influenced not only by genetic variation but also by regulatory mechanisms affecting gene expression across tissues and individuals. Local breeds are generally considered less performant but more resilient to environmental stress which might be reflected in the methylation patterns and levels. Understanding genome-wide DNA methylation variability is therefore essential for explaining phenotypic diversity, environmental epigenetic effects, and regulatory regions affecting economically important traits. Recent advances in long-read sequencing technologies, particularly nanopore sequencing, allow direct detection of DNA methylation at single-molecule resolution. This enables genome-wide characterization of methylation patterns in individual animals and identification of regions with variable methylation. Such regions may represent regulatory hotspots associated with gene control, chromatin structure, or environmental responsiveness. Genomic DNA from individually sequenced Swabian-Hall pigs was analyzed using long-read nanopore sequencing data. Reads were aligned to the Sus scrofa reference genome (Sscrofa11.1), and per-site DNA methylation calls were extracted directly from aligned BAM files using modkit. CpG methylation site calls with a minimum coverage of five reads were retained for downstream analyses. To focus on CpG sites, methylation calls were intersected with genome-wide CpG coordinates derived from the reference genome sequence with customized bedtools makewindows scripts. Complementary strand CpG sites were combined into CpG dyads by shifting minus-strand coordinates and summarizing methylated and unmethylated read counts per dyad. Weighted methylation levels per dyad were calculated as the proportion of methylated reads divided by all reads per dyad. CpG island annotations were obtained from the UCSC Genome Browser. Dyads overlapping CpG islands were aggregated to compute island-level methylation estimates for each individual. In addition, genome-wide sliding windows of 1 kb window size with 50 % overlap, were used to summarize methylation levels across the genome. For each window, methylation fractions were calculated based on the summed methylated and total read counts of all CpG dyads within the region. Per-sample results were combined into methylation matrices for downstream comparative analyses. After filtering, about 90 to 130 k 5mC calls per sample were retained, of which 11 to 19 k per sample intersected with CpG-dyad coordinates derived from the reference sequence. Summary of CpG dyads in sliding windows returned about 5’000 windows, of which one window had a standard deviation of methylation fraction across individuals of 23> 0.3. These windows were located in eight consecutive clusters on seven chromosomes. Intersection of dyads with 3’900 known CpG islands discovered 55 thereof covered with methylation in the studied pigs. Two islands (14:51706840–51732873 and 12:58569822–58570047), the first also supported by the window approach, showed pronounced variance in methylation levels among samples, making them candidates for differentially methylated regions. Our results demonstrate the feasibility of nanopore sequencing to identify methylation variability and candidate regulatory regions as a basis to study phenotypic diversity in pigs.

Seasonal drought reshapes the rumen microbiome and metabolic potential of Ethiopian Boran cattle

R. Van Damme[1], L. Nasirzadeh[2], W. Ayalew[3], T. Klingström[1], G. M. Tarekegn[4], S. Flores[1], E. Bongcam-Rudloff[1]
[1] Swedish University of Agricultural Sciences, Animal Biosciences, Ulls väg 26, 756 51 Uppsala, Sweden, [2] Linköping University, Department of Biomedical and Clinical Sciences (BKV), Campus Valla, 581 83 Linköping, Sweden, [3] South China Agricultural University, State Key Laboratory of Swine and Poultry Breeding Industry, Wushan Road 483, 510642 Guangzhou, China, [4] Scotland's Rural College, W Mains Rd, EH9 3JG Edinburgh, United Kingdom

Increasing drought frequency associated with climate change threatens livestock production in semi-arid regions. The rumen microbiome is essential for plant fibre degradation and nutrient utilisation, yet its response to extreme drought conditions remains poorly understood. We hypothesised that drought alters rumen microbial composition and metabolic potential in Boran cattle, an indigenous Ethiopian breed adapted to harsh environments. Rumen samples were collected from Boran cattle during the dry season (February) and the rainy season (April). The study initially included 20 animals, but the severe 2022 Horn of Africa drought resulted in the death of 13 animals before the second sampling. Metagenomic sequencing was performed using Illumina short-read and Oxford Nanopore long-read sequencing. Taxonomic reads profiles were generated independently for both datasets, and only taxa detected by both technologies were retained. Illumina reads were used for quantitative analysis. Hybrid assemblies combining Illumina and Nanopore reads were generated using the MUFFIN workflow to reconstruct metagenome-assembled genomes (MAGs) and proceed with functional annotation and pathway reconstruction. Result visualisation was performed using PANKEGG. Taxonomic reads analysis revealed clear seasonal shifts in rumen microbial composition. During drought conditions, the genera Butyrivibrio and Prevotella were the dominant taxa associated with plant degradation. In contrast, Fibrobacter became the most abundant cellulose-degrading genus during the rainy season. Genome-resolved analysis supported these findings: Fibrobacter MAGs were recovered from all rainy-season samples but were absent from drought samples, whereas Prevotella MAGs were detected in all samples across both seasons. Functional analysis of MAGs showed reduced completeness of starch and sucrose metabolism pathways in drought samples compared with rainy-season samples. At the sample level, pathway completeness increased during the rainy season, with Fibrobacter contributing approximately 25% of the detected pathway genes. Overall, metabolic pathway completeness was consistently lower in drought samples. These differences likely reflect seasonal variation in feed availability and composition. During drought, cattle mainly consume dry shrubs and straw containing higher lignin levels, which may limit cellulose degradation by Fibrobacter. In contrast, Prevotella and Butyrivibrio appear more tolerant to lignified plant material and may dominate under drought conditions. Reduced microbial metabolic potential during drought may therefore decrease feed utilisation efficiency when forage resources are limited. Despite the reduced sample size, this study provides evidence that extreme drought conditions substantially reshape rumen microbial communities and their metabolic capabilities in Boran cattle. Understanding microbiome responses to environmental stress may help improve livestock resilience to increasingly frequent climate extremes.

Independent validation of Enterosignatures reveals reproducible community patterns and stress-associated assembly under porcine commercial conditions

A. Clavell-Sansalvador[1], I. T. Vourlaki[1], R. Río-López[2], A. Ruiz De Valbuena[3], I. Huerta[4], A. Romagosa[4], C. Y. Chen[5], J. W. Holl[5], A. Dalmau[2], Y. Ramayo-Caldas[1]

[1] IRTA, Genetics and Animal Breeding program, Ctra. C-59, Km. 12,1, 08140 Caldes de Montbui, Spain, [2] IRTA, Animal Welfare, Finca Camps i Armet, s/n, 17121 Monells, Spain, [3] Grupo AltoPaso, Av. de Oza, 240, 7a, A, 15006 A Coruña, Spain, [4] PIC Genus Plc, Carrer Pau Vila, 22, 2º6ª, 08174 Sant Cugat del Vallès, Spain, [5] PIC Genus Plc, 100 Bluegrass Commons Blvd #2200, 37075 Hendersonville, United States

Porcine gut microbiota represents a highly complex and dynamic ecosystem, whose organization and relationship with host phenotypes are important for animal health and welfare, food security, environmental sustainability, and even biomedicine. The concept of Enterosignatures (ES), defined as commonly co-occurring bacterial guilds, has been recently proposed in a Duroc pig population. The present study aims to independently validate the existence of pig ES across different breeds during the fattening period under commercial production conditions. Furthermore, we explore ES assembly in pigs exposed to prolongate social stress and examine their associations with host performance. To achieve this goal, we conducted a longitudinal study with 114 healthy pigs including 54 females (purebred Large White) and 60 males (purebred Large White and crossbred Large White x Landrace (F1)) housed under either control or social stress conditions (high-density stocking) during the fattening period. Body weight (BW) and fecal samples were collected at three time points across the fattening period. Enterosignatures composition was then determined from the fecal microbiota using Non-negative Matrix Factorization (NMF). Despite differences in genetic background and production systems in the pig industry, our findings confirm that the porcine fecal microbiota during the fattening period can be described by combinations of four reproducible ES. Consistent with pioneering reports, ES assembly was driven by Prevotella, Lactobacillus, Clostridium, and Streptococcus genera, which confirm their key ecological role on community structure, reinforcing their contribution in maintaining porcine fecal functional stability and host-microbiome symbiosis. We replicated previously documented impact of prolongated social stress on ES assembly, which was characterized by an increase in ES-Streptococcus and a decrease in the abundance of beneficial ES-Lactobacillus. Differences in body weight (BW) were observed primarily in females, with the control group weighing 7.4 % more than stressed females. Moreover, we replicated the negative association during the fattening period between host-performance and the abundance of ES-Streptococcus and ES-Prevotella. In contrast, no significant differences were observed in males, likely due to the large observed variability on BWs (SD in stressed males was 12.47 kg in comparison to 8.63 kg in females), since male population consisting of purebred Large White and F1 crosses with Landrace. In summary, our study independently validates the existence of porcine ES and their association with host performance during the fattening period, demonstrating strong reproducibility and highlighting the potential of the ES concept for microbiome-tailored strategies to improve pig health, welfare, and performance under commercial production conditions.

Shotgun Metagenomic Characterization of the Rumen Microbiome in Response to the Bovaer Feed Supplement in Lactating Holstein Cows

N. Frías-Reid[1], R. R. Lobo[2], J. L. Mejía-Méndez[1], C. Senés-Guerrero[3], M. De Donato-Capote[1], D. E. Navarro-López[1]
[1] Tecnologico de Monterrey, School of Engineering & Sciences, Epigmenio González 500, San Pablo, 76130 Queretaro, Mexico, [2] Nestlé Research, Department of Animal Sciences, Route du Jorat 57, 1000 Laussane, Switzerland, [3] Tecnologico de Monterrey, School of Engineering & Sciences, Av. General Ramon Corona 2514, Nuevo México, 45138 Zapopan, Mexico

Enteric methane from dairy cattle is a major contributor to agricultural greenhouse gas emissions. Dietary supplements present a promising mitigation strategy, but their specific effects on the community structure and functional potential of the rumen microbiome remain poorly understood. The present study aims to further explore the effects by which Bovaer® 10 can reduce enteric methane emissions by characterising the shift in the structure and function of the rumen microbiome of lactating Holstein dairy cows. A 6-week randomized controlled trial was conducted (Nov-Dec 2024), comprising a 2-week covariate period followed by a 4-week experimental period. Twenty cows were divided into 10 blocks based on parity (2 ± 1), milk yield (43.2 ± 10.0 kg/d), and days in milk (123 ± 15). Within each block, animals were randomly assigned to a control (CTR; n=10) or a treatment group (Bovaer; n=10). The basal diet was formulated to meet the nutritional requirements of the herd. Animals under treatment received a basal diet supplemented with Bovaer® 10 (600 mg/kg DMI). Feed intake was recorded using automated feeding stations (Hokofarm®, The Netherlands). Rumination boluses from animals of 5 blocks (CTR = 5; Bovaer = 5) were collected via non-invasive sampling during the 2nd (covariate) and 5th (experimental) week of the trial. DNA was extracted and subjected to shotgun metagenomic sequencing on an Illumina NovaSeqX platform, generating an average of 81 million raw reads per sample. Reads were quality-filtered, host-depleted, and taxonomically profiled. Microbial diversity was analysed via alpha (Shannon, Simpson, observed richness) and beta diversity metrics (Bray-Curtis's distance) with PERMANOVA. Overall, communities maintained high diversity (Shannon: 5.28 ± 0.61) and substantial richness (636 ± 175 microbial taxa). β-diversity analysis revealed that Bovaer treatment explained 25.3% of community variation (PERMANOVA, $p = 0.01$), while timepoint alone has minimal effect ($p > 0.16$). A significant treatment × time interaction was observed ($p = 0.01$), suggesting divergent temporal trajectories between groups. Moreover, a significant treatment × time interaction was observed for total archaea ($p = 0.03$), where the Bovaer group showed a 23% reduction in archaeal relative abundance from the covariate to experimental period (2.69% to 2.08%; Cohen's d = -0.95), whereas the CTR group exhibited an increase (1.29% to 2.11%; Cohen's d = 1.32). Methanobrevibacter, the dominant methanogenic genus and the primary target of Bovaer, had a tendency treatment × time interaction ($p = 0.06$) with a 31.2% reduction in relative abundance (5.19% to 3.57%; Cohen's d = -0.79) in response to the diet supplement. Particularly, Methanobrevibacter sp. 900314635 was observed to have a 30.5% decrease with the Bovaer treatment. Other archaeal species showed a more stable decline response to Bovaer (1.30% to 0.95%) (e.g., Methanomethylophilus sp001481295). In conclusion, shotgun metagenomics analysis demonstrates that Bovaer® 10 not only suppresses key methanogenic archaea but also redirects rumen microbial development toward a less methane-productive state, indicating that its methane-mitigating effect arises from both direct inhibition of methanogenesis and broader ecological restructuring within the rumen. Keywords: Rumen Microbiome, Bovaer, Ecogenomics

