[1] International Livestock Research Institute (ILRI), Livestock Genetics, Nutrition and Feed Resources (LGNFR) Program, P.O. Box 5689, Addis Ababa, Ethiopia, P.O. Box 5689 Addis Ababa, Ethiopia, [2] International Livestock Research Institute (ILRI), Livestock Genetics, Nutrition and Feed Resources (LGNFR) Program, P.O. Box 30709, Nairobi 00100, Kenya, P.O. Box 30709 Nairobi, Kenya

Low dairy productivity in many low- and middle-income countries (LMICs) is largely driven by limited availability and poor quality of feed, strong seasonal fluctuations in forage supply, low animal productivity, and increasing climate variability. Improving feed systems is therefore central to enhance dairy productivity, strengthening resilience, and reducing greenhouse gas emission intensity. The ILRI (International Livestock Research Institute) aims to impact the livelihoods of millions of smallholder farmers in LMICs by enhancing dairy productivity through climate-resilient approaches that improve feed availability, quality, and utilization, thereby generating synergistic gains in animal performance and health. Our key intervention areas include: (1) the identification and promotion of productive, nutritious, climate-resilient, low-methane forage species through advanced laboratory and field evaluations, together with molecular genetics and genomic tools to capture and utilize available genetic diversity, including materials conserved in genebank collections; (2) Use of alternative feeds, including application of strategic supplementation; (3) crop-livestock integration practices that increase biomass production and improve feed nutritive value of crop residues, including the strategic supplementation of residues with legumes or concentrates for a more balanced nutrient supply; (4) improved feed conservation techniques to reduce seasonal feed shortages; and (5) greater utilization of locally available feed resources to enhance resilience to climate variability. These interventions are integrated with dairy genetics and animal health technologies to generate synergistic improvements in productivity, health, and feed efficiency. Integrated "best-bet" technology packages are being developed and promoted, and subsequently scaled through multiple delivery pathways, including digital platforms and artificial intelligence-supported decision tools. The approach also integrates economic and policy dimensions, including livestock master plans, investment opportunities, and inclusive business models that support scaling of improved feeding and dairy practices. Particular attention is given to gender- and youth-responsive approaches to strengthen participation in emerging milk, feed and forage value chains. Together, these integrated strategies provide a pathway for sustainable intensification of dairy systems in LMICs while improving livelihoods and environmental outcomes. In this presentation, we aimed to share our experiences and strategies in addressing key challenges and constraints through coordinated research and development interventions. Presenting this synthesis at the annual meeting of the European Federation of Animal Science (EAAP) provides an opportunity to share lessons from LMICs and contribute to broader scientific discussions on sustainable dairy production. Keywords: Sub-Saharan Africa, sustainable dairy systems, improved feed system, unified approach, climate resilience.

Delivering Genetic Gains for Productivity, Climate Resilience, and Low Emissions in African Dairy Systems through ILRI-Led Genomics-Based Breeding

I. Houaga[1,2], R. Mrode[1,3], S. W. Alemu[1], G. Gebregziabher[1], J. Ojango[1], S. Meseret[4], E. T. Lyatuu[5], C. Ekine-Dzivenu[1,6], A. Frank-Lawale[1]

African dairy production systems face the intertwined challenges of low productivity and high climate vulnerability resulting in low profits for smallholder farmers. Drawing on flagship initiatives including the Africa-Asia Dairy Genetic Gains program and Enviro-Cow project, this paper summarizes ILRI's genomics-enabled and digital approaches to genetic gains while delivering low-emission, resilient, disease resistant, and productive dairy cattle for dairy systems across Africa. The phenotypic data collected includes milk yield, body weight, milk quality traits, somatic cell score, reproductive performance, and CH_4 recorded on smallholder farms across Kenya, Ethiopia, Tanzania, and Uganda. This is collected using digital tools developed using the Open data kit (ODK) and a customized mobile app developed for smallholder farming systems. Animals are genotyped and genomic Estimated Breeding Values (GEBVs) are computed using a single-step Genomic Best Linear Unbiased Prediction (ssGBLUP) method. Top ranked bulls based on their GEBVs are selected and promoted for use through artificial insemination. Key results from the enviro-cow project to date include: (i) preliminary heritability estimates for enteric CH_4 of $h^2 = 0.19 \pm 0.04$ (genomic HBLUP, year-season averaged model) based on 945 crossbred dairy cows with 15,723 Laser Methane Detector records and 459 genotyped animals (90,407 SNPs) across Ethiopia and Tanzania— estimates comparable to global dairy populations ($h^2 = 0.20–0.30$). Building on these findings, the ongoing Global Methane Genetics (GMG) Initiative at ILRI aims to advance innovations in breeding climate-smart dairy cattle across Kenya, Ethiopia, South Africa, Burkina Faso, and Benin, phenotyping approximately 4,255 animals and collecting 1,000 rumen microbiome samples with the goal of demonstrating that Africa can lead in reducing livestock methane emissions through genetic improvement. Evidence generated by ILRI and its partners across diverse dairy production systems in East Africa shows that data-driven breeding programs can substantially increase rates of genetic gain while enhancing climate resilience and livelihood outcomes. We further highlight the critical role of institutional innovation, inclusive breeding strategies, public–private partnerships, and national breeding program development in enabling effective implementation. Future activities will focus on expanding genomic evaluations to national and regional systems and embedding climate-smart and low-emission selection indices into routine national genetic evaluations. These efforts are expected to measurably improve smallholder productivity, strengthen climate resilience, and contribute to regional and global dairy sustainability targets.
Keywords: Genomic selection, methane emissions, rumen microbiome, digital phenotyping, smallholder systems

Investing in dairy for inclusive rural transformation: priorities and challenges from different regions and systems

A. Mottet[1], P. Ndungu[2]
[1] International Fund for Agricultural Development, Via Paolo di Dono 44, 00142 Roma, Italy, [2] Food and Agriculture Organisation of the United Nations, Viale delle Terme di Caracalla, 00142 Roma, Italy

Dairy production is a key pathway for inclusive rural development, contributing to income generation, nutrition, and employment for millions of rural households worldwide. As demand for milk and dairy products continues to grow, particularly in Africa and Asia, investments in sustainable dairy systems are becoming increasingly important for strengthening food systems and improving rural livelihoods. This presentation builds on 5 decades of dairy development in the IFAD as part of its mandate to reduce rural poverty and enhance food security by enabling smallholders, pastoralists and rural entrepreneurs to build resilient and profitable agricultural livelihoods. For example, in East Africa, where dairy production is largely dominated by smallholder farmers, investments focus on strengthening productivity and value chains. This includes promoting improved dairy breeds, better feed and forage systems, access to animal health services and stronger farmer cooperatives. These interventions help smallholders increase milk yields, improve milk quality and access reliable markets, while also supporting inclusive rural livelihoods, particularly for women and youth. In Central Asia, dairy production is based on pastoral and agro-pastoral systems that rely on seasonal grazing and extensive livestock management. Development programmes emphasize sustainable rangeland management, improved "last-mile" and remote veterinary and breeding services, and better access to diversified markets for livestock products. Strengthening pastoral value chains and community-based resource management helps improve livestock productivity while maintaining the resilience of pastoral livelihoods and ecosystems. In Eastern Europe and the Caucasus, dairy sectors are characterized by emerging medium to large scale farms and evolving market structures. Increasing farm productivity while strengthening milk quality and safety standards, and supporting modern processing and market linkages, is essential. These investments help producers meet growing consumer demand while enhancing competitiveness and sustainability in regional dairy industries. Environmental sustainability should be a systematic requirement in dairy investments. Livestock systems are closely linked to land, water and biodiversity resources, and well-managed dairy production can contribute to sustainable landscape management. Many programmes promote integrated crop–livestock systems, improved manure management and sustainable pasture practices that enhance soil fertility, reduce environmental degradation and improve resilience to climate shocks. This can be facilitated by leveraging supplementary funds such as the Green Climate Fund, the global Environment Facility or the Adaptation Fund to co-finance development projects, provide technical assistance and support environmental outcomes. One health approaches are also key to support pandemic prevention, preparedness, and response (PPR) initiatives, especially in rural communities. This should not only focus on animal health and disease surveillance but also include the health of ecosystems (e.g. pasture restoration) and the management of livestock-wildlife interactions. Dairy development also offers important opportunities for social inclusion. Women often play a central role in dairy production, milk processing and marketing, making the sector particularly relevant for women's economic empowerment. Dairy development programmes frequently include targeted support for women and youth, including access to training, financial services and leadership roles within producer organizations.

Innovations in temperate grazing dairy systems in Australia driven by precision management of pasture and livestock

F. R. Dunshea[1,3], I. Sawyer[2], F. Ahmadi[1]
[1] The University of Melbourne, School of Agriculture, Food and Ecosystems Sciences, Royal Parade, 3010 Parkville, Australia, [2] Feedworks, PO BOX 369, 3434 Romsey, Australia, [3] The University of Leeds, Faculty of Biological Sciences, LS2 9JT Leeds, United Kingdom

Australian dairy production systems are predominantly pasture-based, with farm performance and productivity largely determined by the efficient utilisation of pasture and livestock, in contrast to confinement systems reliant on capital-intensive infrastructure (e.g., housing and TMR infrastructure). A major constraint to land-use efficiency is difficulty of consistently implementing optimal grazing management. Pasture utilisation is maximised when grazing is aligned with plant physiological stage, typically around the 2 to 3-leaf stage in temperate systems, and when post-grazing residuals are maintained at levels supporting regrowth while minimising wastage. In practice, labour and operational constraints often limit the ability to achieve this level of precision. Virtual fencing technologies (e.g., Halter) provide a promising tool by enabling automated and flexible control of animal movement. This allows more consistent timing of grazing events and improved control of post-grazing residuals, reducing both under- and over-grazing. Thus, optimised grazing timing and residual management can increase pasture growth and grazed harvest, with anecdotal evidence suggesting increases in home-grown forage production of approx. 10–20%, where the technology is effectively applied. Importantly, these benefits are achieved with reduced labour input, increasing the likelihood that optimal grazing strategies are consistently implemented while contributing to improved labour efficiency and farmer wellbeing. Complementing improvements in land utilisation, wearable technologies target the livestock asset by enabling more precise, individualised animal management. Advanced identification and feeding systems allow delivery of customised feed amounts and formulations to individual cows within a herd during milking sessions, for example by increasing feed allocation to postpartum cows and reducing inputs for cows in later lactation. At the animal level, rumination monitoring provides reliable, real-time indicators of rumen function, enabling earlier detection of nutritional imbalances than traditional approaches used to identify conditions such as subacute ruminal acidosis, which are typically based on production responses such as milk yield and composition, and visual assessment such as faecal characteristics. This is particularly valuable in grazing systems where highly digestible, low-structural fibre spring pastures, and large concentrate feeding, may increase the risk of ruminal dysfunction, and where decisions about effective fibre provision are often uncertain despite adequate total grazed feed availability. Overall, competitiveness in grazing dairy systems is fundamentally driven by efficient pasture utilisation and animal productivity. These technologies can enhance control over these key assets by improving pasture management and enabling more responsive, animal-level interventions, thereby supporting increased productivity per hectare and per cow while maintaining the low-capital structure underpinning the efficiency and resilience of Australian grazing enterprises.