Metagenomic insights into the host–microbiome interaction for genetic mitigation of methane emissions in cattle

Z. Cai[1], S. Zhang[1], M. A. Satti[1], N. Saedi[1], E. Karaman[1], G. Sahana[1]
[1] Aarhus University, Center for Quantitative Genetics and Genomics, C.F. Møllers Alle 3, 8000 Aarhus, Denmark

The agricultural sector contributes 56% of total methane emissions in the EU, with cattle responsible for about two-thirds of these emissions. Targeting rumen methanogenic microbes represents a promising and direct strategy for methane mitigation in livestock. Emerging evidence shows that methane production and methanogen abundance are partly under host genetic control, making selection for low-emitting animals with a favourable rumen microbiome a sustainable, long-term solution for climate-smart livestock breeding. To advance low-methane breeding, we investigated the genetic parameters of methane emissions and the host control of the rumen microbiome using data from 500 Holstein cows. All cows were genotyped using a 70K SNP array, and methane emissions were measured using sniffers installed in automatic milking systems. Both 16S rRNA amplicon sequencing and whole-metagenome sequencing were applied to identify key microbial species, genes, and pathways, and to evaluate how microbiome information can improve the prediction of breeding values for methane. We observed, while metagenomic sequencing provides deeper insights into microbial functional potential, it tends to underestimate low-abundance taxa. Conversely, amplicon sequencing captures low-abundance methane-related species more effectively, although it is affected by biases from variable gene copy numbers and PCR amplification. Using the newly developed MetaMAG pipeline (https://github.com/msatti123/MetaMAG_Explorer), we identified 111 novel microbial species, several of which participate in hydrogen-utilizing and fermentation pathways, including acetate, fumarate, succinate, and acetyl-CoA pathway. Notably, the succinate pathway emerged as a key mechanism that may redirect energy flow from CH_4 formation toward propionate production, while the acetyl-CoA pathway supports acetate synthesis, both VFA that provide energy to the host animal. Preliminary analyses indicate that approximately half of the microbiome species (n = 3,493) exhibit heritable abundance patterns, with heritability estimates ranging from 0.05 to 0.56. Among these, 52 species belong to archaea. GWAS identified significant loci for 139 microbial species ($p < 3.45 \times 10^{-9}$), with most associated variants located in regulatory regions, suggesting that host control of the rumen microbiome is largely mediated through gene regulatory mechanisms. Statistical models were evaluated to estimate breeding values for methane emissions by integrating genetic and microbiome information. Furthermore, the models were used to quantify the relative contributions of host genetics and the rumen microbiome to the observed variation in methane emissions. Rumen microbiome explained 0.06-0.38% of the phenotypic variation in methane, though its genetic component was limited. Contribution of rumen microbiome to methane heritability was largest with 16S rRNA amplicon data compared to metagenome sequencing, suggesting that 16S rRNA amplicon data can be useful to incorporate into genomic prediction of methane. The prediction accuracy of methane was doubled when 16S rRNA amplicon data was added on top of genetic marker data. Amplicon-based microbiome profiles outperformed metagenomic data due to better detection of low-abundance taxa relevant to methanogenesis.

Runs of homozygosity reveal genomic regions associated with tropical climate adaptation in tropically adapted taurine cattle

G. H. C. Borges[1], V. Ligori[2], E. R. Carrara[2], G. Z. Sussai[2], R. R. Vicentini[2], L. E. F. Zadra[1,2]
[1] São Paulo State University "Júlio de Mesquita Filho" (UNESP), School of Agricultural and Veterinary Sciences, Animal Science, Prof. Paulo Donato Castellane Access Road, s/n, Rural Area, 14884-900 Jaboticabal, Brazil, [2] Institute of Animal Science, Beef Cattle Division, Carlos Tonani Highway, Km 94, P.O. Box 63, 13460-000 Sertãozinho, Brazil

Locally adapted cattle breeds to tropical environments, such as the Brazilian taurine breed Caracu, represent important genetic resources due to their resistance to heat stress and other environmental challenges. In this context, monitoring genetic diversity is essential, as long-term selection within closed herds can increase inbreeding and reduce variability. Runs of homozygosity (ROH) provide a genomic measure of autozygosity, enabling the detection of inbreeding patterns and the identification of regions potentially affected by selection. The aim of this study was to characterize patterns of ROH and to identify homozygous regions shared among individuals in a closed Caracu herd that has been selected for body weight for more than four decades. A total of 935 animals from the Advanced Research and Development Center for Beef Cattle of the Institute of Animal Science, located in Sertãozinho, São Paulo, were genotyped using the Bovine GGP 100K panel. ROHs were identified based on criteria previously established in studies on the Caracu breed, considering minimum length and marker density. The genomic inbreeding (FROH) was estimated from the proportion of the genome covered by ROH. Shared segments among individuals were evaluated to identify homozygosity islands, defined as regions with ROH overlap frequencies greater than 50% in the population. ROHs were detected in all individuals and across all analyzed chromosomes (BTA), reflecting the demographic history and selection processes of the population. A predominance of short ROHs was observed, with 38% of ROHs ranging from 2 to 4 Mb and 35% from 1 to 2 Mb, suggesting the influence of more ancient inbreeding events. BTA20 stood out by presenting the highest average FROH and by harboring the only homozygosity island identified. This island spanned 2.73 Mb, located between positions 38.26 and 40.99 Mb, encompassing 115 SNPs. The identified region contains relevant genes associated with adaptation to tropical environments, including CAPSL, IL7R, SPEF2, PRLR, AGXT2, DNAJC21, BRIX1, RAD1, TTC23L, RAI14, C1QTNF3, SLC45A2, RXFP3, ADAMTS12, TARS1, and NPR3. These genes are involved in processes such as pigmentation, cellular response to heat stress, physiological regulation, and metabolic mechanisms associated with heat tolerance. Collectively, these genes suggest a contribution to protection against solar radiation, maintenance of cellular homeostasis under high temperatures, and increased environmental resilience. These findings reinforce the importance of locally adapted taurine breeds as sources of adaptive genetic variability. Even under a long history of selection for a single exclusively productive trait, such as body weight, the Caracu breed has maintained genomic regions related to its adaptive traits. Furthermore, this study highlights the potential of using genomic information to support conservation strategies and breeding programs aimed at adaptation to high-temperature environments, especially in the context of current and future climate change scenarios.

Updated genome scan for homozygous haplotype depletion identifies a POMT2 nonsense variant causing embryonic loss and stillbirth in Normande cattle

C. Roy[1,2], A. Barbat[1], F. Besnard[1,2], L. Dorso[3], C. Escouflaire[1,2], J. Jourdain[4], C. Grohs[1], M. Boussaha[1], S. Minéry[1,6], M. Chambrial[5], D. Boichard[1], C. Hozé[1,2], A. Vinet[1], S. Fritz[1,2], A. Capitan[1]

[1] Université Paris-Saclay, INRAE, AgroParisTech, 4 rue Jean Jaurès, 78350 Jouy-en-Josas, France, [2] Eliance, 149 rue de Bercy, 75012 Paris, France, [3] ONIRIS, CHUV, 119 Route de Gachet, 44000 Nantes, France, [4] Synetics France SAS, 4 Rue Eric Tabarly, 35530 Noyal-sur-Vîlaine, France, [5] ORIGENPLUS, 38 rue de la Mérillière, 61300 L'Aigle, France, [6] IDELE, 149 rue de Bercy, 75012 Paris, France

Genome-wide detection of homozygous genotype depletion among animals genotyped for genomic evaluation is a proven strategy to uncover recessive loci causing either embryonic lethality or early juvenile mortality. Here, we present an updated analysis based on the largest dataset assembled to date for the Normande breed, including 239,675 genotyped animals with available ancestor genotype information. By analyzing sliding windows of 20 markers across more than 44,000 phased and imputed SNPs from the Illumina BovineSNP50 array, we identified two significant signals. The strongest signal, located on chromosome 11 (one homozygote observed vs. 119 expected; Bonferroni-adjusted Poisson P (Padj) = 1.8 $x10^{-50}$), corresponded to a previously reported missense variant in the CAD gene. The second most significant signal (Padj = 6.0 x10-18) on chromosome 10 showed only one observed vs. 54 expected for its lead haplotype. Reproductive performance was significantly reduced in at-risk matings (carrier × carrier). Conception rate after AI was 41.37% versus 46.47% (χ^2 $p < 0.01$), in controls (carrier sire × non-carrier dam). The 56-day non-return rate declined by 5.6 percent point (60.93% vs. 66.57%; χ^2 $p < 0.05$). These reductions were smaller than the 25% decrease expected under complete embryonic lethality, suggesting incomplete penetrance or variable expressivity of the C10P89 haplotype. In contrast, survival was strongly affected: birth survival dropped from 90.42% to 66.81%, and postnatal survival remained lower at 7 days and 30 days ($p < 0.001$, Bonferroni correction). Most losses were stillbirths, indicating the primary effect occurs in late gestation or the perinatal period. A search for candidate variants, leveraging whole-genome sequences of 5 Normande heterozygous bulls, 154 Normande wild-type bulls, and 1,006 individuals from 19 additional breeds, identified a single deleterious candidate variant: a stop-gain mutation in the Protein O-Mannosyltransferase 2 gene (POMT2; Chr10:g.88499167C >T; POMT2 p.W334X). The POMT2 gene encodes an enzyme involved in the glycosylation of α-dystroglycan. This process is essential for maintaining the stability of muscle fibres and ensuring normal brain development. Notably, several deleterious missense variants in POMT2 have been associated with congenital muscular dystrophy and brain defects in humans, whereas complete knockout of the gene results in embryonic lethality in mice. If expressed, the mutant protein would be truncated by approximately 62% and would lack several essential functional domains. Large-scale genotyping of the POMT2 variant in 94,727 Normande cattle using the custom Illumina EuroGMD revealed an absence of homozygotes. The allele frequency was estimated to be 1.8%. Among 1,275,893 additional animals from 20 breeds, all were wild type except nine Holsteins, which had some degree of Normande ancestry. In conclusion, we report a novel recessive genetic defect in Normande cattle, primarily responsible for stillbirth and, to a lesser extent, reduced fertility. The identification of the likely causative variant, now included on the genomic evaluation array, will allow efficient monitoring and help prevent future at-risk matings.

Population genomics of 1,060 French dairy, beef, and local cattle breeds using whole-genome sequencing-derived SNP panel

A. Molee[1], P. Faux[2], C. Grohs[1], C. Escouflaire[1,3], S. Fritz[1,3], D. Boichard[1], P. Croiseau[1], A. Capitan[1], M. Boussaha[1]
[1] Université Paris Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy en Josas, France, [2] Université de Toulouse, INRAE, ENVT, GenPhySE, 31326 Castanet-Tolosan, France, [3] Eliance, 149 Rue de Bercy, 75012 Paris, France

Abstract Cattle domestication, together with other evolutionary forces such as selection and demographic changes, has significantly shaped genome-wide genetic variation, contributing to a wide range of genetic diversity and giving rise to the modern cattle breeds. French cattle populations represent substantial genetic diversity, comprising approximately 40 recognized breeds with diverse production purposes and local adaptations. Given their remarkable phenotypic diversity, it is necessary to study how the genetic variation across French cattle breeds is structured, as it may reflect potential shared ancestry, historical demographic events, selection practices, and geographical adaptation. To better understand the genetic structure of French cattle breeds, we conducted, in this study, a population structure analysis by combining a Principal Component Analysis (PCA), Admixture, and pairwise Fst (fixation index). The analysis was performed on single-nucleotide polymorphisms (SNPs) obtained from whole-genome sequencing data of 1,060 individuals representing 21 French cattle breeds. As expected, we observed notable genetic divergence between Holstein and the other 20 cattle breeds, reflecting Holstein's distinct origin, breeding history, and strong selection for milk production traits. Meanwhile, within the remaining 20 breeds, we noticed significant evidence of genetic overlap, suggesting potential historical gene flow and shared ancestry. The SNP panel we have constructed provided a valuable understanding of the genetic variation and relationships between French cattle breeds. Moreover, it will serve as a critical foundational material for future research on selection signatures aimed at identifying genomic regions and variants under selection pressures, thereby improving targeted breeding strategies and contributing to an effective conservation program of local breeds. In conclusion, our study represents comprehensive information on population structure and potential historical events within the French cattle population. Our study will be valuable for future projects on selection signature analysis, and conservation and breeding programs aiming to enhance the sustainability of the agriculture industry.

Allele-specific methylation and parent-of-origin QTL mapping reveal potential epigenetic mechanisms underlying genomic imprinting and beef traits in Nelore cattle

J. J. Bruscadin[1,2], T. F. Cardoso[2], S. C. M. Niciura[2], W. J. D. S. D. Diniz[3], J. Virginio Da Silva[1,2], P. S. N. De Oliveira[2], J. Afonso[2], A. M. G. Ibelli[2], A. Zerlotini[4], G. B. Mourao[5], L. L. Coutinho[5], L. C. D. A. Regitano[2]

[1] Federal University of São Carlos, Center of Biological and Health Sciences, Washington Luis Highway, 235 Km, 13565-905 Sao Carlos, Brazil, [2] Embrapa Southeastern Livestock, Washington Luiz Highway, 234 Km, 13560-970 Sao Carlos, Brazil, [3] Auburn University, College of Agriculture, 151 S College St, 36830 Auburn, United States, [4] Embrapa Digital Agriculture, 239 Dr. André Tosello Avenue, 13083-886 Campinas, Brazil, [5] University of Sao Paulo, Department of Animal Science, 11 Padua Dias Avenue, 13418-900 Piracicaba, Brazil

Parent-of-origin effects (POEs) occur when phenotypic variance depends on whether an allele was inherited from the sire or the dam. When a POE impacts gene expression patterns by silencing the allele derived from one specific parent, genomic imprinting occurs. Allele-specific methylation (ASM) can contribute to genomic imprinting and allele-specific expression (ASE). In this study, we investigated ASM and POEs in skeletal muscle of Nelore (Bos indicus) steers to uncover regulatory mechanisms underlying fatty acid composition, mineral concentration, and meat and carcass quality traits. Using reduced-representation bisulfite sequencing (RRBS) and sample-matched genotypes from 12 animals, we identified 8,074 ASM regions, including 269 that were consistently detected across all samples, indicating reproducible ASM signatures in bovine muscle. ASM events were not uniformly distributed but were predominantly enriched in promoters. We also detected loci with dense ASM events overlapping or near ASE SNPs previously reported in the same population, suggesting regulatory hotspots where genetic and epigenetic allelic mechanisms converge. ASM density increased toward chromosome ends, consistent with broader chromosomal regulatory contexts enriched for CpG islands. Integration with imprinting resources supported the biological relevance of our findings. ASM occurred within eleven genes previously reported as imprinted in cattle, including the IGF2R locus, imprinted in muscle. IGF2R showed multiple ASM regions (including promoter ASM regions with predicted transcription factor (TF) binding sites) and an intronic ASE SNP. Additionally, 111 ASM regions were assigned to genes previously reported to be monoallelically expressed, representing potential new candidates for imprinting in cattle. To quantify POEs at the phenotype level, we applied an omnibus test to perform a parent-of-origin GWAS and identified 1,817 PO-QTLs distributed across five clusters of correlated traits, with the strongest signal observed in polyunsaturated fatty acid-related phenotypes. Cluster-specific enrichments were biologically coherent for each trait cluster, and candidate loci showed predicted TF and miRNA binding effects. Overlap between ASM and PO-QTLs was limited (seven PO-QTLs overlapping ASM SNPs; ~0.38%), likely reflecting reduced informative SNP density in conserved ASM/imprinted regions and limited statistical power. Overall, the integration of our variants and ASE SNPs showed 600 variants overlapping previous ASE data from the same population, prioritizing epigenetically regulated loci for functional validation. Our findings advance understanding of regulatory variation affecting beef quality traits in Nelore cattle. Keywords: epigenetics, Bos indicus; beef.

Beyond SNPs: INDELs as functional drivers of feed efficiency in Nellore cattle

M. Teodoro[1,2], G. Gubiani[3], A. Maiorano[4], L. Mota[2], A. Cánovas[1], F. Baldi[2,3]
[1] University of Guelph, Centre for Genetic Improvement of Livestock, Department of Animal Biosciences, 50 Stone Road East, N1G 2W1 Guelph, Canada, [2] São Paulo State University, Department of Animal Science, Via de Acesso Professor Paulo Donato Castellane, s/n, Zona Rural, 14884-900 Jaboticabal, Brazil, [3] University of São Paulo, Department of Veterinary Medicine, Avenida Duque de Caxias Norte, 225, 13635-900 Pirassununga, Brazil, [4] Federal University of Uberlândia, Department of Animal Science, BR-050 - KM 78, 38410-337 Uberlândia, Brazil

Selection for feed efficiency (FE) is fundamental to the profitability, sustainability, andreduction of the environmental footprint of tropical beef cattle production systems.While SNP-based analyses have advanced, evidence remains limited regarding thecontribution expressed insertion-deletion variants (INDELs) to residual feed intake(RFI) variation, specifically in Nellore cattle and their functional interpretation throughbiological pathways. As structural variants that can alter protein-coding sequences andregulatory regions, INDELs represent a potentially important source of functionalvariation. The objective of this study was to identify functional INDELs associated withRFI in two RFI groups of Nellore cattle using RNA-Sequencing data. Transcriptomicdata from five tissues (liver, muscle, hypothalamus, pituitary, and adrenal glands) wereanalyzed from 18 Nellore bulls (9 high-RFI vs. 9 low-RFI). The INDELs were detectedusing CLC Genomics Workbench (Aarhus, Denmark) and its functional impact wasassessed using the Ensembl variant effect predictor (VEP) based on the ARS-UCD1.3assembly. Metabolic pathway enrichment analysis was conducted using the softwareDAVID. Results showed that expressed INDELs carried high-impact functionalconsequences mapping to multiple metabolic pathways. Among the 285 INDELsdetected, 155 were shared between groups, reflecting shared genetic variation. In thelow-RFI (efficient) group, 67 exclusive INDELs were identified within 106 genes.Among them, 7 INDELs showed amino acid changes (AAC), 5 INDELs with spliceeffects (SE), and 2 variants with both AAC and SE events. The VEP analysis prioritized8 variants as having high predicted functional consequences (frameshifts and stop-gained) and 5 with moderate impact. The high-RFI (inefficient) group harbored 63INDELs located within 103 genes, including 7 AACs, 4 SEs, 1 with both AAC and SEevent, and 9 high-impact transcripts. Pathway analysis of expressed INDELs revealed 8significantly enriched pathways in the low-RFI group and 10 in the high-RFI group (P <0.05). Specifically, the low-RFI group included phagosome and cytoskeleton in musclecells, whereas the high-RFI group involved HIF-1 and cAMP signaling. Biologically,pathways in low-RFI cattle focused on cellular recycling and structural integrity. Incontrast, high-RFI cattle prioritized energy-intensive signaling and immune alerts,suggesting a metabolic trade-off that diverts resources from production. These resultsdemonstrate that expressed INDELs carry a disproportionate functional effect,potentially altering key metabolic pathways associated with RFI. The higher frequency of prioritized high-impact INDELs in inefficient animals suggests a greater geneticburden affecting metabolic stability. Characterizing these structural variants identifiespromising targets for genomic selection to improve nutrient utilization in Nellore cattle,advancing the development of efficient herds aligned with sustainable beef productionsystems.

Ovine hypothalamic neurons under proteostatic pressure during leptin resistance

E. Oclon[1], D. Zieba[2]
[1] University of Agriculture in Krakow, Department of Infectious Diseases and Public Health, Al. Mickiewicza 21, 31-120 Krakow, Poland, [2] University of Agriculture in Krakow, Department of Animal Biotechnology, Al. Mickiewicza 21, 31-120 Krakow, Poland

KNDy neurons of the mediobasal hypothalamus constitute a key regulatory node integrating metabolic and endocrine signals controlling pulsatile gonadotropin-releasing hormone (GnRH) secretion and reproductive function. Proper functioning of these neurons depends on their ability to sense metabolic cues such as leptin and circulating nutrients. Metabolic disturbances associated with obesity and chronic lipid oversupply frequently lead to leptin resistance, disrupting hypothalamic signaling and contributing to impaired reproductive regulation. Increasing evidence suggests that metabolic stress may also affect cellular proteostasis by altering protein turnover, folding and degradation pathways essential for neuronal homeostasis. However, the molecular mechanisms linking metabolic stress with proteostatic regulation and intracellular signaling in hypothalamic neurons remain insufficiently characterized. The aim of this study was to identify proteomic and phosphoproteomic alterations associated with lipid-induced metabolic stress in ovine hypothalamic neurons. An immortalized ovine KNDy neuronal cell line (FRI273), derived from fetal sheep mediobasal hypothalamus and kindly provided by Dr. Patrick Chappell, was used as an in vitro model of hypothalamic neurons integrating metabolic and reproductive signals. Cells were cultured in high-glucose DMEM supplemented with 10% FBS and exposed to palmitate (5 mM, 24 h) to model lipid-induced metabolic stress associated with leptin resistance. Untreated cells served as negative controls and NEFA-free BSA was used as vehicle control. Quantitative TMTpro-16plex proteomic and phosphoproteomic analyses were performed using LC–MS/MS on an Orbitrap Exploris 480 mass spectrometer. Data were processed using MaxQuant and Perseus (v1.6.15.0) against the Ovis aries UniProt reference database. Proteomic profiling quantified 7,712 proteins, of which 1,123 were significantly altered in palmitate-treated neurons compared with controls (FDR < 0.05). Proteins involved in protein quality control and degradation pathways were markedly increased, including sequestosome-1 (SQSTM1; FC 4.31), GABARAPL2 (FC 5.39), PDIA6 (FC 1.55) and alpha-crystallin B chain (HSPB1; FC 1.65), indicating activation of autophagy-related and chaperone-mediated proteostasis mechanisms. Phosphoproteomic analysis identified 4,086 phosphosites, of which 739 showed significant changes (FDR < 0.05). Differential phosphorylation affected regulators of cytoskeletal organization and signal transduction, including vimentin (FC 2.69), microtubule-associated protein 1B (FC 1.45) and tubulin (FC 1.30). Altered phosphorylation was also observed in signaling regulators such as stathmin, PEA-15, 14-3-3 proteins and AKAP-associated signaling components, indicating remodeling of cytoskeletal dynamics and kinase-dependent signaling pathways. Collectively, these data indicate that lipid-induced metabolic stress linked to leptin resistance subjects ovine hypothalamic neurons to significant proteostatic strain, resulting in reconfiguration of phosphorylation-dependent signaling pathways. Coordinated alterations in protein turnover and signaling processes may represent adaptive mechanisms allowing hypothalamic neurons to maintain functional stability while integrating metabolic signals affecting neuroendocrine regulation of reproduction. This research was financially supported by the National Science Centre, Poland (Grant No. UMO-2023/51/B/NZ9/00651).