Production Efficiency Trends in Thai Dairy Farms through Strategic Benchmarking

P. Pattamanont[1], S. Khongkrapan[1], J. Khemsawat[1], B. Granzin[2]
[1] Ministry of Agriculture and Cooperatives, Department of Livestock Development, 69/1 Phayathai Rd., 10400 Bangkok, Thailand, [2] Australasian Dairy Consultants Pty Ltd, Tregeagle, 2480 NSW, Australia

The Thai dairy industry between 2023 and 2025, comprising 15,300 farming households and a national milking herd of 247,900 cows, is a vital agricultural sector producing approximately 1.05 million tons of raw milk annually. The efficiency of Thailand's dairy production, however, is under considerable pressure from high input costs and climate-related impacts, requiring effective transformation strategies. While literature suggests that benchmarking is a powerful tool for performance improvement, the practice remains relatively new to the Thai dairy industry. Consequently, the Thailand–Australia partnership project on dairy farm benchmarking has been established to facilitate precision farm management, thereby reducing the risk of financial loss of dairy farm business. This study aimed to monitor progress in the production efficiency of participating dairy farms. A framework of twenty benchmarks was developed based on preliminary findings, where Principal Component Analysis was applied to check multicollinearity and identify primary drivers of efficiency. Data were categorized into herd structure, production performance, and feeding inputs. Milk income over feed cost (MIOFC) was selected as the key comparative variable and was validated using the Pearson correlation coefficient to demonstrate its relationship with other efficiency indicators. Farms in the top quartile of MIOFC were classified as frontier farms, and the remaining 19 variables were analyzed in relation to this classification. Linear mixed models, controlling for variability at farm level, were utilized to identify significant performance differences across years. Results revealed six benchmarks that differed significantly across years ($p < 0.01$), regardless of farm system variability, which were total herd size, milk yield per cow per day, milk fat, feed cost, milk price, and milk revenue. Average herd size increased significantly from 62 in 2023 to 81 in 2025. Furthermore, a 10% higher ratio of replacement heifers to cows observed in 2025 may indicate a growing emphasis on genetic improvement. Although overall production efficiency improved, high feed costs which accounted for 64.8% of milk revenue remained a primary concern. Analysis by milk yield quartile showed that the average yield in the lowest quartile was 11.7 liters per cow per day. Yields below this level of production could be associated with a high risk of financial loss once other production costs were considered. The observed transition toward larger herd sizes and improved MIOFC, driven by gains in daily milk yield and components, indicated a structural intensification against rising input costs. However, the high proportion of feed costs relative to revenue emphasized the continued financial vulnerability of small-holder farm systems. The identification of this yield level provides a critical benchmark to sustain farm business, as farms producing below this level are unlikely to achieve a positive net profit margin. In conclusion, the monitored benchmarks provide a tool to track production efficiency and implement precision management strategies which could lessen the current poor terms of trade in the Thai dairy sector.

The natural additive Fator P included in diets of increases affinities of antibodies specific for salivary proteins of Rhipicephalus microplus ticks in beef and dairy cattle

L. Fernandes[1], L. Ferreira[1], R. Bin[2], I. Santos[2], R. Paranhos[3]
[1] Premix Nutrição Animal, Research, development and innovation, Milton José Robusti Street, 75, 14021-613 Ribeirão Preto, Brazil, [2] University of São Paulo, Ribeirão Preto Medical School, Bandeirantes Avenue, 3900, 14049-900 Ribeirão Preto, Brazil, [3] University of Franca, Dr. Armando de Sáles Oliveira Avenue, 201, 14404-600 Franca, Brazil

Infestations by R. microplus are responsible for reducing meat and milk productivity in cattle farming. Parasitism by ticks is mediated by a large repertoire of salivary proteins that they secrete into the blood pool they make in their hosts' skin. Modern management practices combined with precision nutrition have been an important strategy to curb the spread of tick populations by strengthening animal health, increased resistance against ectoparasites and reduced herd infestation in a sustainable manner. In this case, the inclusion of natural additives in the diet can enhance the maturation of the immune response, to increase the functional affinity of antibodies against R. microplus antigens and to modulate the host's immune system. Fator P is a natural zootechnical feed additive that has been shown to improve several production features in beef and dairy cattle. Due to its composition and to the mechanisms by which vertebrate hosts generate high affinity specific antibodies, we hypothesised that Fator P improves the affinities of saliva-specific antibodies in bovines of a genetically tick-susceptible breed. In order to test this hypothesis in part, we measured levels and affinities of antibodies specific for select recombinant tick salivary antigens in blood from bovines that had been treated or not with Fator P and infested artificially with unfed larvae of R. microplus. Purebred, castrated Holstein steers, aged 18 to 20 months were randomized into two groups (N= 8/group) based on weight, body condition score, paternity and innate tick loads. The study was blinded and both groups were confined in individual pens in a feed lot with an empty pen separating each animal; the test group received Fator P (dosed at 6,0 gr / animal / day) and both groups received 2,2% of body on a dry matter (DM) in diet. Blood samples for serum were collected on days 28, 56, 63, 70, 87, and 119 after the start of treatment with the additive. Avidity was measured using 6, 7, 8 or 9 M urea washes in a conventional ELISA that employed recombinant antigens cloned from genes encoding select secreted proteins from salivary glands of R. microplus. The statistical method used was the Mann-Whitney test, with p-values <0.05. Sera collected on the first day of treatments contained saliva-specific antibodies that presented a similar percentage of avidity amongst both groups ($p=0.9214$). After the 28th day of treatment, the percentage of antibody avidity increased significantly, from 0.09% to 0.27% ($p<0.0001$) for the group treated with Fator P and from 0.10% to 0.11% for the control group. After that, the results remained constant until day 119, varying from 0.30% to 0.55% ($p<0.0001$) and from 0.10% to 0.11% for the treated and control group animals, respectively. Fator P promoted a significant increase in the avidity of saliva-specific antibodies in treated cattle. This process depends on affinity maturation of antibodies in germinal centres (GCs) of lymph nodes, and Fator P may improve it because B lymphocytes do not rely on aerobic glycolysis but actively oxidize fatty acids when hyperproliferating in GCs. We predict that natural additive Fator P can action on precision nutrition on targets metabolic processes that improve antibodies responses, including to tick saliva, explaining the reduction of tick loads that is also observed in bovines that receive this additive.

Mitigation of enteric methane emissions by dietary essential oil supplementation in tropical feedlot systems

C. Franzon[1], J. Michelini[1], M. Dalafini[1], F. Oristanio[2], M. Marques[1], E. Furlan Junior[1], E. Magnani[1], L. Drouet[2], R. Dari[3], T. Da Silva[1], R. Branco[1]

[1] Animal Science Institute, Livestock Sustainable Center, Road Washington Luis, km 445, 15130-000 São José do Rio Preto, Brazil, [2] MixScience, Avenue Ker Lann, cs 17228, 35172 Bruz Cedex, France, [3] Salus Animal Nutrition, Avenue Marginal SP-340,km 141,2, 13833-591 Santo Antonio da Posse, Brazil

Enteric methane (CH_4) emissions from beef cattle represent a major contributor to the carbon footprint of livestock systems and a loss of dietary energy. Developing effective mitigation strategies for tropical production systems is therefore essential to improve the environmental sustainability of beef production. Essential oil (EO) compounds have emerged as promising rumen modulators capable of altering microbial fermentation pathways and reducing methanogenesis without compromising animal performance. This study evaluated the effect of a plant-derived feed additive containing carvacrol and capsaicin (ValoPro-E) on productive performance and enteric CH_4 emissions of feedlot-finished Nellore bulls under tropical conditions. Forty-eight non-castrated Nellore bulls (initial body weight = 333.6 ± 4.1 kg) were assigned to two treatments (n = 24): control (basal diet + mineral premix) or EO supplementation (basal diet + mineral premix + 3 g/animal/day of additive). Diets were formulated according to NASEM (2016) with a forage-to-concentrate ratio of 12:88. Animals were housed into collective pens equipped with automated bunks and scales (Intergado®), allowing individual monitoring of feed intake and body weight. Enteric CH_4 emissions were measured in a subset of animals (n = 12 per treatment) using the sulfur hexafluoride (SF_6) tracer technique with continuous 24-h sampling for five consecutive days. Data were analyzed using mixed models with treatment as fixed effect and initial body weight as covariate ($P < 0.05$). Supplementation with EO did not affect dry matter intake, final body weight, average daily gain, feed efficiency, hot carcass weight or dressing percentage ($P > 0.05$). Generalized additive models indicated that daily BW trajectories differed between treatments ($P = 0.003$), with a plateau in weight gain during the final days observed in treatment control but not in EO-treated animals. However, EO supplementation reduced absolute CH_4 emissions compared with control group (174.6 vs. 193.1 g CH_4/day; $P = 0.002$), representing a 9.5% reduction in enteric CH_4 production. In addition, CH_4 intensity was reduced relative to carcass weight ($P = 0.002$), final body weight ($P < 0.001$), and CO_2-equivalent emissions per kilogram of meat produced ($P = 0.02$) for EO-supplemented animals. Methane yield (CH_4/DMI) was not affected. These results demonstrate that EO supplementation can reduce enteric CH_4 emissions while maintaining productive performance in tropical feedlot systems. This strategy represents a practical nutritional approach to support climate-efficient beef production in tropical regions, contributing to the mitigation of greenhouse gas emissions in the global livestock sector. This study was supported by FAPESP (grants 2017/50339-5, 2021/11922-2) and CNPq.