The in ovo application of synbiotics may influence the humoral immune response against homologous antigens—transgenerational insights

T. Stefaniak[1], J. Madej[1], J. Bajzert[1], K. Bobrek[2], M. Bednarczyk[3], E. Grochowska[4]
[1] Wrocław University of Environmental and Life Sciences, Department of Immunology, Pathophysiology and Veterinary Preventive Medicin, Norwida 31, 50-375 Wrocław, Poland, [2] Wrocław University of Environmental and Life Sciences, Department of Epizootiology and Clinic of Birds and Exotic Animals, pl. Grunwaldzki 45, 50-366 Wrocław, Poland, [3] Bydgoszcz University of Science and Technology, Department of Animal Biotechnology and Genetics, Mazowiecka 28, 85-084 Wrocław, Poland, [4] Nicolaus Copernicus University in Toruń, Collegium Medicum, Faculty of Health Sciences, Łukasiewicza 1, 85- 821 Bydgoszcz, Poland

In humans, the use of probiotics in patients with allergies suggests their potential role in inducing immune tolerance. The in ovo application of synbiotics on day 12 of egg incubation exposes the embryo's developing immune system to foreign antigens. This exposure may influence the processes of immune recognition and discrimination between self and non-self. This study aimed to evaluate whether single (F1 generation) or repeated (F1–F3 generations) in ovo administration of a synbiotic (PoultryStar® SolUS, DSM-Firmenich; hereafter referred to as PS), or synbiotic combined with choline, applied into the air chamber on day 12 of incubation, may modulate the humoral immune response recognition against surface antigens of the probiotic in three conscutive generations. Serum samples in the F1 generation were collected from seven 14-day-old chickens and seven 21-week-old birds from the following groups: control (C), SYNs (single in ovo synbiotic stimulation in F1), and SYNCHs (single in ovo synbiotic+choline stimulation in F1), all treated on day 12 of embryonic incubation. In the F2 and F3 generations, serum samples were obtained from seven 14-day-old chickens and seven 21-week-old birds from the following groups: C, SYNs, SYNr (repeated in ovo synbiotic stimulation across F1–F3), SYNCHs, and SYNCHr (repeated in ovo synbiotic + choline stimulation across F1–F3), all treated on day 12 of embryonic incubation. Serum IgG and IgM antibodies directed against outer membrane complex (OMC) antigens of the synbiotic preparation, harvested using Triton X-114 extraction, were determined by ELISA. IgG antibodies against SDS-PAGE separated antigens were determined in immunoblotting. The delayed-type hypersensitivity (DTH) reaction following intradermal injection of synbiotic antigens was measured in 42-day-old F3 chickens. In the serum of 14-day-old and 21-week-old F1 birds, the detection of OMC bands differed between control and treated animals in Western blotting. The sera of birds treated with synbiotic recognized a different spectrum of antigens than the group treated with symbiotic + choline. ELISA intensity of IgG and IgM serum antibody reactivity against harvested synbiotic antigens did not differ between control and treated groups within generations, although the mean values were markedly lower in treated than in control animals. Serum antibody reactivity decreased progressively across subsequent generations in both 14-day-old and 21-week-old birds. The broad spectrum of recognized antigens found in control and treated birds concurrently indicates the possible cross-reactivity between antigens solubilized from PS synbiotic and environmental bacteria antigens recognized by examined birds. The exposure of developing embryos to the PS antigens may modulate the development of humoral immunity against environmental antigens. The question arises whether the introduction of PS antigens/probiotic bacteria with potentially tolerogenic effects into the facility environment may be an important factor influencing not only treated but also control animals.

Homozygous haplotype enrichment/depletion mapping identified a recessive variant in ALKBH8 causing rearing-loss in Brown Swiss cattle

S. Glatthard[1], F. R. Seefried[2], A. S. Leonard[3], H. Pausch[3], C. Drögemüller[1], J. Jacinto[1,4], N. K. Kadri[3]
[1] University of Bern, Institute of Genetics, Bremgartenstrasse 109a, 3012 Bern, Switzerland, [2] Qualitas AG, Chamerstrasse 56, 6300 Zug, Switzerland, [3] ETH Zürich, Institute of Agricultural Sciences, Universitätstrasse 2, 8092 Zürich, Switzerland, [4] University of Bern, Clinic for Ruminants, Bremgartenstrasse 109a, 3012 Bern, Switzerland

Most cattle breeds have a small effective population size and are therefore susceptible to the emergence of deleterious recessive traits. Such traits are typically investigated using phenotype-driven approaches that require clearly affected individuals; however, these strategies may fail to detect conditions with late onset or nonspecific clinical presentation, including immune, reproductive, or metabolic disorders. We aimed to discover cryptic recessive variants in Swiss dairy cattle affecting survival by exploiting population-scale genomic data together with extensive life-history records. Brown Swiss (BS) cattle, the second most popular dairy breed in Switzerland have experienced increasing inbreeding due to intensive selection and the widespread use of elite sires, facilitating the expression of recessive alleles. Life-history records from 67,912 genotyped BS animals were analyzed to identify cases of juvenile mortality (≤180 days) using carcass disposal records. Recessive haplotypes associated with juvenile death were detected using imputed genotypes for more than 600K genome-wide SNPs and Homozygous Haplotype Enrichment/Depletion mapping. Expectations for haplotype homozygosity in case and control groups were estimated based on genotyped parents and grandparents. Haplotypes showing ≥25% enrichment of homozygosity in cases and ≤−25% enrichment in controls were considered candidate associations. Selected homozygous animals underwent long-read whole-genome sequencing (WGS), followed by detailed clinicopathological evaluation. We identified a haplotype on chromosome 15 associated with increased juvenile mortality in the homozygous state. The allele frequency of the linked haplotype in BS was estimated to be 4%. Haplotype carrier prediction was performed on a population level using available genotyping data from the Swiss genomic selection. This allowed the identification of living young homozygous haplotype carriers. Five homozygous animals consistently exhibited failure to thrive characterized by recurrent respiratory disease and diarrhea, reduced body condition, and a rough hair coat. Marked brown discoloration of the incisors was observed in all affected animals. Hematological analyses revealed hypoglobulinemia. Intestinal coccidiosis was detected in all examined calves. Pathology revealed bronchopneumonia, accompanied by eosinophilic enterocolitis in the two examined cases. These findings indicate failure to thrive and immunodeficiency in homozygotes. Long-read WGS of two homozygous calves revealed a single structural variant consisting of a 10.4-kb ERV_classII LTR insertion in exon 3 of ALKBH8 representing a loss-of-function similar to the APOB insertion found in cholesterol deficiency affected Holstein cattle. Our results provide strong evidence for a previously unrecognized hereditary rearing-loss disorder in BS cattle and illustrate how integrating genomic resources with life-trajectory data, clinical research and molecular genetics enables the detection of cryptic recessive conditions. Indirect and direct carrier detection enables targeted breeding strategies essential to prevent homozygous animals reducing rearing losses and improve animal welfare.

Unravelling signatures of Red Holstein introgression and its haplotype structure in Fleckvieh cattle

J. Schröder[1], M. Upadhyay[2], N. Krattenmacher[1], R. Emmerling[3], C. Edel[3], D. Seichter[4], I. Medugorac[2], G. Thaller[1]
[1] Institute of Animal Breeding and Husbandry, Kiel University, Olshausenstr. 40, 24098 Kiel, Germany, [2] Population Genomics Group, Department of Veterinary Sciences, Ludwig-Maximilians-University Munich, Lena-Christ-Str. 48, 82152 Martinsried, Germany, [3] Institute of Animal Breeding, Bavarian State Research Center for Agriculture, Prof.-Dürrwaechter-Platz 1, 85586 Poing, Germany, [4] Tierzuchtforschung e.V. München, Senator-Gerauer-Str. 23a, 85586 Poing, Germany

Between the 1970s and the 1990s, Red Holstein (RH) sires were crossbred into the German Fleckvieh (FV) population to enhance milk yield and udder traits while maintaining breed-specific characteristics of the dual purpose FV cattle. Through the use of RH bulls and their male offspring, RH-derived chromosomes and chromosomal fragments were incorporated into the FV genome and subsequently selected positively or negatively according to the breeding goal. In this context, it is of interest which genomic regions exhibit above-average RH proportions and whether certain regions show significantly lower RH contributions than expected. Therefore, the aim of this study was to quantify the genome-wide distribution of RH introgression in FV cattle, and to characterize the underlying haplotype structure and diversity of the introgression segments. For this purpose, a total of 58,849 haplotyped and imputed genotypes, comprising 50 pure FV animals (born before Dec. 31, 1985), 65 pure RH animals (born before Dec. 31, 1995), and 58,734 FV animals with an initially unknown proportion of RH ancestry (born after Jan. 1, 2010) were analyzed. Identity-by-descent (IBD) segments of RH origin were detected from phased genotype data using the software hap-IBD (Zhou et al., 2020). Based on these segments, individual genomic RH proportions were estimated and a genome-wide map of RH haplotype frequencies was constructed to identify regions deviating from the expected RH contribution. Across the 58,734 FV animals, the mean genomic RH proportion was 4.39% (SD = 2.35%, SEM = 0.01%), ranging from 0% to 39.08% after excluding 136 non-representative animals. Considering the average observed RH proportion in our FV population of 4.39%, we identified chromosomal regions with significantly higher frequencies of RH haplotypes than expected (e.g. BTA 8: 54.2-112.3 Mb, up to 20.38% RH haplotypes per position; BTA 20: 58.3-64.2 Mb, up to 12.71% RH haplotypes per position; BTA 25: 21.4-38.7 Mb, up to 17.56% RH haplotypes per position). At peak positions, introgression can be largely explained by a limited number of donor haplotypes: on BTA 8, more than 80% of the introgressed haplotypes could be traced back to the RH sires JAMES RED, TOPPER and SKAKERAK, whereas on BTA 20 and 25, a single haplotype originating from JAMES RED accounted for 71% and 61% of RH-derived segments, respectively. In addition, window-based analyses were conducted to identify regions of reduced haplotype diversity, providing a more refined understanding of the introgression pattern. Ongoing analyses aim to investigate introgression dynamics at the level of individual RH sires to further elucidate founder-specific contributions to the FV genome. Overall, this approach may also be valuable for investigating introgression patterns in other cattle breeds or animal species with known crossbreeding history.

How farms are impacted and deal with climate change in grassland systems: the case of Occitanie dairy sheep farms in southern France

V. Colonna Ceccaldi[1,2], A. Meynadier[1], M. Loubière[1,2], C. Blayac[3], O. Patout[3], C. Domange[2]
[1] GenPhyse, Université de Toulouse, INRAE, ENVT, 31326 Castanet-Tolosan, France, [2] Ecole d'Ingénieurs de Purpan, Université de Toulouse, 75 voie du TOEC, 31076 Toulouse, France, [3] Agronomes Vétérinaires Eleveurs Mutualistes, Cap du Crès, 12100 Millau, France

In France, sheep milk is mainly produced in 3 production areas located in dry and poor disadvantaged mountain regions of the south of the country. Among these areas, Occitanie is the largest one and accounts for 74% of the national production, with flocks of Lacaune dairy sheep breed. Because of the Roquefort protected designation of origin specifications and varied local soil and climate conditions, dairy sheep farms mainly rely on cultivated grasslands and spontaneous vegetation. Lacaune ewes receive diet based on fresh and preserved grass. In this mid-mountain region, where Mediterranean and semi-continental climates coexist, climate change is mainly manifested by inconsistent annual conditions, particularly in recent years, with alternating cold and dry year (2021), hot and dry year (2022), and very wet years (2023 and 2024). Not all farms have the same response to these changes. Some have implemented adaptation practices making them more resilient, while others, which are more robust, suffer less from the consequences of this high climate variability. Nevertheless, some farms remain vulnerable and must therefore deal with the consequences of climate change. It may have direct impacts on the health and performances of the dairy ewes, but also on the main source of animal feed, grassland, in both terms of yields and forage quality, and utilization of pastures. This work therefore aimed to characterize the effects of climate change on dairy sheep farms in Occitanie, with a particular focus on farm technical-economic results, including milk composition and production, feed autonomy, and sheep health. Monitoring meteorological data and the results of 30 dairy sheep farms in the region over the period 2020–2024 allowed to identify farms that are resilient and/or robust in response to climate change from those being more vulnerable. At the same time, a characterization of adaptation practices or trade-offs implemented by farmers to reduce their vulnerability in terms of feed autonomy, herd health, and variations in milk production and quality, was performed. This work will identify levers that can be used to make dairy sheep farms in the Occitanie region less vulnerable to climate change.