Effect of 3-NOP and dietary NDF concentration on methane emission and ruminal synthesis of vitamin B12 in dairy cows

S. Lashkari[1], M. R. Weisbjerg[1], S. K. Jensen[1], S. Fedosov[2], C. W. Heegaard[2], A. L. F. Hellwing[1], P. Lund[1]
[1] Aarhus University, AU Viborg, Research Centre, Foulum, Department of Animal and Veterinary Sciences, DK, 8830 Tjele, Denmark, [2] Aarhus University, Department of Molecular Biology and Genetics, Universitetsbyen 81, 8000 Aarhus, Denmark

Dietary inclusion of 3-NOP, through its inhibition of methanogenic archaea activity, combined with a low dietary concentration of neutral detergent fiber (NDF), which is positively associated with ruminal vitamin B12 synthesis, may increase the risk of impaired ruminal synthesis of vitamin B12. The present study aimed to evaluate the effect of dietary NDF concentration in combination with 3-NOP on methane emissions, and ruminal synthesis of vitamin B12 in dairy cows. Four multiparous Danish Holstein cows were fitted with a rumen cannula and a T-shaped cannula in the duodenum. The study design was a 4×4 Latin square with 4 treatments over 4 periods of 21 days. Each period consisted of 14 days of adaptation, 3 days of digesta collection, and 4 days of gas exchange measurements in respiration chambers. The basal diets (g/kg DM) consisted of 505 grass silage, 136 rapeseed meal, and 10 mineral and vitamin supplements combined with either 350 barley (low NDF diet; LoNDF) or 350 dried sugar beet pulp (high NDF diet; HiNDF) and were supplemented with either 0 or 60 mg 3-NOP/kg DM (Bovaer). Therefore, cows were fed four diets as follows: LoNDF, LoNDF_3-NOP, HiNDF, and HiNDF_3-NOP. Dietary NDF concentrations (g/kg DM) were 312 ± 21 and 371 ± 12 (mean ± SD) in LoNDF and HiNDF diets, respectively. Eight duodenal samples were collected at 8–10 h intervals, pooled, and analyzed for vitamin B12. Dry matter intake (DMI; kg/d) affected by dietary NDF concentration ($P < 0.01$) and was higher in the low NDF diets (22.3) compared to the high NDF diets (20.4). Methane production (g/d) was 23% lower ($P < 0.01$) in the diets supplemented with 3-NOP (334) compared to the non-3-NOP supplemented diets (432). Methane yield (g/kg DMI) was 22% lower ($P < 0.01$) in the diets supplemented with 3-NOP (15.8) compared to the non-3-NOP supplemented diets (20.2). Hydrogen (H2; g/d) production was affected by 3-NOP ($P < 0.001$), and it was higher in the diets supplemented with 3-NOP (9.9) compared to the non-3-NOP supplemented diets (0.6). Duodenal concentrations of all corrinoids (i.e. B12-like molecules = cobalamin + analogues; nmol/kg DM) were 2742, 2527, 3302, and 3222 for LoNDF, LoNDF_3-NOP, HiNDF, and HiNDF_3-NOP, respectively and were affected by dietary NDF concentration ($P < 0.01$). Duodenal concentrations of the active vitamin B12 (i.e. cobalamin) were affected by dietary NDF concentration ($P < 0.01$), with higher concentrations in the high NDF diets (839 nmol/kg DM equal to 1.14 mg/kg DM) compared with the low NDF diets (592 nmol/kg DM equal to 0.80 mg/kg DM). There was no interaction between dietary NDF concentration and 3-NOP for the aforementioned variables. In conclusion, DMI increased when dietary NDF concentration was reduced. Methane production and methane yield were lower in the diet supplemented with 3-NOP. The findings indicate that dietary NDF concentration is a major driver of rumen vitamin B12 synthesis, as increasing dietary NDF increased duodenal vitamin B12 concentration without any concurrent adverse effect of 3-NOP.

Effects of 3-nitrooxypropanol (3-NOP) supplementation on enteric methane emissions and milk production in dairy cows fed canola meal or soybean meal

C. Benchaar[1], F. Hassanat[2], S. Terry[3]
[1] Agriculture and Agri-Food Canada, Sherbrooke Research and Development Centre, 2000 rue College, J1M 0C8 Sherbrooke (QC), Canada, [2] Agriculture and Agri-Food Canada, Quebec Research and Development Centre, 2560 boulevard Hochelaga, G1V 2J3 Quebec (QC), Canada, [3] Agriculture and Agri-Food Canada, Lethbridge Research and Development Centre, 5403 1re Avenue S., T1J 4B1 Lethbridge (AB), Canada

The objective of this study was to evaluate the effects of including 3-nitrooxypropanol (3-NOP; Bovaer 10®; dsm-firmenich, Switzerland) in dairy cow diets based either on soybean meal (SBM) or canola meal (CM) on enteric CH4 emissions (production, yield, and intensity), and milk performance (production and composition). Twelve multiparous Holstein cows were used in a replicated 4 × 4 Latin square design (35-d periods; 14-d adaptation) with a 2 × 2 factorial arrangement of treatments. Cows were fed ad libitum (5% refusals, as-fed basis) a TMR containing either SBM or CM as the main protein source, without or with 3-NOP (60 mg/kg of diet DM). The diets were isonitrogenous, and CM (23% of diet DM) replaced SBM and soybean hulls. Milk production and milk composition were measured for 7 d, and CH4 emissions were measured for 4 d using respiratory chambers. Data were analyzed using the MIXED procedure of SAS with fixed effects of meal source (CM vs. SBM), 3-NOP (with vs. without) and their interaction; square and cow within square were considered random effects. Significance was declared at $P \leq 0.05$. No meal source × 3-NOP interaction was detected for any of the response variables. Dry matter intake (DMI) was unaffected by the treatments, averaging 29.9 kg/d. Milk yield tended ($P = 0.09$) to be greater in cows fed CM (+1.1 kg/d), but was unaffected by 3-NOP. Yields of energy-corrected milk (ECM) and milk components (fat, protein, and lactose) were unaffected by the meal source or 3-NOP. However, cows fed CM exhibited lower MUN concentration than cows fed SBM (12.1 vs. 13.3 mg/dL; $P < 0.01$). Replacing SBM with CM reduced enteric CH4 production (g/d), yield (g/kg DMI) and intensity (g/kg ECM) by 12% on average. Supplementation with 3-NOP reduced CH4 production, yield, and intensity by 28% compared with unsupplemented cows. In conclusion, replacing SBM with CM tended to increase milk yield (+2.5%) and significantly reduced enteric CH4 emissions (-12%), while also lowering MUN concentration, suggesting improved nitrogen utilization. Regardless of meal source, dietary supplementation with 3-NOP decreased CH4 emissions by 28% without affecting intake or milk production. The combined strategy of feeding CM and 3-NOP reduced enteric CH4 production, yield, and intensity by an average of 36% compared with feeding SBM without 3-NOP.

Effects of 3-nitrooxypropanol, nitrate, and rumen-protected fat, alone and in combination, on gaseous emissions and performance of lactating dairy cows

G. Vivares[1,2], W. Muizelaar[1], J. Dijkstra[2], A. Bannink[1], S. Van Gastelen[1]
[1] Wageningen University & Research, Wageningen Livestock Research, PO Box 338, 6700 AH Wageningen, Netherlands, [2] Wageningen University & Research, Animal Nutrition Group, PO Box 338, 6700 AH Wageningen, Netherlands

3-nitrooxypropanol, nitrate and rumen-protected fat have shown anti-methanogenic properties in ruminants, each following a different metabolic mode of action. However, their combined effects are less clear. Hence, our aim was to evaluate the addition of 3-nitrooxypropanol, nitrate and rumen-protected fat, either alone or in combination, to the diet of lactating dairy cows. We hypothesized that the CH4 mitigating effects of the individual interventions would be additive when combined. The experiment followed a randomised complete block design and included a 2-wk covariate period for baseline measurements followed by a 12-wk treatment period. Sixty-four Holstein-Friesian dairy cows (130 ± 27 DIM and 33 ± 5.6 kg/d fat- and protein-corrected milk (FPCM) at the start of trial; mean ± SD) were blocked by parity, DIM, and FPCM yield, and randomly allocated to 1 of 8 treatments: a control diet (CON; 39% grass silage, 27% maize silage and 34% concentrates on DM basis), the individual addition of Bovaer® (3-nitrooxypropanol, 3NOP), SilvAir® (nitrate, NIT) or Mega-Max 2.0® (rumen-protected fatty acids, FAT), the combination of 2 of these compounds (3NOP+NIT, 3NOP+FAT, or NIT+FAT), and a treatment combining all 3 compounds (3NOP+NIT+FAT). The realized doses were 68.4 mg 3NOP/kg DM, 14.1 g NIT/kg DM and 23.8 g FAT/kg DM. Measurements of CH4, H2, and CO2 were performed using 3 GreenFeed units. Data were analysed using repeated-measures mixed models in R, including treatment, time, and their interaction as fixed effects, with block as a random effect and cow nested within block as a repeated factor over time. Preliminary results show that total DMI was lower ($P < 0.01$) for both 3NOP+NIT (20.7 kg/d) and 3NOP+NIT+FAT (20.8 kg/d) compared to CON (22.9 kg/d). Methane yield (g/kg DMI) was not significantly affected by FAT, but was reduced ($P < 0.01$) by 20.1% for 3NOP and 20.7% for NIT compared to CON (20.8 g CH4/kg DMI). Dual combinations of 3NOP, NIT, and FAT did not result in significantly larger reductions of CH4 yield compared to 3NOP and NIT alone. Combining all 3 interventions achieved the largest inhibition of CH4 yield (-30.4%) differing from all other treatments ($P < 0.01$). Similar responses were observed for H2 yield, which did not differ between FAT and CON (0.05 g/kg DMI for both), but increased ($P < 0.01$) with NIT (0.12 g/kg DMI) and 3NOP (0.21 g/kg DMI). Dual combinations containing 3NOP or NIT did not increase H2 yield beyond that of 3NOP or NIT alone, respectively. Also, combining all 3 interventions resulted in a similar H2 yield level as that of 3NOP alone. None of the treatments differed from CON for CO2 yield, but the CO2 yield of FAT (631 g/kg DMI) was lower than both 3NOP+FAT (677 g/kg DMI) and 3NOP+NIT (675 g/kg DMI; $P = 0.05$). The FPCM yield was higher for FAT (36.2 kg/d) and lower for 3NOP+NIT (31.4 kg/d) compared to CON (34.8 kg/d; $P < 0.01$). Depending on the combination of 3NOP, NIT and FAT, reductions in CH4 emissions did not always appear additive and were sometimes accompanied by numerical decreases in DMI or FPCM (e.g., 3NOP+NIT). Conversely, some combinations showed trends towards greater CH4 inhibition with less impact on DMI or FPCM (e.g., when combining FAT with 3NOP or NIT) or smaller increases in H2 yield (e.g., NIT+3NOP compared with 3NOP). Understanding the mode of action of each intervention and its effects on rumen function and post-absorptive metabolism is key to adequately recommending combinations of 3-nitrooxypropanol, nitrate and rumen-protected fat.