Grassland Yield and Quality in Relation to Farming System and Intensity

M. Klopčič[1], M. Bric[1], G. Šink[1], M. Komainda[2]
[1] UL-Biotechnical faculty, Animal Science, Groblje 3, 1230 Domžale, Slovenia, [2] Georg-August-University Göttingen, Department of Crop Sciences, Grassland Science, Von-Siebold-Str. 8, 37075 Göttingen, Germany

Slovenia is a land of permanent grasslands, which represents an important source of forage on cattle farms. High-quality voluminous forage represents an important part of the feed ration on every cattle farm and, consequently, the basis for profitable ruminant husbandry. The introduction of a reliable, user-friendly and affordable method for assessing the increase in the mass of grass on meadows and pastures is necessary from the point of view of the effectiveness of the permanent grassland management. In the past, a lot of efforts has been invested in development of methods for indirect and non-invasive assessment of the growth of grass. The most effective and precise method is to take measurements with the help of a digital platemeter. This measures the height in relation to the density of compressed grass, which directly depends on the amount of dry matter (kg DM/ha). Differences in grass height, density, botanical composition, season and management method can thus increase the error in the prediction of grassland mass estimation. Assessment of grass mass must be carried out weekly during the growing season. The obtained results later serve us to calculate the daily amount of the available amount of grass or pasture. Accurate and quick assessment of the available grass or pasture on the farm helps in making strategic decisions from the point of view of permanent grassland and improvement of grazing management. As part of the pilot EIP project entitled "Feed ratio and biodiversity under climate change conditions – the example of a cattle farm", we carried out measurements of grass mass yields on three pilot cattle farms during the growing season on a weekly basis, with the help of a Jenquip EC20 digital platemeter.

Seasonal variation of water-soluble carbohydrates of temporary grassland in a Mediterranean agroforestry system

T. Malizzi[1], F. G. Cella[1], M. Finocchi[1], A. Ripamonti[1], E. Senatore[1,2], A. Silvi[1], A. Mantino[1,2], M. Mele[1,2]
[1] University of Pisa, Department of Agriculture, Food and Environment, Via del Borghetto 80, 56124 Pisa, Italy, [2] University of Pisa, Centre of Agro-environmental Research "Enrico Avanzi", via Vecchia di Marina, 6, 56122 Pisa, Italy

In 2017, a Long-Term Experiment (LTE) based on a 40-ha agroforestry trial site was established in Pisa (Tuscany, Italy) to study the diversification of farming systems. The investigated system is based on a seven-year crop rotation consisting of durum wheat, sorghum, faba bean, and four years of mixed temporary grassland intercropped with rows of poplar trees spacing 30 m between and 10 in rows. In 2025, a field campaign was carried out to evaluate the effect of tree presence on the water-soluble carbohydrate (WSC) of herbage mass obtained from a temporary grassland during its first year of establishment. WSC are an important energy source for grazing animals, but high concentrations have been linked to pasture-associated laminitis and acidosis. The experimental design aimed to mimic grazing activity according to biomass accumulation. Samples were collected at five different distances from the tree row according to a replicated transect design, to evaluate yield and nutritional characteristics of the herbage. The temporary grassland was sown in October 2024, and the first harvest was carried out in April 2025 to ensure adequate root establishment. Following harvests were performed when herbage reached an average height of about 0.12 m, measured using a plate grassmeter and herbage dry matter (DM) production was determined. Samples were analysed for botanical (grasses, legumes, and other species) and chemical composition, with a focus on WSC. The average DM production over the harvest was 2.78 ± 1.96 Mg ha^{-1} and varied significantly during the season, consistent with Mediterranean climatic patterns. The first harvest showed higher biomass production, whereas the second and third harvests showed an average reduction of about 71% compared with the first harvest. The botanical composition consisted of 75.32 % ± 24.12 grasses, 4.45 % ± 13.87 legumes, and 20.23 % ± 23.48 other species throughout the entire period. A significant tree effect on DM production was observed only at the second harvest, with higher yields near trees and a greater proportion of grasses in that zone. However, the tree presence did not significantly affect WSC content. WSC averaged 75 ± 25 g kg^{-1} DM, consistent with literature values, but decreased from 100.03 g kg^{-1} DM, at the first harvest, to 72.67 and 53.57 g kg^{-1} DM at the second and third harvests, respectively.The same trend was observed for glucose and fructose, which decreased by one quarter and one third, respectively, leading to a marked reduction in herbage WSC content. Fructans concentrations remained stable, averaging 23.85 ± 4.98 g kg^{-1}DM. However, considering seasonal trends in total WSC and its individual components, the relative contribution of fructans to total WSC increased during the season. Sucrose and raffinose showed low concentrations compared with the other WSC components, averaging 1.31 ± 0.95 and 1.40 ± 1.29 g kg^{-1} DM, respectively. Raffinose did not significantly vary among harvests, whereas sucrose approximately doubled its concentration from the first to the last harvest. In conclusion, seasonal trends showed decreasing WSC, even if fructans content was stable in herbage DM and increased its concentration in the WSC in later harvests. These findings provide original knowledge of WSC dynamics in Mediterranean temporary grasslands in agroforestry systems.

Rewetting a major Dutch peat region: assessing protein production under environmental policy targets

H. Van Dijk[1], B. Van Selm[3], D. Tamsma[2], C. Van Middelaar[1], S. Oosting[1], R. Ripoll-Bosch[1]
[1] Wageningen University and Research, Animal Production Systems Group, de Elst 1, 6708WD Wageningen, Netherlands, [2] Wageningen University and Research, Plant Production Systems Group, Bornsesteeg 48, 6708PE Wageningen, Netherlands, [3] Bioeconomy Science Institute, Private Bag, Private Bag 3132, 3240 Hamilton, New Zealand

The majority of peatlands in the European Union are drained to increase agricultural production, resulting in greenhouse gas emissions, soil subsidence and biodiversity loss. Therefore, restoration of peatlands plays a major role in the transition towards a more sustainable food system. The European Green Deal, through the Nature Restoration Regulation, aims to recover the contribution of agricultural peatlands to ecosystem services and biodiversity conservation. Proposed measures include rewetting drained peat soils (i.e. increasing the groundwater level) and reducing nitrogen inputs. In the light of these policy objectives, using a case study of the Netherlands, where peat soils are predominantly used as permanent pasture for dairy production, we explore how peatlands can contribute to protein production while meeting environmental policy targets. We use a food system optimization model, FOODSOM, to maximize protein output in several scenarios, simulating increasingly ambitious policy targets. Scenarios ranged from maximizing protein production without policy constraints, to letting 10% of land aside, partial rewetting of peat areas and full rewetting of peat areas. Preliminary results show that across scenarios, total protein production reduced by 17%, with a 25% reduction in milk-based protein. This coincides with the observed 25% reduction in the number of dairy cows, which was accompanied by a shift to more low-productive dairy cows. Total greenhouse gas emissions from the food system reduced on average by 37% across scenarios, with a 47% reduction in emissions originating from peat soils. In a next step, the impact of grassland diversification (i.e. the introduction of herb-rich grasslands) on the protein production potential of the region will be further explored to optimize the performance of grasslands on peat soils. Overall, our results suggest that there is room to keep peat soils productive while adhering to environmental targets. Yet, substantial changes in farming systems and business models are required.

Tree thinning effects on animal performance in tropical silvopastoral system

J. Pezzopane[1], R. Pasquini Neto[2], H. Brunetti[3], C. Bosi[4], P. Oliveira[1], A. Garcia[1], L. Pinho[5], A. Souza[5], G. Ramos[5], A. Bernardi[1], A. Pedroso[1]

Silvopastoral systems (SPS), which integrate pasture, trees, and animals in the same area, represent a sustainable alternative for pasture-based livestock production. One of the main challenges of these systems is maintaining the productive potential of pastures and, consequently, livestock production. This study aimed to evaluate the effect of tree thinning in a silvopastoral system on animal production compared with full-sun pasture-based production systems. The study was carried out at Embrapa Pecuária Sudeste, in São Carlos, São Paulo State, Brazil (21°57′ S, 47°50′ W; 860 m a.m.s.l.), from 2020 to 2023. The evaluated systems were: an extensive system (EXT), consisting of Urochloa decumbens cv. Basilisk pasture under continuous stocking, without liming or fertilization; an intensive system (INT), consisting of U. brizantha (Hochst. ex A. Rich.) Stapf cv. BRS Piatã pasture managed under rotational stocking; and a silvopastoral system (SPS), consisting of U. brizantha Stapf cv. BRS Piatã pasture managed under rotational stocking, shaded by rows of eucalyptus (Eucalyptus urograndis, clone GG100). The trees were planted in 2011 at a spacing of 15 × 2 m (333 trees ha^{-1}), oriented approximately east–west, thinned in 2016 to 15 × 4 m (166 trees ha^{-1}), and thinned again in 2019 to 30 × 4 m (83 trees ha^{-1}). The INT and SPS were consisted of four 3-ha areas, subdivided into six 0.5-ha paddocks, managed under rotational grazing with liming and fertilization (132 kg N ha^{-1} $year^{-1}$) and grazed by Nellore and Canchim (3/8 Zebu × 5/8 Charolais) beef steers, totaling 16 animals per system. The EXT system consisted of two 3-ha areas, without subdivision, stocked with a total of eight animals. Photosynthetically active radiation (PAR) transmission in the SPS, as well as animal performance and productivity expressed as average daily gain (ADG, kg day^{-1}), stocking rate (SR, animal units ha^{-1}), and live weight gain per ha (LWGha, kg ha^{-1} $year^{-1}$), were evaluated. Data were subjected to analysis of variance using PROC MIXED of SAS software, and means were compared using Fisher's test ($p < 0.05$). PAR transmission in SPS ranged from 71% in Year 1 to 60% in Year 3. ADG did not differ among production systems and was higher in Year 3 (0.561 kg day^{-1}) compared with Years 1 (0.451 kg day^{-1}) and 2 (0.406 kg day^{-1}), which did not differ from each other. There was a significant interaction between systems and experimental years for SR and LWGha. Stocking rates were similar between INT and SPS in Years 1 (~2.14 AU ha^{-1}) and 2 (~2.40 AU ha^{-1}), which were higher than EXT (1.34 and 1.33 AU ha^{-1}, respectively). In Year 3, SR was highest in INT (2.57 AU ha^{-1}), followed by SPS (2.14 AU ha^{-1}) and EXT (1.33 AU ha^{-1}). LWGha was similar between INT and SPS in Years 1 (~360.3 kg ha^{-1} $year^{-1}$) and 3 (~439.1 kg ha^{-1} $year^{-1}$), which were higher than EXT (130.5 and 255.9 kg ha^{-1} $year^{-1}$, respectively) . In Year 2, LW was highest in INT (728.4 kg ha^{-1} $year^{-1}$), followed by SPS (613.4 kg ha^{-1} $year^{-1}$) and EXT (285.7 kg ha^{-1} $year^{-1}$). These results demonstrate that tree thinning in tropical silvopastoral systems enables high animal productivity, comparable to that in well-managed pasture systems without trees.
Acknowledgments: FAPESP (Grant No. 2023/02444-5)

Role of Grasslands in Enhancing Sustainability and Product Quality in Cattle Farming. Insights from the INTAQT project.