Exploring the effects of 3-nitrooxypropanol in diets varying in crude protein and starch content on methane and nitrogenous greenhouse gases emissions from dairy cows

S. Van Gastelen[1], H. J. C. Van Dooren[1], J. Faas[2], M. Kambara[3], A. Haruno[3], L. F. M. Tamassia[2], A. Bannink[1]
[1] Wageningen University & Research, PO Box 338, 6700 AH Wageningen, Netherlands, [2] dsm-firmenich, Wurmisweg 576, 4303 Kaiseraugst, Switzerland, [3] Ajinomoto CO. Inc., 1-1, Suzuki-cho, 210-8681 Kanagawa, Japan

This study aimed to investigate additive effects of 3-nitrooxypropanol (3-NOP) in diets varying in crude protein and starch content on CH4 and nitrogenous emissions from dairy cows. In total, 64 Holstein-Friesian dairy cows were enrolled with a milk yield of 37.4 ± 7.22 kg/d (mean ± SD) at 166 ± 30 DIM. Cows were blocked in groups of 4 and within block randomly allocated to 1 of 4 mechanically ventilated barn units (mimicking regular cow housing, floor, and manure management), with cows within barn unit receiving the same treatment. The experiment lasted 10 weeks; 2 weeks covariate for baseline measurement and 2 treatment periods (both comprising 2 weeks adaptation and 2 weeks measurement). A control diet (CON) with 177 and 173 g/kg DM CP and starch, respectively, and a low protein high starch diet (LPHS) with 154 and 255 g/kg DM CP and starch, respectively were supplemented with 0 or 60 mg 3-NOP/kg DM (NOP0 and NOP60, respectively). All diets consisted of 39% grass silage, 23% corn silage, and 38% concentrates (DM basis). The differences in CP and starch content between CON and LPHS were realized by a different concentrate composition for both diets. The LPHS diet was supplemented with rumen-protected lysine (AjiPro-L) to maintain metabolizable lysine. Additional concentrate was fed in the GreenFeed system that was used to measure enteric CH4 emissions. Ventilation rates and concentrations of CH4, NH3, and N2O were measured in background and exhaust air of each barn unit. Data were analyzed on barn unit and subjected to ANOVA using the MIXED procedure in SAS. Baseline, 3-NOP, diet, and 3-NOP × diet were fixed effects, and barn unit, period and treatment sequence were random effects. No interactions between 3-NOP and diet were observed. Enteric CH4 emission and manure CH4 emission represented on average 72.5% and 27.5%, respectively, of total CH4 emissions. Enteric CH4 emissions were reduced by 22.7% ($P \leq 0.02$) with NOP60 compared to NOP0. Barn emission of NH3 and N2O were lower (-29% and -14%, respectively; $P \leq 0.03$) for LPHS compared to CON. In conclusion, enteric CH4 emissions were reduced by 3-NOP irrespectively of the dietary CP and starch content, and LPHS reduced nitrogenous emissions as result of the lower CP content.

Effects of feeding palmitic and stearic acids as triglycerides on milk production and methane emissions in dairy cows

S. M. Jespersen[1], G. Giagnoni[1], L. Wiking[2], M. R. Weisbjerg[1]
[1] Ruminant Nutrition, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark, [2] Food Chemistry, Department of Food Science, Agro Food Park 48, 8200 Aarhus N, Denmark

Dietary fat supplementation is a nutritional strategy to mitigate enteric methane (CH_4) emissions from dairy cows. However, responses depend on fatty acid type and associated effects on production. This study hypothesized that supplementation with saturated fatty acids C16:0 and C18:0 as triglycerides (TG) at increasing levels, would reduce daily enteric methane production (CH4 g/day) and increase energy-corrected milk (ECM) yield and thereby reduce methane intensity (CH4 g/ECM). It was also hypothesized that the effects were linear to supplementation level. The effects of increasing dietary concentrations of TG rich in palmitic acid (P-TG) or stearic acid (S-TG) on dry matter intake (DMI), CH_4 emissions and milk composition were studied. The experiment included 48 lactating Danish Holstein cows (24 primiparous and 24 multiparous) and was conducted at Aarhus University research facilities. Six dietary treatments were evaluated: a control diet and low (L), medium (M), and high (H) inclusion levels (1.43, 2.87, and 4.30% of dry matter) supplied as S-TG (LS, MS, HS) or P-TG (MP, HP). The diets were formulated with a 70:30 silage-to-concentrate ratio (silage: 50:50 DM grass–clover and maize silage) and offered ad libitum as a PMR. Additionally, up to 1 kg DM concentrate was provided in the GreenFeed units for enteric CH_4 measurement. Each cow received four of the six treatments, one in each period, for a total of four periods, each lasting three weeks (incomplete 6×4 Latin square). The first two weeks served as adaptation and the third week was used for sampling. Emissions of CH4 were measured using the GreenFeed system to obtain individual gas production. Daily dry matter intake (DMI) and milk yield were recorded, and in sampling weeks milk samples were analyzed for protein, lactose, and fat content. Data were analysed using a linear mixed-effects model in R (v4.4.2; lme4 package). Dietary treatment, period, days in milk (DIM), and parity were included as fixed effects, including the interactions between DIM and parity and between treatment and parity, with cow as a random effect. Model assumptions were evaluated graphically. Results are presented as estimated marginal means (emmeans), and linear and quadratic contrasts were estimated. Supplementation with P-TG increased ECM yield compared with the control (37.5 kg/d), reaching 40.0 and 40.7 kg/d for MP and HP, respectively (treatment, $p < 0.001$). Milk fat percentage and fat yield increased with P-TG supplementation (4.82% for control vs. 5.03% and 5.08% for MP and HP; treatment, $p < 0.001$). Although milk protein percentage decreased, daily protein yield increased (1.29 kg/d for control vs. 1.33 and 1.34 kg/d for MP and HP; treatment, $p < 0.001$). Feed efficiency (ECM/DMI) increased with P-TG supplementation (1.58 for control vs. 1.65 and 1.68 for MP and HP; treatment, $p < 0.001$). Consequently, CH_4 intensity decreased as a linear effect (12.1 for control vs. 11.0 and 10.7 CH_4/kg ECM for MP and HP; treatment, $p < 0.001$, linear $p < 0.001$). Total daily CH_4 emissions were not significantly affected by any fat supplementation. Supplementation with S-TG did not affect ECM or milk composition. DMI increased linearly for cows on the S-TG diet and for multiparous cows on the P-TG diet ($p < 0.001$ and $p = 0.02$ respectively). In conclusion, supplementation with P-TG increased ECM yield and feed efficiency and reduced methane intensity.

Immunonutrition in ruminants

A. Schwarm[1]
[1] Norwegian University of Life Sciences, Oluf Thesens vei 6, 1433 Ås, Norway

The Nutrition Commission proposed inviting me as a speaker. I was asked to provide this abstract and a review until September in case I get invited. In my talk/review I will link nutrition, immunology, rumen microbiome, feed efficiency and enteric methane emission in ruminants. How does nutrition influence immune and microbial function in ruminants with low/high feed efficient phenotypes and with low/high methane emitting phenotypes? How can we adjust nutrition to optimize immune and microbial function in ruminants differing in methane and feed efficiency phenotypes? The review aims to provide an overview of existing knowledge, gaps in knowledge and suggestions for moving from descriptive to mechanistic studies. This abstracts hasn't matured yet, but I highlight relevant reports. Arshad et al. (2024) reported that immune cells in high feed efficient cows (low RFI) exhibit an increased metabolic function, which might influence nutrient partitioning and utilization and serve as a source of variation in feed efficiency that warrants further investigation. In our study in press in Journal of Dairy Science (Nur Cahyo et al. 2026), high feed efficient, early-lactating cows (high ECM/DMI) showed a stronger immune response, but also a higher methane yield (high CH4/DMI). Reiche et al. (2025) reported a higher proportion of IgA-coated archaea in feces of 3-NOP fed cows compared to control cows, indicating an active role of the immune system in inhibiting rumen microbial function. Gibson et al. (2016) demonstrated a more efficient immune response in Brown Swiss compared to Holstein cows, with the former being known for a comparable lower feed efficiency and greater methane emissions. Genes but even more environmental factors such as nutrition affect feed efficiency, rumen microbiome and immunological condition. Research in methane mitigation by feeding measures focusses on feed efficiency and more recently on additive effects of multiple feed additives. Immuno-microbial-nutrition is an emerging research field, considering the relevance of immune and microbial function for the ruminant host. Effects of efficiency phenotype and forage to concentrate ratio on milk production and methane intensity in dairy cows

M. Vadroňová[1], P. Fant[1], K. Kozicka[1], P. Huhtanen[2], M. Ramin[1]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Skogsmarksgränd 17, 90183 Umeå, Sweden, [2] Natural Resources Institute Finland, Production Systems, Tietotie 4, 31600 Jokioinen, Finland

Enhancing the efficiency of animal production has become increasingly important to address the rising global food requirements, lower the environmental footprint of livestock systems, and ensure economic sustainability for producers. Oxygen (O2) uptake, carbon dioxide (CO2) output, and heat production (HP) are closely linked to metabolic energy losses and have been shown to explain a large proportion of the variation in residual feed intake (RFI) in respiration chamber experiments. For this reason, indicators such as residual CO2 production (RCO2: observed CO2 – predicted CO2), residual O2 consumption, and residual heat production (RHP), calculated in a manner comparable to RFI, may serve as alternative measures of efficiency. The objective of this study was to evaluate the effects of efficiency phenotype and dietary forage to concentrate ratio (F:C) on feed intake, milk production, and methane (CH4) intensity in dairy cows using a 3-period switchback design. A 2-week pretrial was conducted with 44 Nordic red dairy cows fed a 55:45 F:C diet (F55). Residual heat production was calculated from gas exchange measurements using the GreenFeed system. Cows were ranked by RHP, and the 16 cows with the most negative values were classified as efficient, whereas the 16 cows with the most positive values were classified as inefficient. Residual heat production differed between efficiency phenotypes, averaging −9.7 ± 1.37 in efficient cows and 10.8 ± 0.68 in inefficient cows (mean ± SEM). Cows were then blocked by parity, RHP, days in milk and energy corrected milk (ECM). Within each efficiency group, 8 cows were assigned to F55 and 8 to a 70:30 (F70) F:C diet. Each period lasted 28 d; cows received the same diet in periods 1 and 3 and the alternate diet in period 2. Data were analyzed using a mixed model in SAS including fixed effects of efficiency group, diet, period, sequence, and carryover (previous diet), with block nested within efficiency group and cow nested within block as random effects. Dry matter intake did not differ between efficient and inefficient cows (21.6 vs. 20.4 kg/d; P = 0.31). Efficient cows produced more milk (31.9 vs. 24.8 kg/d; P < 0.01) and more ECM (36.6 vs. 31.3 kg/d; P < 0.01) than inefficient cows. Methane intensity (g CH4/kg ECM) was lower in efficient than inefficient cows (10.3 vs. 13.6; P < 0.01). Methane yield (g CH4/DMI) was lower for the efficient cows compared to inefficient cows (17.4 vs. 20.7; P < 0.01). The efficiency phenotype was consistent across diets, with efficient cows producing more milk, less CH4 per unit of ECM and DMI under both F:C ratios (F70 and F55). Keywords: residual heat production; feed efficiency; enteric methane; energy-corrected milk; GreenFeed system; forage to concentrate ratio

Effect of supplementing lactating dairy cows diet with an Asparagopsis taxiformis based product on enteric gaseous emission, lactation performance, and active compound milk residues

S. Danesh Mesgaran[1], W. Xu[1], J. L. Romano-Muñoz[2], A. López-Juárez[2], A. González De Cosío-Barrón[2], A. Rytz[1], M. Bobkov[1], M. Coulet[3], E. Soussan[1]
[1] Nestlé Institute of Agricultural Sciences, Rte du Jorat 57, 1000 Lausanne, Switzerland, [2] Tecnológico de Monterrey, Escuela de Ingeniería y Ciencias, Epigmenio González 500, 76130 Santiago de Querétaro, Mexico, [3] Nestlé Institute of Food safety and analytical Sciences, Rte du Jorat 57, 1000 Lausanne, Switzerland

Seaweed feed additives, particularly Asparagopsis taxiformis (AT) and armata, are of great interest due to their mode of action by directly blocking a key step of methanogenesis in the rumen. We hypothesized that the AT-based feed additive Brominata™ will reduce enteric methane (CH4) emissions in lactating dairy cows without affecting their performance or health, and that bromoform and its metabolites residues in milk will remain below levels of consumer health concern. Forty Holstein cows were enrolled in a randomized complete block design with repeated measures per cow over a 14-wk period, including 2-wk covariate and 12-wk of treatment. The study comprised two experimental diets: (1) a control diet; and (2) a control diet supplemented with Brominata™ at 0.45% inclusion rate on dry matter (DM) basis. Individual feed intake was recorded using automatic feed bins (RIC System, Hokofarm). Milk yield was recorded automatically at every milking (VMS™, DeLaval). Enteric gaseous emissions were measured using GreenFeed systems (C-Lock). Milk samples were collected bi-weekly to determine lactose, fat, and protein levels. Individual milk samples at wk6, -10, and -14 of the experiment were taken to measure bromoform, bromine, bromide and iodine concentration. Supplementation with Brominata™ reduced CH4 production by 20% ($p< 0.05$). CH4 yield (adjusted for DM intake) and intensity (adjusted for energy-corrected milk (ECM)) dropped by 19 and 26%, respectively, ($p<0.05$). Hydrogen production increased more than 2-fold in the treatment group compared to the control ($p< 0.05$). Dry matter intake was not significantly different between the experimental groups ($p= 0.09$). Milk yield and ECM were significantly higher by 5 and 8%, respectively, in animals supplemented with Brominata™ throughout the period of supplementation ($p< 0.05$). Feed efficiency, considering ECM, increased by 6.5% in the treatment group compared to the control ($p< 0.05$). Although milk protein and lactose concentrations were not affected by supplementation with Brominata™, milk fat concentration in treatment group increased by 8% ($p< 0.05$). Residual bromoform concentration in the milk was not significantly different between both groups, however bromine and bromide concentrations in the milk were significantly higher by 161% in the treatment group ($p< 0.05$). Although there are no health concerns from exposure via milk alone for these metabolites in any of the target consumer groups, iodine levels in feed premix need additional attention, as inclusion of Brominata™ increased the iodine concentration in milk by 68% ($p< 0.05$). The effective dietary inclusion rate of the additive did not lead to adverse effects on animal health and welfare. In conclusion, Brominata™ was able to mitigate the CH4 emission in lactating dairy cows without an adverse effect on animal health or posing consumer safety risks. The positive impact of Brominata™ on milk yield, ECM and feed efficiency merits further investigation.

Effect of a dietary cinnamaldehyde–eugenol–capsicum oleoresin blend on production and methane emissions in Holstein lactating cows

C. Christodoulou[1], S. M. Tondini[2], D. J. Humphries[1], H. Khelil-Arfa[2], P. Kirton[1], A. K. Jones[1], C. Panzuti[2], D. Luebe[2], S. Stergiadis[1]

[1] University of Reading, Department of Animal Sciences, Earley Gate, PO Box 237, RG6 6EU Reading, United Kingdom, [2] ADM International Sàrl., La Pièce 3, 1180 Rolle, Switzerland

Enteric methane emissions from ruminants are a major contributor to agricultural greenhouse gases, and despite phytogenic feed additives being proposed as mitigation strategies, reported responses in dairy systems remain variable. The objective of this study was to evaluate a dietary blend of cinnamaldehyde, eugenol, and capsicum oleoresin on production, feed efficiency, and enteric methane emissions in mid-lactation Holstein cows. Forty-two lactating cows were assigned to two treatments (n = 21 each): a control diet (Control) based on maize silage, grass silage, and concentrate blend, or the same diet supplemented with 1.2 g/cow/d of the XTract Ruminant X60-7065 essential blend (XTract). Cows were group-housed but individually fed using Calan gates (Calan Broadbent Feeding System; Calan Gates, American Calan; NH, USA); dry matter intake was recorded weekly, milk yield twice daily, and weekly milk samples were analysed for solids composition. Methane emissions were measured daily using the GreenFeed system (C-Lock Inc., Rapid City, SD). The feeding trial lasted 84 days, following a 2-week covariate period. Data were analysed using a repeated-measures linear mixed effects model including treatment, week, and the treatment × week interaction as fixed effects. Parity, days in milk, and the coefficient of variations for DMI and bodyweight were included as additional covariates. Cow nested within block was fitted as a random effect, and week was specified as the repeated measurement. Tukey's honestly significant difference test was used for pairwise comparisons when the effect of the fixed factors was significant ($P < 0.05$). Milk yield and feed efficiency did not differ between treatments ($P > 0.05$). XTract Ruminant X60-7065 supplementation reduced milk urea concentrations by 9.3% ($P = 0.004$; from 291 to 264 mg/L), while fat, protein, casein, lactose, and fatty acid profile were unaffected overall ($P > 0.05$). A treatment × week interaction was observed for the concentrations of milk protein ($P = 0.042$) and casein ($P = 0.037$), with higher values in XTract Ruminant X60-7065 group in Week 3 (+6.4% and +5.1%), but the difference was not statistically significant during the rest of the weeks. Methane production (g/d), yield (g/kg DMI), and intensity (g/kg milk yield and energy-corrected milk) were numerically reduced by 3.2%, 5.6%, 4.0%, and 4.5%, respectively, but the effect was not statistically significant ($P > 0.05$). However, a significant treatment × week interaction ($P = 0.049$) indicated lower methane production in the XTract Ruminant X60-7065 group (–5.2 to –7.3%) in Weeks 6–7 of the experimental period. The numerical reductions in methane emissions in the present study fell outside the statistical power threshold to detect significant effects in methane output (approximately 13%). Overall, these findings suggest that under the dietary and management conditions applied, the phytogenic blend had modest effects on production parameters and methane emissions. The reduction in milk urea and the higher milk protein and casein concentrations in parts of the study may indicate an improved nitrogen use efficiency; this warrants further investigation to include direct measurements of nitrogen balance (intake and excretion in faeces and urine), rumen ammonia concentration, and microbial protein synthesis, to confirm and clarify the biological mechanism behind this response.

Do cows rank similar in methane yield in first and second lactation?

M. H. Kjeldsen[1], T. De Evan[2], P. Lund[1], M. R. Weisbjerg[1]
[1] Aarhus University, Animal and Veterinary Sciences, Blichers Alle 20, 8830 Tjele, Denmark, [2] Universidad Politecnica de Madrid, Departamento de Produccion Agraria, ETSIAAB, 28040 Madrid, Spain

Dairy cows vary individually in methane (CH4) yield (CH4/dry matter intake (DMI)) and in related traits. Identification of the phenotypic traits related to variation in CH4 yield is essential for proper use of this variation to decrease CH4 emission from dairy production, both by management and by breeding. The aim of the present study was to examine whether the rankings in CH4 yield and correlated traits measured in first lactation were repeated in second lactation. Forty-eight 2nd parity cows, which at experiment onset were 99 ± 54 (mean ± SD) days in milk, were enrolled in a 3×3 Latin square design with 3-week periods and 3 treatments: Control, 3-NOP (Bovaer, 60 mg 3-NOP/kg DM) and Nitrate (Silvair, 8.5 g nitrate/kg DM). Diet composition was (g/kg DM): 262 grass-clover silage, 228 maize silage, 221 rapeseed meal, 146 barley, 86 beet pulp, 19 minerals and vitamins, and 38 concentrate mix offered in GreenFeed. Feed intake, milk yield and composition, CH4 emission (GreenFeed), and rumen fluid VFA composition (Ruminator samples) were measured in the last week of each period. All 48 cows had already been enrolled in 1st parity in a larger (201 cows) experiment with similar design, diets, treatments, and recordings, though cows were enrolled continuously 2–3 weeks after calving in the 1st parity experiment. Both experiments were analysed with mixed models with treatment and period as fixed and cow as random effects, and random cow effects (RCE) were extracted as estimates of each cow's phenotype. Forty-four cows were used for the calculations in the present study. The RCE from the two experiments (1st and 2nd parity) were correlated using Pearson correlations. Correlations between phenotypes (RCE) for CH4 yield (g/kg DMI) in 1st and 2nd parity were 0.48 ($P = 0.001$). Further, traits correlating to CH4 yield in 1st parity were examined for correlations between 1st and 2nd parity. Traits correlating positively with CH4 yield in 1st parity, milk fat yield (kg/d, $r = 0.55$, $P < 0.001$) and rumen acetate (mol/100 mol, $r = 0.48$, $P < 0.001$) also correlated positively between 1st and 2nd parity. Traits correlating negatively with CH4 yield in 1st parity, milk yield (kg/d, $r = 0.71$, $P < 0.001$), energy corrected milk yield (kg/d, $r = 0.66$, $P < 0.001$), rumen valerate proportion (mol/100 mol, $r = 0.60$, $P < 0.001$), rumen propionate proportion (mol/100 mol, $r = 0.54$, $P < 0.001$), and DMI (kg/d, $r = 0.52$, $P < 0.001$), likewise correlated positively between 1st and 2nd parity. According to the correlations, cows' CH4 yield ranked similarly in 1st and 2nd parity. The same applied to several other traits identified to correlate positively or negatively with CH4 yield in 1st lactation. This indicates, that both CH4 yield and several traits correlated to CH4 yield, such as well-known phenotypes as feed intake and milk production, but also phenotypes as rumen volatile fatty acid fermentation pattern correlate positively between 1st and 2nd parity and thereby could be used as supporting traits for cows' CH4 yield.