B. Martin[1], E. Caumette[1], R. Eppenstein[2], F. Klevenhussen[3], J. F. Hocquette[1]
[1] Université Clermont Auvergne, VetAgro Sup, INRAE, UMR 1213 Herbivores, Theix, 63122 Saint Genès Champanelle, France, [2] Research Institute of Organic Agriculture FiBL, Ackerstr. 113, 5070 Frick, Switzerland, [3] University of Kassel, Faculty of Organic Agricultural Sciences, Nordbahnhofstr. 1a, 37213 Witzenhausen, Germany

The EU cattle sector relies on a wide variety of farming systems. The EU Horizon 2020 INTAQT project (Grant Agreement No. 101000250) has sought to understand how the diversity of farming systems and practices influences the quality and authenticity of cattle and chicken products, as well as the sustainability of their production. A key concept of the project is "One Quality", which considers intrinsic product quality alongside broader issues such as environmental impact, feed-food competition, and animal welfare. For cattle, the project is based on a network of 131 beef and dairy farms spanning eight European countries and covering a wide range of systems, from the most extensive to the most intensive.We defined levels of intensification based on inputs relating to animals (e.g. concentrates) and land (e.g. fertilisers). For both beef and dairy farms, intensification improves productivity and the efficiency of total feed and land use, but the benefits tend to plateau in high-input systems. However, when considering only human-edible protein in feed and arable land use, intensification exacerbates feed-food competition, with grass-based beef and dairy systems being net human-edible protein producers. Intensification also reduces the provision of regulating ecosystem services by farms, which balance the well-documented higher GHG emissions of extensive farming when expressed per kg of product. Intensification did not affect the animal welfare indicators recorded on-farm, but it was associated to a reduced outdoor access during the life of cattle. None of the chemical contaminants analysed (heavy metals, myco- and plant-toxins, dioxins, PCBs, PFAS) in beef liver and milk exceeded the official safety limits. In our farm network, access to pasture in extensive farms did not result in increased product contamination. However, the important amount of maize silage and concentrates used on intensive farms led to a slight increase in aflatoxin M1 in milk, although the upper limits were never exceeded.The project confirmed the well-documented influence of feeding fresh grass on the sensory properties of cheese and revealed that grass-based farming systems produce yellower and creamier UHT milk with a stronger flavour than UHT milk from maize-based systems. However, these grass-based cheeses and UHT milks were not necessarily more appreciated by naive consumers in blind tests. Similarly, the eating quality of beef striploin, as evaluated by naive consumers, was not related to the intensity gradient of the farming systems.Finally, high variability was observed for most nutritional quality traits both in beef and milk, which should be considered by nutritionists. Some quality traits were strongly related to farm intensification, which reduced for instance the concentration of beneficial fatty acids in beef and milks. Intensification also reduced the levels of vitamins E and B2 in milk, while increasing the levels of vitamins B5 and P. The most significant changes were primarily associated with the proportion of grass in the diet and the age at slaughter (for beef).Overall, this project reveals the central role played by grasslands in the « One Quality » of cattle products, whether positive or negative according to the quality traits considered. However, it should be noted that high variability is generally observed within each farm type for most quality traits, indicating potential for improvement. www.h2020-intaqt.eu

Living with wolves? Cross-country differences in perceived predator constraints to agroecological grazing

A. Van Den Pol-Van Dasselaar[1], I. M. Jitea[2], A. Krause[3]
[1] Aeres University of Applied Sciences, De Drieslag 4, 8251 JZ Dronten, Netherlands, [2] University of Agricultural Sciences and Veterinary Medicine Cluj-Napoca, Calea Mănăștur 3-5, 400372 Cluj-Napoca, Romania, [3] Grünlandzentrum Niedersachsen/Bremen, Albrecht-Thaer-Straße 1, 26939 Ovelgönne, Germany

Agroecological grazing is not only shaped by ecological conditions but also by the social and institutional context. Understanding constraints perceived by future farmers is essential for maintaining and improving grassland-based livestock systems. Within the Grazing4AgroEcology project, a survey conducted in 2023 among young livestock farmers and agricultural students (≤40 years) in eight European countries explored perceived barriers to grazing. Predators such as wolves were frequently mentioned among the top five barriers to grazing, but strong regional differences were observed. The share of respondents selecting predators in their top five barriers to grazing ranged from 7% in Ireland to 78% in South Tyrol (Italy), with relatively high values in Germany (64%) and Sweden (53%), and moderate values in the Netherlands (19%), France (22%), Romania (22%), Portugal (23%) and Sardinia (Italy) (24%). These perceptions did not align with actual wolf densities. Countries with long-standing high wolf populations, such as Romania, showed relatively moderate concern. In contrast, countries where wolves have only recently returned or expanded, such as Germany, reported higher perceived barriers despite lower ecological densities. This suggests that predator presence becomes constraining particularly in "return contexts", where grazing systems, advisory structures and governance arrangements are still adapting to the change. This indicates that perceived predator pressure is shaped not only by the number of predators present but also by the pace of change and experience with coexistence. Where interaction with wildlife has historically been part of livestock production, grazing systems are perceived as more resilient to predator presence. In regions experiencing recent predator return, uncertainty, institutional adaptation gaps and limited practical experience may affect grazing decisions and continuity. This pattern is relevant for countries such as the Netherlands, where wolf presence is a recent but rapidly developing reality. After more than a century of absence, the first individual wolf was recorded in the Netherlands in 2015, followed by re-establishment of territorial wolves from 2018 onwards. The number of wolf packs increased from one between 2019–2021 to eleven in 2024 with an estimated total number of 100-150 wolves. Over the same period, confirmed livestock attacks rose from 426 cases in 2023 to 795 in 2024, resulting in over 2,400 killed animals. While full monitoring results for 2025 are not yet available, preliminary data indicate continued population growth alongside persistently high levels of livestock damage. For comparison, Romania, which is about 6 times the size of the Netherlands, is home to one of the largest wolf populations in Europe, with estimates often ranging between 2,500 and 3,000 individuals. There were reported livestock losses that can be managed by local shepherds using compensation schemes. Improving the sustainability of grassland-based systems in return contexts requires not only technical mitigation measures but also coordinated governance responses and knowledge exchange. Supporting learning processes, advisory capacity and collaborative design of grazing strategies may enable workable coexistence between livestock and wildlife. In regions undergoing predator return, grazing resilience will depend on the adaptive capacity for coexistence rather than predator density alone.

Beyond predation Hotspots: Livestock resilience during 26 years of wolf recolonization in the French Alps

M. Virapin[1,2], S. Raniolo[2,3], G. Brunschwig[1], E. Sturaro[2]
[1] VetAgro Sup, INRAE, University of Clermont-Auvergne, UMR 1213 Herbivores, 89 Av. de l'Europe, 63370 Lempdes, France, [2] University of Padova, Department of Agronomy, Food, Natural Resources, Animals and Environment, Vle dell'Università, 16, 35020 Legnaro PD, Italy, [3] University of Padova, Department of Land, Environment, Agriculture and Forestry, Vle dell'Università, 16, 35020 Legnaro PD, Italy

Mountain livestock systems operate within complex socio-ecological contexts and face increasing challenges. In the European Alps, mountain livestock systems rely on seasonal grazing on large alpine pastures, where interactions between livestock and wildlife can occur. Among wildlife species, the wolf (Canis lupus) has received increasing attention in livestock systems during recent decades following the recolonization of Alpine territories. This study analyzed the dynamics of spatial patterns of geolocated wolf predation on cattle and ovicaprids between 1998 and 2024 in the department of Savoie (French Alps), a mountainous territory characterized by extensive pastoral activity and strong altitudinal gradients. This study aimed to explore possible relationships between wolf predation and landscape composition, livestock distribution, and wildlife abundance. The analysis was conducted at the scale of inter-municipal administrative units (EPCI), which represent relevant territorial entities for agricultural organization and local governance. Each spatial unit was characterized in terms of landscape composition in relation to land cover (number of patches, average patch area, average Euclidean distance among patches, cover percentage), livestock system densities (dairy cattle, beef cattle, sheep and goats during 2000, 2010, and 2020), wildlife presence (wild ungulates from the official census between 1998 and 2024) and wolf predation (7 347 events resulting in 19 917 livestock losses between 1998 and 2024). Spatial analyses were performed to explore the distribution and concentration of predation events. Kernel Density Estimation (KDE) was used to identify areas of higher predation intensity, while Emerging Hot Spot Analysis (EHSA) was applied to examine spatio-temporal trends in predation events over the study period. Preliminary results revealed that ovicaprid predation was predominant and increased significantly over the years, with a peak during summer and heterogeneous spatial patterns characterized by persistent hotspots throughout the study period. Some areas showed increasing predation events, coinciding with and located close to the first colonized areas, while others exhibited decreasing trends, and still others showed no defined trends. The areas with the highest wolf predation were characterized by high ovicaprid density, low forest fragmentation, and abundant grassland-sparse vegetation patches. No relationship with wild ungulate populations was detected. Interestingly, the areas with increasing wolf predation also showed increasing livestock density, especially for ovicaprids, and only marginal decreases in cattle density, suggesting resilience of local livestock systems. This study contributes to improving knowledge about large carnivore-livestock interactions through the characterization of predation distribution trends in mountain contexts. This approach provides a spatial framework for analyzing predation patterns, laying the groundwork for assessing predation risk exposure and supporting local stakeholders in improving local strategies and prevention measures.

Seven New Rules for Worm Control In Sheep

N. Cotter[1,2]
[1] Nuffield Farming Scholarships Trust Ireland, Tully West, Co. Kildare, R51 A384 Kildare, Ireland, [2] Cotter Agritech, Dromtrasna North, Co. Limerick, V94 A3H3 Abbeyfeale, Ireland

Sustainable Control of Parasites in Sheep (SCOPS) recommendations have provided clear guidance on resistance prevention for over 20 years, yet adoption remains low. Survey data (n=16,000, 2022) show 83% of Irish sheep farmers have never tested drench efficacy, 43% never calibrate dosing equipment, and 52% do not routinely quarantine, with adoption lower in cattle. In New Zealand, triple active resistance increased from 7% to 40% of tested farms (2020-2024), demonstrating how quickly efficacy can deteriorate. Further, climate change is increasing parasite challenge on farm. The objective was to identify practices used by farmers and programmes that have successfully maintained or restored drug efficacy. A mixed methods study (2023-2025) reviewed 217 publications and conducted semi-structured interviews (n=144) with parasitologists, veterinarians, breeders and farmers across five continents, purposively sampled across high-resistance (Australia, New Zealand), moderate-resistance (Ireland, UK) and low-resistance (Sweden) regions. Qualitative data was analysed using thematic analysis. Thematic analysis identified seven common practices among successful farmers and programmes: Start with the basics: Quarantine, efficacy testing and gun calibration are foundational, yet survey data showed most farms are not implementing these.Don't put all your eggs in the FEC basket: Knowledge transfer programme managers (n=4) recommended combining FEC with stockmanship, growth rate and pasture risk assessment rather than relying on FEC thresholds alone.The training should be hard so the game is easy: Breeders selecting for worm tolerance in Australia and New Zealand (n=9) reported halving treatment frequency within 5-7 years without compromising growth.The majority of lambs, a minority of ewes; almost never all: Adult ewes are generally accepted to have acquired immunity and not require routine treatment. However, survey data showed only 13% of farmers never treat ewes, and of those who do, 97% treat all animals. Published trial data support targeted selective treatment (TST). Blanket monthly treatment reduced ivermectin efficacy from 95% to 60% over five years whereas TST maintained efficacy at 87% with equivalent lamb growth and 45% less anthelmintic (Kenyon et al., 2013).Go beyond drugs, drugs and more drugs: Avoidance of parasites outperforms treatment. Published data showed unparasitised lambs had 50% higher ADG than parasitised lambs treated every 21 days. Co-grazing with cattle reduced parasite challenge by 40-60%.Shoot 'em, stab 'em, drown 'em: Multi-active combination treatment is standard practice in Australia and New Zealand. Modelling data indicates combinations extended time to drug failure from 87 to 300 treatments versus sequential use. A 7-year study (n=105 US farms) showed herbicide resistance developed 83 times slower with combination treatment. In human medicine, combination therapy for HIV, TB and malaria halved deaths from 4.8 to 2.5 million (2004-2024). Despite this evidence, combinations are unutilised in Europe.As much as necessary, as little as possible, but not zero: Parasitised lambs produce 33% higher methane emissions. Among UK organic farmers (n=226), only 20% achieved zero ewe treatments. As such, zero treatment is not a realistic target.Seven practices were identified among farmers and programmes that have maintained or restored drug efficacy. Analysis of knowledge transfer programmes (n=4) identified facilitator-led workshops, peer-to-peer farm visits, annual efficacy testing and investment in handling infrastructure as critical for adoption. These elements are being tested through the PARASCOPE EIP Project in Ireland (2026).