Effect of rice bran supplementation on nutrient utilization and methane emissions of beef heifers grazing native pasture

C. Ferrés-Castells[1], G. Fernandez-Turren[1]
[1] Instituto Nacional de Investigación Agropecuaria (INIA), Ruta 8 km 281, Uruguay, 33000 Treinta y Tres, Uruguay

Beef cattle raised on native grasslands experience strong seasonal fluctuations in forage supply, leading to inconsistent growth of replacement heifers. Winter supplementation with full fat rice bran is commonly used in rice-growing areas to improve performance, yet the effects of this practice on enteric methane emissions remain unclear. This study evaluated the effects of rice bran supplementation on nutrient intake, digestion, N and water balance, and methane emissions in beef heifers grazing native pastures during winter. The experiment was conducted at Palo a Pique Experimental Unit of INIA, Treinta y Tres, Uruguay (33ºS and 56ºW) during the winter season (i.e. July to September). Forty-eight Aberdeen Angus × Hereford heifers (355 ± 6,4 kg BW) were blocked by BW and randomly assigned to one of two treatments: (i) native pasture (NP, n = 24), and (ii) native pasture plus rice bran supplementation at 0.7% of BW (SUP, n = 24). All heifers grazed together, and SUP received their supplement once daily. Measurements were conducted during two consecutive periods (40 days) in which animals remained under the same treatment. Methane emissions were measured using the GreenFeed® system. To estimate intake and digestibility of nutrients, the animals (n = 10/treatment) were allocated in daily individual paddocks (100 m2) with a daily forage allowance of approximately 30 kg of DM per animal for 5 consecutive days in each of the two periods. The pasture intake was estimated individually as the difference between the pre- and post-grazing forage mass. Apparent total-tract nutrient digestibility was determined by collecting total feces deposited each day in each grazed paddock. To estimate the voluntary water intake, the amount of water offered and left water orts from each per animal was measured using a individual bins (capacity 100 L). Daily methane emissions did not differ between treatments. Supplementation increased nutrient DM intake ($P < 0.01$) through a positive associative effect and improved intake and digestibility of organic matter, crude protein, ether extract, and non-structural carbohydrates ($P<0.01$). Nitrogen intake and faecal nitrogen excretion increased with supplementation ($P<0.01$), whereas urinary nitrogen excretion decreased ($P<0.01$), suggesting greater absorbed more favorable nitrogen incorporated in body tissues partitioning. Voluntary water intake was unaffected. Rice bran supplementation enhanced nutrient intake without increasing absolute emissions, demonstrating that moderate lipid-rich supplementation is an effective strategy to improve the efficiency and environmental sustainability of in rangeland systems.

Methane emission response to feed supplements differs among cows

K. Veerkamp[1], M. Van Tol[1,2], B. Kemp[1], W. Van Straalen[2], A. Van Knegsel[1]
[1] Wageningen University and Research, Adaptation Physiology Group, PO Box 338, 6700 AH Wageningen, Netherlands, [2] Schothorst Feed Research, Meerkoetenweg 26, 8218 NA Lelystad, Netherlands

Feeding strategies in dairy cows may be used to mitigate methane emission and reduce the impact of dairy farming on global warming. Feed supplements, added to the basal ration, can reduce methane emissions through different pathways that interfere with methanogenesis in the rumen. Given that methane emission itself is highly variable among cows, the efficacy of various supplements may also differ among animals. Therefore, our aim was to evaluate between-cow variation in the methane response to three different supplements and explore what cow characteristics predict the response. Thirty-two Holstein Friesian dairy cows each received four treatments for four weeks in a Latin-square design. Treatments included three different supplements, as well as a control treatment without any supplement. Supplement 1 consisted of a mixture of fats, supplement 2 of a blend of essential oils, and supplement 3 of a blend of seaweeds. Methane concentration and airflow were measured in a Greenfeed station and converted to individual production (g) per cow per day. Cow characteristics (27 in total), including various variables describing cow condition and behaviour, were also measured by a reticulum bolus and a neck sensor. Each of the variables was extracted for the last week of each treatment, assuming that the cow had adjusted to the treatment by then. The response in methane production to each of the supplements was extracted by subtracting the methane production from the production in the control treatment. Stepwise linear regression models were developed for each supplement to predict the methane production response to the supplement using cow characteristics. Cow characteristics were added to or removed from the model using stepwise forward and backward regression, based on partial F-tests evaluating the change in residual sum of squares (model entry criterion $p<.05$; removal criterion $p>.10$). Methane emission response to each of the three supplements varied greatly among cows, and the supplement optimal for methane reduction differed across cows. For supplement 1, methane reduction was stronger for cows with a higher minimum reticulum pH and longer rumination time in the control treatment (full model adj. $R^2=.23$, $p=.02$). For supplement 2, reduction was stronger for cows that drank smaller portions of water more frequently (full model adj. $R^2=.37$, $p<.001$). For supplement 3, reduction was stronger for cows with a higher dry matter intake and that drank smaller portions of water (full model adj. $R^2=.33$, $p<.01$). In conclusion, individual response to feed supplements for methane mitigation differed among cows. Individual cow characteristics, including reticulum pH, water drinking behaviour and dry matter intake, were associated with the individual cow response to the methane-mitigating feed supplements. These results suggest that each of the supplements targets methane emission through different physiological mechanisms. Fat supplements are known to especially target fiber-digesting microbes that thrive under healthy rumen pH conditions, which might explain their greater effectiveness in cows with a higher minimum reticulorumen pH. Essential oils and seaweeds seem to perform better with a steady rumen passage rate, as caused by frequent small drinking bouts. However, physiological mechanisms need further exploration, which we plan to do by including results from blood and milk sampling. The developed models require validation on a larger dataset. Ultimately, they have the potential to enable precision supplement tuning, contributing to reducing methane emissions in dairy cows.

Dietary sweet chestnut tannins decrease diarrhea incidence and litter nitrogenous gas emissions in pre-weaning holstein calves

E. Scaglia[1], L. Gogna[1], A. Antonioli[1], V. Sergi[1], L. Giagnoni[1], G. Gilioli[1], V. Caprarulo[1,2]
[1] Università di Brescia, Department of Civil, Environmental, Architectural Engineering and Mathematics, Via Branze 43, 25123 Brescia, Italy, [2] Istituto Zooprofilattico Sperimentale della Lombardia ed Emilia Romagna "B. Ubertini",, Via Bianchi 9, 25124 Brescia, Italy

Tannins are plant bioactive compounds with the potential to enhance animal health and reduce the environmental footprint of livestock production. This study investigated the effects of supplementing hydrolysable tannins from sweet chestnut (Castanea sativa Mill.) on the growth performance, intestinal health, and nitrous oxide (N_2O) and ammonia (NH_3) emissions from the litter of Holstein calves. Twenty-four pre-weaning female Holstein calves were assigned to two experimental groups for a 56-day trial: a control group (CTRL) fed with milk replacer, and a treatment group (TRT) fed milk replacer supplemented with 10 g of tannins. Body weight (BW) and rectal temperature (RT) were recorded at d 0, 7, 14, 21, 28, 35, 42, 49, and 56. Milk intake (MI), hay intake (HI), average daily feed intake (ADFI) of solid feed, average daily gain (ADG), and fecal and clinical scores were recorded daily. Fecal samples were collected at d 0, d 28, and d 56 to determine total bacterial counts, coliforms, and Lactobacillus spp. Blood samples were collected at d 0 and d 56 for metabolic profile analysis. After the in vivo trial, litter (feces, urine, and straw) was collected from individual boxes and pooled into dynamic chambers to evaluate emissions between the two groups for an additional 49 days. Emissions of nitrous oxide (N_2O), and NH_3 (mg/g/h) were monitored by Gasmet-GT5000, and chemical analyses were performed at d 0 and d 49. Over the 56-day trial, no significant differences were observed between TRT and CTRL groups for MI, HI, BW, ADG, and RT ($P>0.05$). However, tannin supplementation significantly reduced ADFI ($P<0.01$) without compromising growth performance. The TRT group showed significantly higher frequency of normal fecal consistency (FS 0-1 score; $P<0.01$) and reduced diarrhea incidence (FS 2-3 score). Fecal color analysis revealed more brown feces in TRT versus more yellow feces in CTRL ($P<0.01$). Clinical scores and remained unaffected by treatment, and blood metabolic parameters remained within normal physiological ranges. Bacterial counts showed no group differences between groups, total bacteria and coliforms remained stable, while Lactobacillus spp. increased in both groups over time. Tannin supplementation significantly influenced litter emissions, reducing NH_3 (-58%, $P<0.01$) and N_2O (-60%%, $P<0.01$) emission. Particularly, NH_3 emissions were lower at d 0 and 1 ($P<0.01$), while N_2O emissions decreased at d 1, 2, and 5 in the TRT group. Litter temperature increased in the TRT group at d 0, d 1, and d 2 ($P<0.05$). Chemical analysis indicated lower total solids, ash, and total carbon in TRT litter at day 49, consistent with observed emission reductions. Furthermore, tannins reduced both ammonia and nitrous oxide emissions from calf litter, likely by modulating organic matter fermentation and enhancing litter stabilization. These findings highlight tannins as a promising feed additive to improve calf health while simultaneously reducing the environmental impact of livestock operations.

Rumen microbial adaptation time following dietary shifts and diurnal variation post-feeding

A. A. Schönherz[1], S. C. H. Hansen[1], M. H. Kjeldsen[1], M. R. Weisbjerg[1], Z. Cai[2], S. J. Noel[1]
[1] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark, [2] Aarhus University, Center for Quantitative Genetics and Genomics, C. F. Møllers Allé 3, 8000 Aarhus, Denmark

Diet strongly shapes the rumen microbiome. While fermentation parameters such as volatile fatty acids and dry matter (DM) intake generally stabilize within two weeks after dietary change[1], the adaptation period required for the microbial community itself remains poorly characterized. In addition, diurnal fluctuations associated with feeding may influence microbial composition, potentially confounding treatment effects in nutritional intervention studies. This study aimed to determine (i) whether a two-week adaptation period is sufficient for rumen microbial stabilization and (ii) the impact of diurnal variation on microbial ecology. We hypothesized that the rumen microbiome stabilizes within two weeks after a dietary shift and varies across the day. Eight rumen-cannulated, second-parity Holstein cows were housed individually and fed two experimental diets differing in roughage proportion (LOW: 35% DM; HIGH: 63% DM) in a crossover design, with each diet fed for three weeks. In the first period, half of the cows received LOW and half HIGH, and in the second period, cows were switched to the opposite diet. Cows had ad libitum access to feed and water and were offered fresh feed at 08.00 h. To assess microbial adaptation, rumen grab samples were collected once before the first diet shift and weekly for three weeks in each period (N=56). To evaluate diurnal variation, additional samples were collected at five time points within a day (06:00, 09:00, 11:00, 14:00, and 22:00 h) at the end of week three of each period (N=80). All samples underwent shotgun metagenome sequencing, with a subset of the diurnal samples subjected to metatranscriptome sequencing (N=48). Analyses included microbial composition, diversity metrics, differential abundance, and functional profiling. The largest shifts in microbial composition occurred within the first week following dietary change. However, microbial composition did not fully stabilize within two weeks. Microbial richness declined immediately after diet shift, with stronger reductions under LOW. Richness and Shannon diversity remained below baseline during LOW feeding, whereas cows receiving HIGH showed rapid recovery and a progressive increase, reaching highest richness and diversity three weeks. Across all sampling weeks, alpha diversities remained consistently higher in HIGH than LOW. Diurnal patterns revealed short-term dynamics in response to offering fresh feed. Richness and Shannon diversity increased after feeding, peaked three hours post-feeding, and returned to pre-feeding levels. Although similar patterns were observed under both diets, statistically supported was detected only under LOW. Diurnal compositional changes were detected but with a small effect size, primarily driven by pre- and early post-feeding samples (2 h before vs. 1 h after feeding), while samples within the six-hour post-feeding window remained relatively stable. Diurnal sampling time explained substantially more variation in microbial activity than composition, indicating stronger temporal effects on microbial function than community structure. Findings indicate that both adaptation period and sampling time influence rumen microbiome measurements. Overall, these results emphasize the need for adaptation periods longer than two weeks and carefully defined sampling protocols to ensure that rumen microbiome data accurately reflect dietary effects rather than transient microbial fluctuations.

Validation of global methane prediction equations for Austrian dairy cows under silage-based rations

M. Gierus[1], F. Oberhollenzer[1], L. Dardabou[1], G. Terler[2]
[1] Institute of Animal Nutrition, Livestock Products and Nutrition Physiology, BOKU University, Muthgasse 11, 1190 Vienna, Austria, [2] Institute of Livestock Research, Agricultural Research and Education Centre Raumberg-Gumpenstein (HBLFA Raumberg-Gumpenstein), Altirdning 11, 8952 Irdning-Donnersbachtal, Austria

Accurate prediction of enteric methane (CH_4) from dairy cows is key to mitigating agriculture's climate impact. This study validated 21 international CH_4 equations using respiration chamber data from Austrian cows fed Central European silage-based diets. Data from 76 lactating cows (56 Holstein-Friesian, 20 Fleckvieh) were analyzed. Cows differed in days in milk (20–300 d), parity (1–4), body weight (550–750 kg), and milk yield (20–55 kg/d). Diets comprised grass silage (35–45% NDF in DM), hay, maize silage, and concentrates. Dry matter intake (DMI) ranged from 15–28 kg/d; measured CH_4 was 219–476 g/d. Methane was recorded in two parallel respiration chambers (Innova 1412i) at 20°C and 60% relative humidity, with 2 d adaptation and 2 d measurement. Equations ($r^2 \geq 0.65$) were classified as simple (1 parameter; e.g., Jiao et al., 2014; Ribeiro et al., 2020), moderate (2–4; e.g., Yan et al., 2009), or complex (≥5; e.g., Jentsch et al., 2007; Marumo et al., 2023). Inputs included DMI, gross energy intake (GEI), body weight, forage share, NDF, digestibility (dCP, dEE, dCF, dNFE), and milk traits. Units were standardized (Kirchgessner et al., 2014: 1 g CH_4 = 1.4 L = 55 kJ). Outliers (1.5×IQR) were removed, <5% values imputed, and daily means calculated. Models were evaluated by sum of squared errors of prediction (SSEP), error decomposition, ANOVA ($p < 0.05$), and Bland–Altman analysis. Applicability considered farm data availability. Ribeiro et al. (2020) Eq. 49 ($CH_4 = 3.35 + 0.047 \times GEI$) performed best (SSEP 0.214 g^2/d; ratio 1.0; $R^2 \approx 0.90$), followed by Ribeiro et al. (2020) Eq. 1 ($4.15 + 0.822 \times DMI$; 0.216) and Marumo et al. (2023) ($38.0 + 19.22 \times DMI$; 0.218). Simple GEI- and DMI-based models dominated. Jentsch et al. (2007) Eq. 5 performed worst (SSEP 16.998). Complex digestibility models tended to overpredict high and underpredict low emissions. Bland–Altman plots showed minor bias around 300–350 g/d, with underprediction in early lactation and overprediction at high DMI. Agreement was slightly better for Fleckvieh. ANOVA confirmed significant differences ($p < 0.01$); top models achieved 15–80× lower SSEP than the weakest. GEI and DMI were confirmed as main CH_4 drivers (Ellis et al., 2007; Marumo et al., 2023). Ribeiro et al. (2020) Eq. 49 is recommended for Austrian systems due to high accuracy, simplicity (GEI = DMI × energy density), and robustness across silage diets. DMI-based models are practical alternatives. Notably, the Brazilian equation outperformed European and North American models. These equations support inventories, feed optimization (e.g., concentrate changes reducing CH_4/kg milk by 10–20%), and integration into breeding or ration tools. Regional validation supports EU targets (40% reduction by 2030). Future work should link CH_4 and DMI prediction and test pasture systems to enable mitigation without productivity loss. [1] University of Pisa, Department of Agriculture, Food and Environment, Via del Borgetto 80, 56124 Pisa, Italy,
[2] University of Pisa, Centre of Agro-environmental Research "Enrico Avanzi", Via Vecchia di Marina 6, 56122 Pisa, Italy

Interest in spot sampling strategies to estimate enteric methane emissions is consistently increasing. These approaches are generally less expensive, highly adaptable to different rearing systems without necessarily being linked to experimental facilities (e.g., commercial barns), and economically convenient. Meanwhile, natural feed additives are emerging as potential strategies to mitigate the environmental impact of ruminants, particularly methane emissions. In our previous in vitro study, several natural compounds, their natural-identical forms, and combinations of essential oil molecules and tannin extracts were tested. The in vitro screening included 12 individual bioactive compounds and 36 mixtures. Among these, one additive composed of tannins (quebracho) and essential oils (carvacrol, eugenol and limonene) showed promising effects in reducing methane and ruminal ammonia at a dosage of 133 mg/L of ruminal liquor for the tannin extracts and 100 mg/L for the essential oil blend. The aim of the present study was therefore to evaluate methane emissions and milk yield following supplementation of the same additive (ADD) to a control basal diet (CON) in dairy cows reared in an indoor commercial barn. A total of twenty mid-lactation Holstein-Friesian cows were included in the study and allotted to two groups of 10 cows, balanced for milk yield (20.3 ± 3.2; 21.4 ± 3.2 L), body weight (693 ± 68; 689 ± 48 kg), days in milk (145 ± 61; 145 ± 55), and parity (2.0 ± 1.1; 2.0 ± 0.9). The basal diet was a total mixed ration containing (g/kg): 920 organic matter, 140 crude protein, 30 ether extract, 180 starch, and 410 neutral detergent fiber. The additive was top-dressed and its intake was monitored until complete consumption to achieve a ruminal dosage comparable to that used in the in vitro study. The trial lasted 10 weeks, during which a hand-held laser methane detector (LMD) was used in week 0 (covariate period) and from weeks 6 to 10, following the adaptation period to the additive. Milk yield was recorded daily. Methane data for each period were derived from six spot measurements of 5 minutes each, performed over three days per week and considered representative of a 24-h period. Data were processed using a common local maximum algorithm to detect "peaks", and absolute methane production was calculated using the equation proposed by Sorg et al. (2018): CH_4 (g/d) = 150 + 2.2 × peaks (ppm × m). Statistical analysis was performed using a linear mixed model including treatment and week as fixed effects, cow as a random effect, and the corresponding baseline value of the variable as a covariate. Methane emissions varied across weeks but remained consistent between treatments. For example, at week 10, estimated methane emissions were 403.1 ± 11.8 and 412.8 ± 13.7 g/d for CON and ADD, respectively. Similarly, methane intensity (25.6 ± 1.70 g/L of milk), milk yield (16.9 ± 0.86 L/d) and fat yield (0.7 ± 0.05 kg/d) did not differ between treatments. Further studies are needed to validate the design of the spot-sampling measurements to determine whether the sampling scheme applied was sufficiently accurate to detect emissions differences between groups and, more generally, whether the natural additive itself may produce detectable effects under experimental conditions.

Effects of individual and stacked feed additives on in vitro methane production

Í. R. R. Castro[1], B. Hiley[1], O. C. Carballo[2], G. Scoley[2], S. Huws[1]
[1] School of Biological Sciences, The Institute for Global Food Security, 19 Chlorine Gardens, BT9 5DL Belfast, United Kingdom, [2] Agri-Food and Biosciences Institute, Large Park, BT26 6DR Hillsborough, United Kingdom