Effects of previous feed intensity on level of compensatory growth in growing cattle on semi-natural grasslands

L. Hessle[1], M. Jardstedt[1], J. Becker[2], A. Hessle[1]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Box 234, 53223 Skara, Sweden, [2] University of Bern, Department of Clinical Veterinary Medicine, Bremgartenstrasse 109a, CH 3012 Bern, Switzerland

Semi-natural grasslands are habitat types characterized by substantial biodiversity and they are therefore of high conservational value. Continued livestock grazing over years is required for the values to maintain, but achieving high weight gains of growing cattle grazing semi-natural grasslands can be challenging. Previous research has identified the phenomenon of compensatory growth, which implies a negative correlation between feed intensity during an indoor period and weight gain during the subsequent grazing period. Compensatory growth is thought to be caused by increased appetite in combination with larger digestive tract in proportion to body mass and lower maintenance requirements in previously restrictively fed animals compared to more intensively fed animals. In addition to dietary composition and intensity level, intrinsic properties of the animal, such as gender and breed, or a natural variation over the year due to changes in metabolic rate or hormonal status can affect to what extent compensatory growth occurs. The aim of this study was to investigate the effect of previous indoor feed intensity on weight gain in growing cattle grazing semi-natural grasslands, i.e., compensatory growth. Data from growing cattle reared at SLU Götala Beef and Lamb Research Centre, south-western Sweden, in 36 trials from 1998 to 2025 was used. Average daily live weight gain (ADG) of 849 growing steers, heifers and bulls of dairy, beef, and dairy × beef breeds during their first indoor period after weaning (IP) and following grazing period (GP) was compiled. Diets during IP consisted of mainly grass-clover silage (50% – 100% of diet) in combination with grain and for young animals also protein feeds. During GP, the animals grazed heterogenous semi-natural grasslands with dry, mesic and wet areas as well as both open meadow and areas with scattered trees and shrubbery. For a preliminary comparison between levels of feed intensities, a sub-sample of 356 animals from seven trials, each with two indoor feed intensities (LOW and HIGH), was selected. The length of IP and GP for all animals was 184 ± 36 days (mean ± SD) and 168 ± 22 days, respectively, and the length of IP and GP for animals in the sub-sample was 180 ± 41 days and 155 ± 19 days, respectively. Across all animals, ADG was 0.88 ± 0.28 kg for IP and 0.56 ± 0.29 kg for GP. For animals in the subsample, ADG was 0.99 ± 0.26 kg for IP and 0.47 ± 0.31 kg for GP. When the subsample was split into feed intensities, a numerically higher ADG was observed during IP for the HIGH animals, 1.07 ± 0.20 kg/day, compared to the LOW animals, 0.9 ± 0.28 kg/day. During GP the opposite was observed, were the LOW animals expressed a numerically higher ADG, 0.57 ± 0.20 kg/day, than the HIGH animals, 0.37 ± 0.36 kg. Hence, the lower ADG during IP for the LOW animals was partly offset by their higher ADG during GP, where they managed to compensate 43% of the lost weight gain, i.e., 79 kg of 177 kg. A shorter GP (155 days) vs. IP (180 days) might partially explain why a higher recovery was not observed during GP. These findings indicate that the LOW animals experienced compensatory growth, which is consistent with previous research. More detailed results on the full data set will be available once the statistical analyses have been completed.

Body reserves dynamics of dual-purpose crossbred (Bos taurus × Bos indicus) cattle across successive production cycles under contrasting semi-extensive grazing farms in Cuba

B. Cormary[1,2], M. Rodríguez[3], V. Pérez[3], A. Tesnière[4], P. Salgado[1], R. Pedraza[5], J. Pires[6], N. Friggens[7], E. González-García[4]

[1] CIRAD, SELMET, Univ. Camagüey (UC), Cuba, [2] MUSE, Institut Agro, 34000 Montpellier, France, [3] CIMAGT, Lomo de Tierra, Havana, Cuba, [4] INRAE, SELMET, 34000 Montpellier, France, [5] UC, CEDEPA, Camagüey, Cuba, [6] INRAE, Herbivores, 63000 Clermont-Fd, France, [7] INRAE, Pegase, 35000 Rennes, France

Future livestock farming systems (LFS) must be adapted to challenges imposed by climate change (CC), which are particularly important in low-input tropical LFS, mainly those based on grass and forage resources. The strategic and efficient use of the two complementary but antagonist phases of body reserves (BR) in ruminants [i.e., mobilization (BRM) and accretion (BRA)], plays a crucial role in the contribution of the animal component to the overall resilience of the LFS, when facing feed scarcity and fluctuations in nutritive value over time. Therefore, exploring the factors affecting BR dynamics (BRD) and the inherent intra-herd variability becomes a research priority in the current context, which has been mainly worked in temperate latitudes. The aim of this work was to characterize the BRD of tropical cows across successive production cycles reared under contrasting semi-extensive grazing LFS in Camagüey (Cuba; 21°N-77°W). Dual-purpose crossbred Bos taurus × Bos indicus cows (n=109), belonging to eight farms randomly selected in the region, were individually and longitudinally monitored to characterize their BRD over two consecutive years (April 2024-2026). The BR biomarkers assessed were: two zootechnical parameters (BW, body weight; BCS, body condition score), five metabolites (NEFA, non-esterified fatty acids; BHB, β-hydroxybutyrate; URE, urea; TGL, triglycerides; GLU, glucose) and the metabolic hormone T3 (triiodothyronine). Reproductive events were recorded and cows were phenotyped during eight key physiological stages (PhySt; i.e., early, mid, and late pregnancy; early, mid and late lactation; and dry period or maintenance). Relevant environmental and biological factors influencing BR traits were evaluated by performing analyses of variance (ANOVA) using the linear mixed model package (lmerTest) of the R Software (R Core Team, 2026; version 4.5.2). The cow was considered as random effect to take into account repeated measurements on the same animal over time. The farm (i.e., and their associated management practices), the climatic season (dry or rainy), the parity (primiparous or multiparous), the cow's PhySt, and their first-order and three-way interactions were considered as fixed effects. The BRD was strongly influenced by the farm management practices (mainly feeding-nutrition and reproduction). Unexpectedly, non-significant isolated effect of the year season was consistently observed on the BRD, which is in agreement with the complexity of the tropical research setting evaluated here (i.e., commercial LFSs without heat detection, calving synchronization or diet supplementation). The relevance of physiological effects (PAR, PhySt) was confirmed as the key modulating factors driving BRD, with BRM occurring from late pregnancy to early lactation, and BRA from mid-lactation to mid-pregnancy. These are the first results obtained on this subject under Cuban and Latin-American conditions. We provide relevant insights that allow a better understanding to decrypt the mechanism responsible of BRD in tropical cows, as well as their adaptive capacities in the current CC context. Future research efforts are warranted, considering the potential for leveraging this complex trait to establish adaptive farming practices and strengthen the resilience of semi-extensive pasture-based LFS in challenging tropical conditions.

Forage quality of rewetted peat grasslands: a preliminary evaluation

J. Mačuhová[1], S. Thurner[1]
[1] Bavarian State Research Center for Agriculture, Institut for Agricultural Enginnering, Vöttinger Str. 36, 85354 Freising, Germany

Rewetting of peat grasslands aims to reduce greenhouse gas emissions; however, its effects on fodder productivity and harvestability remain unclear. To evaluate potential forage quality, samples were collected before each planned cut from one rewetted meadow (3.6 ha; rewetted two years ago) and one unrewetted control meadow (4.2 ha). Both meadows have been managed extensively in recent years, with up to two and three cuts per year, respectively. Samples were taken from up to three predefined areas per meadow, dried at 40 °C, and subjected to an extended Weender analysis. The forage is typically used for feeding beef cattle (silage or hay) and horses (grass cobs). Statistical analyses were performed in SAS (PROC MIXED), with meadow as a fixed effect and cutting date nested within meadow as a random effect. Due to persistently wet conditions during the harvest season, only one cut could be obtained from the rewetted meadow, carried out over three dates (July 18 to September 4). Not all harvested material could always be collected. The first cut of the control meadow was also conducted over three dates within two weeks (starting July 4), whereas subsequent cuts were harvested on single dates (last cut on October 19). No significant differences ($P > 0.05$) were observed between meadows for the evaluated parameters. Metabolizable energy for ruminants (mean ± SD) was 9.67 ± 0.06 and 10.32 ± 0.73 MJ/kg DM, crude protein was 79.42 ± 5.88 and 126.11 ± 49.48 g/kg DM, utilizable protein was 117.89 ± 0.54 and 132.00 ± 15.82 g/kg DM, ash-free neutral detergent fibre was 616.94 ± 4.70 and 499.00 ± 129.95 g/kg DM, and enzymatically soluble organic substance was 468.00 ± 32.05 and 629.33 ± 104.04 g/kg DM in forage from the rewetted and control meadow, respectively. Higher variability of the evaluated forage quality parameters was observed across cuts in the control meadow, consistent with harvest timing and regrowth effects. In contrast, variability among cutting dates was low in the rewetted meadow despite the prolonged harvest period, likely due to the simultaneous presence of senescent and newly emerging biomass. In conclusion, forage quality of the rewetted meadow was comparable to that of the control meadow. Overall, potential forage quality, based on pre-harvest and oven-dried samples, remained within a range considered adequate for beef cattle production, especially when combined with higher-quality forages or maize silage. Further sampling will be conducted to assess the long-term development of forage quality.

Evaluations of selected effects of feeding crushed grain to suckler cow-calves on the animals' fecal indices

H. Scholz[1]
[1] Anhalt University of Applied Sciences, Faculty LOEL, Strenzfelder Allee 28, 06406 Bernburg, Germany

With increasing extensification of grazing areas and changing climatic conditions, a significant deterioration in the energy and nutrient content of pasture forage can be expected in a few years. Suckler cows can compensate for this to some extent by building up and breaking down their body reserves, which is not possible with growing calves. This would reduce the growth performance of the calves and thus also the weaning weight, which, however, has a certain significance for the economy of the process. Against this background, supplementary feeding of the calves with farm energy feeds such as grain can be discussed. The suckler cows calved in the period from the beginning of April to the end of May 2024, which is why 01.05.2024 was assumed to be the middle day of calving. As calves feed mainly on milk in the first 90 days of life (SCHOLZ, 2002), supplementary feeding was started on 01.08.2024. For this purpose, an automatic feeder with a storage container including a calf slop was used, which was placed as close as possible to the water wagon and the containers for the mineral feed. In order to be able to describe the effect of the supplementary feeding, pool faecal samples were analyzed 4 weeks before the start in order to have a baseline value. In the last week before the supplementary feeding, samples of the calves were collected intensively on 3 days and then also analyzed as pool samples. With the start of supplementary feeding, faecal samples were then repeatedly collected on a random day of the week to describe the key figures in the faeces. Dry matter and starch (enzymatic), nitrogen and crude ash were analyzed in the faecal samples. The digestibility of organic matter (OM) from the calves' faeces was calculated according to LUKAS et al. (2005). The average consumption of concentrates in the first 8 weeks after the start of supplementary feeding was 787 g per animal per day. The faeces of the calves showed that in the 3 samples (pools) before supplementary feeding, only low starch contents of a maximum of 6 g per kg DM were determined. With the start of supplementary feeding, there was a significant increase in the starch content in the faeces to over 18 mg per kg DM of faeces. After the peak on day 1 after feeding, the starch content in the feces ranged between 9-11 mg per kg DM. Overall, the use of the supplementary feed can also be assessed as positive from the point of view of the key figures in the feces, especially since the systematic preparation of the calves from suckler cow husbandry for the feeding conditions in the subsequent fattening period seems sensible and also worthwhile.

Investigation of immune parameters, health indicators and growth of German crossbred lambs exposed to natural gastrointestinal nematode infection

R. Martin[1], S. Schmucker[1], V. Stefanski[1], J. Bennewitz[1], M. Schmid[1,2,3]
[1] Institute of Animal Science, University of Hohenheim, Garbenstraße 17, 70599 Stuttgart, Germany, [2] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [3] Faculty of Agricultural, Civil and Environmental Engineering, University Rostock, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany

Gastrointestinal nematode (GIN) infections are of major concern in global sheep farming as they cause massive production losses, treatment costs and impaired animal welfare. The increasing resistance of GIN to anthelminthics has even exacerbated this issue. Since grazing animals are inevitably exposed to GIN, pasture management, selective treatment strategies and breeding for an improved immunity of sheep against GIN are of increasing relevance. Knowledge about the complex infection mechanisms on pasture is essential as well as the identification of systematic effects that may provide guidance for appropriate modelling in quantitative genetic analyses of traits related to natural GIN infections. The aim of the study was to identify significant influences on such traits in crossbred lambs (German Merino x different meat sire breeds). A dataset of 118 lambs originating from a field trial conducted in 2022 at one experimental farm in Southwestern Germany was used. Lambs were raised indoors and subsequently managed in two grazing systems (intensive/extensive) on pasture. After six weeks of natural exposure to GIN, blood and faecal samples were collected at an average age of 11 weeks. Diarrhoea indicators were visually scored. All animals were frequently weighed during the experiment to derive average daily gain. The further phenotypes were diarrhoea indicators (Dag Score, faecal consistency score), haematological traits as well as immunological blood cell counts including eosinophils which play a substantial role in the immune response towards GIN. A mixed linear model was then applied within asreml-R. A random animal effect was included and variance-covariance structures were modelled by a genomic relationship matrix based on 50K genotypes. Systematic environmental effects were included as fixed effects and tested for significance ($p < 0.05$) in a backward elimination approach and using Wald statistics. The tested effects thereby referred to the animal (e.g. sex), the infection (faecal egg counts of the most abundant nematodes, the lambs' co-infection status of cestodes and coccidia), the general pasture system and cortisol concentration as a marker for a putative acute stress response to handling which may influence immune cell counts. In general, the infection related effects were identified as most impactful with all traits, except Dag Score, being significantly influenced by at least one of them. For example, a significant influence of Nematodirus spp. was observed on blood eosinophils and on body weight which was additionally significantly influenced by Trichostrongylidae whereas the genus Strongyloides spp. showed a significant effect on the haematological traits. The effect of the pasture system was not significant for any of the blood based traits but for average daily gain and faecal consistency score. The animal effect was significant for all traits which points to a genetic component. These results underline the complexity of natural mixed GIN infections and how phenotypic trait expression is shaped. They emphasise the importance to further investigate such traits under natural infection conditions on pasture in purebred populations with larger sample size. This is planned in a current follow-up study with several sampling timepoints to further infer the dynamics of infection and immune response.

Transforming Dairy Systems in APHCA Countries: Productivity, Health and Climate-Smart Innovation

Y. Montanholi[1], F. Teillard[1]
[1] FAO Regional Office for Asia and the Pacific, Animal Health and Production Module, Maliwan Mansion, 39 Phra Atit Road, 10200 Bangkok, Thailand

The member countries of the Animal Production and Health Commission for Asia and the Pacific (APHCA)—Australia, Bangladesh, Bhutan, South Korea, India, Indonesia, Iran, Lao PDR, Malaysia, Mongolia, Myanmar, Nepal, Pakistan, Papua New Guinea, Philippines, Samoa, Sri Lanka and Thailand—encompass diverse dairy systems contributing to growing global milk demand. Asia accounts for over 40% of global milk production, with continued growth driven by population increase, urbanization and dietary change. Demand is rising particularly for fresh and processed dairy products in urban areas. This study aims to assess productivity, animal health constraints and climate-related risks across representative systems and to identify priority investment pathways. Production systems range from pastoral (Mongolia, Pakistan, Iran) to smallholder mixed systems (India, Bangladesh, Nepal, Bhutan, Sri Lanka, Myanmar, Lao PDR), peri-urban systems (Indonesia, Philippines, Malaysia), and high-input commercial systems (South Korea, Australia). The analysis focuses primarily on smallholder and peri-urban systems, where most production occurs and constraints are often more pronounced, using commercial systems as reference points. The assessment draws on FAO databases, national sources and field observations from APHCA member countries, applying standardized indicators of productivity, reproduction and health, alongside emission-related metrics. Available evidence, although variable in quality and coverage, suggests that milk yields in smallholder and peri-urban systems are generally lower than in commercial systems, with substantial variation across countries and contexts. Productivity constraints are associated with feed limitations, reproductive inefficiencies and disease burdens, including mastitis and parasitism. Climate variability, input costs and infrastructure gaps further affect system performance. Data systems remain fragmented in many countries, with limited implementation of herd recording and inconsistent alignment with international standards. Animal health service access is uneven, and milk is often marketed informally or used for household consumption, limiting traceability and quality control. These findings should be interpreted cautiously given differences in data availability and system heterogeneity. Potential interventions include genetic improvement, feeding strategies, reproductive management, animal health programs, and improved housing and cooling. Strengthening data systems, extension services, milk quality assurance and value chains may support gradual improvements. Overall, the analysis suggests that integrated approaches addressing productivity, animal health and management may contribute to improved system performance, although outcomes depend on local conditions and adoption. The findings are indicative and highlight the need for improved data and longitudinal evidence to support investment planning.

Scaling up strategic investments in the dairy sector using the LSIPT WebApp: Evidence from a national genetic breeding centre in Bhutan

M. Hamon[1], G. Leroy[1], T. Yangzome Dorji[2], S. Norbu[2]
[1] FAO, Animal Production and Health Division, Viale delle Terme di Caracalla, 00153 Rome, Italy, [2] Ministry of Agriculture and Livestock, Department of Livestock, PO Box 113, 11001 Thimphu, Bhutan

It is often challenging to use science to inform policy decisions because research outputs often arrive too late in the policy cycle and require substantial analysis before they can be translated into clear policy actions – actions that may still fail to secure stakeholder buy-in. One solution is to rely on simpler tools that facilitate evidence-based, participatory dialogue among stakeholders, providing rapid though robust results, including visualizations for decision-makers. For the livestock sector, one such tool is the Livestock Sector Investment and Policy Toolkit (LSIPT) WebApp. This paper presents its application in Bhutan and shows how it generated rapid and clear evidence to support investment in a national breeding program for the dairy sector. The LSIPT has been widely used by the World Bank, FAO, CIRAD and ILRI to provide policy and invest advice to the livestock sector. Using the model, however, requires skills which often made it difficult local ownership. FAO and CIRAD have thus translated LSIPT into a user-friendly WebApp that facilitates stakeholder engagement. The LSIPT WebApp helps stakeholders build consensus on priority livestock investments: it describes current production systems and their likely evolution under a business-as-usual scenario, quantifies the expected financial and economic impacts of proposed investments, and provides summary indicators – such as Net Present Value, profit margins, and poverty or food-security outcomes – to support evidence-based decision-making. In Bhutan, LSIPT first assisted stakeholders in portraying the business-as-usual scenario of the current dairy production system – e.g. herd size and composition, quantity and price of inputs and outputs – and its expected evolution over a 20-year period. It was then used to simulate the impact of two investments at farm level: (i) the installation of a herringbone milking machine, and (ii) importation of purebred Jersey heifers to improve genetic potential. Results indicate that installation of a milking machine increases milk yield and reduces production costs, with a profit margin of 21% and reaching breakeven within five years. The introduction of improved genetics further increases production, assuming appropriate herd offtake management and adaptation of exotic animals to local conditions. Both investments are anticipated to generate positive returns and are bankable in the Bhutan context, suggesting market-based policies could trigger a transformation of the dairy sector. The participatory and user-friendly nature of the LSIPT WebApp enabled stakeholders – including government officials, technical experts, and financial institutions – to jointly explore the impact of alternative investments, strengthening shared understanding of the dairy production systems and facilitating a discussion around the impact of the proposed interventions on the technical and financial parameters more than around the description of the current production systems. This process enhances ownership of results and effectively informs strategic planning. The tool has been used in 17 countries and supports prioritization of livestock policies, efficient resource allocation, and development of investment plans engaging both public and private sectors. Initially developed collaboratively by the World Bank, CIRAD, and FAO, the transition from an Excel-based research tool to a web-based platform translated in several languages has expanded accessibility to a broader community of animal scientists and policymakers.

Building Inclusive and Sustainable Dairy Production: Global Insights on Community-Led Transformation Models from Heifer International

D. Bhandari[1], K. Sah[1], C. Tabora[1]
[1] Heifer International, 1 World Avenue, 72202 Little Rock, AR, United States

Smallholder dairy systems across low- and middle-income countries continue to face persistent constraints in genetics, feeding, climate resilience, and market access. Heifer International's community-led dairy models show that integrated genetic improvement, climate-smart production systems, stronger cooperatives, and market-aligned incentives can deliver rapid productivity gains and build more resilient dairy economies. In Nepal, the Milky Way Program— the country's national initiative to transform its dairy sector—has established a smallholder-managed Model Dairy Village (MDV) as a center of excellence and learning. More than 500 households have adopted advanced dairy technologies and improved management practices through the MDV. A cohort of one hundred Holstein Friesian (HF) heifers imported from South Korea is now producing an average of 5,742 liters per 305-day lactation—nearly 80 percent higher than existing HF crossbreeds in Nepal. Top-performing animals are reaching up to 9,000 liters per lactation, comparable to HF performance levels in Korea. Technologies and best practices proven in the MDV are being disseminated to more than 40,000 dairy-farming households nationwide, in partnership with the Central Dairy Farmers Federation and 120 milk producer cooperatives. Cooperative-led Business Development Services have raised daily milk collection to 1,800 liters, with a plan to reach 10,000 liters per day to support a viable domestic dairy industry and reduce approximately USD 17 million in dairy import costs. The program has also established Nepal's first Holstein Friesian nucleus herd within the MDV to generate high-genetic-merit dairy animals. This herd ensures a steady supply of quality breeding bulls for semen production at the Government's National Livestock Breeding Office (NLBO). To date, eleven high-potential male calves from the MDV have been procured by the NLBO to support national genetic improvement. In addition, the national breeding system has been strengthened through the production and utilization of more than 275,000 frozen semen doses from eight imported HF bulls. Over time, these measures will raise the genetic quality of Nepal's dairy herd, increase milk productivity, and improve farm incomes across the country. Across Africa, Heifer supports inclusive dairy development by strengthening farmer cooperatives, upgrading extension and animal-health systems, and expanding climate-smart forage production. In Rwanda, dairy productivity indicators have improved significantly, with average daily milk yield increasing from 3.5 to 5.9 liters per cow (≈+69%) and the share of milk sold rising to 70% of total output. These gains are supported by 50 new milk collection points and improved market connectivity within one of Heifer's projects. In Honduras, Heifer-supported sustainable livestock practices have increased dairy productivity by about 25%, improved land-use efficiency by 14–32%, enhanced water-use efficiency by 21–48%, and reduced greenhouse-gas emission intensity by 14–16%. These improvements are particularly important in Olancho, where 82% of producers report climate-related impacts such as drought and heat stress. More than 57% of producers are already implementing at least basic sustainable practice packages, and wider adoption could deliver an additional ~30% productivity gain and a 15–17% reduction in emissions intensity. Together, these regionally diverse cases demonstrate how Heifer International's community-centered, integrated dairy system interventions can produce scalable improvements in productivity, environmental performance, and household income and resiliency across varied production systems.

Enhancing dairy productivity in low- and middle-income countries through synergistic approaches