Reducing enteric methane (CH_4) from ruminant livestock is essential for sustainable agriculture, as it is a major greenhouse gas and a loss of dietary energy. Although individual feed additives (FAD) with anti-methanogenic potential can reduce emissions, their effects are often variable and dose-dependent, with potential impacts on rumen fermentation. Therefore, recent research has focused on stacking additives with complementary modes of action to achieve more consistent CH_4 mitigation. We hypothesised that combining FAD with distinct mechanisms would result in greater CH_4 suppression than their individual application. This study evaluated, in vitro, the individual and combined effects of 3 existing or near-to-the-market FAD: a blend of essential oils, bioflavonoids, and tannins (A), nitrate (B; an alternative hydrogen sink), and calcium peroxide (CaO2; C; an oxygen-releasing compound), on CH_4 production and rumen fermentation dynamics. Batch fermentations were conducted in 3 independent runs using perennial ryegrass silage as the substrate, incubated with buffered rumen fluid in 100 mL serum bottles at 39 °C for 48h under anaerobic conditions. Rumen fluid was collected post-slaughter from 5 donor cattle at a commercial abattoir in each run, transported to the laboratory in pre-warmed thermos flasks, strained through cheesecloth, and preserved under CO_2 to preserve anaerobic conditions before incubation. Treatments included A, B, and C at low, medium, and high doses, alongside stacked combinations AB, AC, BC, and ABC and a control diet (CON) tested in triplicates in each run. Methane in headspace gas was quantified at 4, 24, and 48h by gas chromatography and expressed as mL CH_4 per bottle and as a percentage change relative to CON. Data were analysed using SAS (PROC GLM) to assess the effects of treatment, dose, time and run. Model assumptions were verified, and Tukey's post hoc tests were applied when significant effects were detected ($p<0.05$). Calcium peroxide alone was highly effective across all doses. At 24h, CON produced 4.2 mL of CH_4, but C at the high dose produced only 0.7 mL. Similarly, at 48h, CON CH_4 averaged 4.6 mL against 0.7 mL for C-high, both a drop of ≈85%. Nitrate showed a clear dose-dependent response: at 24h the high dose reduced CH_4 from 4.2 to 2.9 mL (≈ -32%), and at 48h from 4.6 to 2.9 mL (≈ -38%). In contrast, A produced little or no mitigation at 24h and only modest reductions at 48h (≈7-15%). When stacked, strong mitigation was observed only when CaO2 was included. At 24h, CON produced 4.2 mL of CH_4, while AC, BC, and ABC all produced ≈0.6 mL, all reductions of approximately 85% (≈ -3.6 mL). At 48h, CON CH_4 averaged 5.1 mL, while AC, BC, and ABC treatments produced only 0.63-0.58 mL, representing reductions of ≈4.5 mL (≈ -89%). By contrast, the AB blend provided minimal mitigation (≈ -8% at 48h). These results do not support additive or synergistic effects beyond those driven by CaO2. Treatments containing CaO2 also consistently lowered headspace pressure and reduced ammonia accumulation over time, indicating altered fermentation pathways. Transient increases in the acetate:propionate ratio were observed during early fermentation but diminished by 48h, suggesting microbial adaptation. In conclusion, the initial hypothesis was only partially supported, as CaO2 was the main driver of CH_4 reduction and stacking with nitrate or compound A maintained but did not enhance it. These findings support further in vivo evaluation of CaO2-based FAD strategies for practical CH_4 mitigation in ruminant diets.

Effects of garlic extract-attapulgite hybrid mixture on performance and enteric methane production in Hanwoo steers

R. Bharanidharan[1], A. A. K. Nirmal Athauda[1], S. H. Beak[2], J. Lee[3], H. K. Kim[2], A. Jo[2], K. H. Kim[1]
[1] Institutes of Green Bio Science and Technology, Seoul National University, 1447 Pyeongchang-daero, Daehwa-myeon, 25354 Pyeongchang-gun, South Korea, [2] Gaia Bio Co., Ltd., 823, Dongtansunhwan-daero, 18471 Hwaseong-si, South Korea, [3] College of Agriculture and Life Sciences, Seoul National University, 1 Gwanak-ro, Gwanak-gu, 08826 Seoul, South Korea

In vivo evaluation of methane (CH_4)-reducing feed additives is essential for the practical implementation of effective enteric CH_4 mitigation strategies in Korea. An in vivo trial was conducted using twelve Hanwoo steers (395 ± 9 kg), randomly allocated to three groups of four animals each. Steers were fed a commercial concentrate and rice straw hay (65:35) either without supplementation (CON) or supplemented with an additive containing garlic extract-attapulgite hybrid mixture (GAA) at 1.0% of dry matter intake (DMI) for 52 days in a completely randomized design. Animals were adapted to the experimental diets for 43 days in pens, followed by a 4-day adaptation period in open-circuit whole-body respiratory chambers (RC). Methane production was subsequently measured for 3 consecutive days using the RC system, and rumen fluid samples were collected on the final day of the trial. Supplementation with GAA reduced ($p < 0.05$) CH_4 production by 11.3% (140.4 vs. 124.5 g/d) and CH_4 yield by 8.2% (20.2 vs. 18.6 g/kg DMI) compared with CON. No negative effects of GAA supplementation on feed intake or animal performance were observed. Ruminal pH, ammonia concentration, and total volatile fatty acid concentration were not affected by treatment ($p > 0.05$); however, GAA supplementation tended to decrease ($p = 0.084$) isovalerate proportion. Overall, GAA supplementation reduced enteric CH_4 emissions without adversely affecting animal performance. Further long-term studies are warranted to evaluate the persistency of its CH_4-mitigating effects.

Effects of low levels of nitrate supplementation on milk and methane production in lactating dairy cows

Y. Roman-Garcia[1], L. Dicks[2], P. Piantoni[1], G. Schroeder[1]
[1] Cargill Animal Nutrition and Health, Innovation Center, 10383 165th Ave NW, 55330 Elk River MN, United States, [2] Cargill Animal Nutrition and Health, Innovation Center, Veilingweg 23, 5334 LD Velddriel, Netherlands

Supplementing nitrate is a well-recognized strategy to reduce enteric methane (CH4) emissions in dairy cows. Most of the previously published studies evaluated nitrate doses of 10 and 20 g/kg of DM, with very limited information available on the effects of lower inclusion levels on methane and performance. The objective of this experiment was to evaluate animal performance and methane production in lactating dairy cows when supplementing diets with lower than the typically studied doses of nitrate. Twelve Holstein cows (averaging 40.2 ± 19.0 kg/d in milk; and 143 ± 89 DIM; mean ± SD) were used in a 4 x 4 Latin square design experiment with four periods of 28 days each (21 d for adaptation and 7 d for data collection). Cows were individually fed a corn silage and alfalfa haylage-based TMR (58% forage, 16.6% CP, 30.5% NDF, 25.2% starch, and 2.6% fat DM basis). Treatments were: 0 (CON), 2.5 (2.5NIT), 5 (5NIT), and 7.5 (7.5NIT) g/kg of DM as nitrate (calcium ammonium nitrate, SilvAirTM, Cargill Inc.). Nitrate replaced urea and calcium carbonate to maintain N and Ca similar among dietary treatments. Gas production was measured using the GreenFeed system (C-Lock Inc.). Each cow was brought to the GreenFeed eight times over three days. The visits were spaced nine hours apart, resulting in eight samples per cow in each period, distributed every three hours throughout the day. Data were analyzed with the lmer package in R with a model that contained the fixed effect of diet and the random effects of period, square, and experimental unit. For repeated measurements throughout the day, treatment, time, and their interaction were also included in the model. Contrasts were used to evaluate the linear and quadratic effects of nitrate dose as well as the overall effect of nitrate. Means in the subsequent text are reported in the following order: CON, 2.5NIT, 5NIT, and 7.5NIT. There was no significant treatment by time interaction for any of the gas measurements. Increasing nitrate supplementation in isonitrogenous diets decreased ($P < 0.01$) methane production linearly (455, 414, 411, and 369 g/d; SEM = 39) with a reduction of -9.02, -9.74, and 18.9% from CON. Production of H2 increased linearly ($P < 0.01$) by 48.7, 70.9, and, 125% compared with CON. Nitrate supplementation linearly ($P < 0.05$) decreased methane yield (17.1, 15.8, 15.8, and 14.1 g of CH4/kg DMI; SEM = 1.0) and methane intensity (10.8, 10.2, 10.0, and 9.22 g of CH4/kg energy-corrected milk; SEM = 0.62). Dry matter intake linearly decreased ($P = 0.01$) when urea was replaced by nitrate (26.5, 25.9, 25.5, and 24.3 kg/d; SEM = 2.1). However, nitrate supplementation did not affect ($P = 0.87$) milk yield (36.8 ± 2.7) and therefore, nitrate supplementation tended to increase ($P = 0.06$) feed efficiency linearly (1.42, 1.43, 1.47, and 1.45; SEM = 0.08) Nitrate supplementation linearly decreased ($P < 0.05$) milk fat content (4.26, 4.16, 4.11, and 4.06%; SEM = 0.18) and milk protein content (3.49, 3.43, 3.43, and 3.42%; SEM = 0.15) and tended to decrease ($P = 0.08$) milk fat yield (1.56, 1.50, 1.50, and 1.45 kg/d; SEM = 0.09) but did not affect milk protein yield (1.26 ± 0.10 kg/d). Treatments did not affect energy-corrected milk yield (41.2 ± 2.84 kg/d). Overall, this study enhances the evidence that nitrate doses of 2.5, 5, and 7.5 g/kg of DM are effective in reducing methane production, yield, and intensity in lactating dairy cows. These results will help to select the most appropriate dose, aligning methane-reduction targets with the economic context of diverse milk production systems.

Mitigation of methane emissions and modulation of rumen microbiome by Asparagopsis-based feed additives in Hanwoo steers

M. Miguel[1], M. N. Aprilliza Am[1], A. R. Son[1], S. H. Kim[1], Y. P. Naing[1], K. S. Baik[1], K. S. Dhia[1], S. Begum[1], Y. I. Cho[1], K. W. Park[1], T. Park[2], D. Lawson[3], S. S. Lee[1]

[1] Sunchon National University, Department of Animal Science and Technology, 255 Jungang-ro, 57922 Suncheon, South Korea, [2] Chung-Ang University, Department of Animal Science and Technology, 4726 Seodong-daero, Daedeok-myeon, 17546 Anseong, South Korea, [3] CH4 Global, Inc., 1199 MacDonald Ranch Drive, 89012 Henderson, United States

Asparagopsis, a red seaweed rich in bromoform, has shown strong methane-reducing potential in ruminants, yet its application in Hanwoo cattle remains underexplored. Therefore, this study evaluated the effects of an Asparagopsis-based feed additive on methane (CH4) emissions, rumen microbial composition, and functional profiles in Hanwoo steers. Twelve Hanwoo steers (625.92 ± 64.14 kg and approximately 21 months old) were used in a replicated 3 × 3 Latin square design with 3 treatments and 3 periods of 21 days. Steers received a basal diet (9.6 kg of commercial concentrate feed and 2.4 kg of forage) with one of three additives: no additive (CON), 0.5% Asparagopsis-based feed additive (AS; CH4 Global, Inc.) containing 4 mg bromoform/g dry matter (DM) (AS4), or 0.5% AS additive containing 7 mg bromoform/g DM (AS7). Enteric CH4 emissions were measured using the GreenFeed system. Methane emission was expressed as CH4 production (g/d), yield (g/kg DMI), and intensity (g/kg $BW_{0.75}$). Shotgun metagenomic sequencing was employed to characterize the microbial composition and functional profile of the rumen microbiome. Results showed that Asparagopsis supplementation markedly reduced CH4 emissions. Specifically, steers supplemented with AS4 and AS7 produced 37.25% and 45.88% less CH4, respectively, than the CON group ($p < 0.001$). Moreover, CH4 yield decreased by 38.06% and 44.78% ($p < 0.001$), while CH4 intensity was reduced by 36.76% and 44.85%, in the AS4 and AS7 groups, respectively ($p < 0.01$). Shotgun metagenomic sequencing revealed a total of 23 phyla, 42 classes, 87 orders, 173 families, and 410 microbial genera in the rumen samples. The bacterial phyla Bacteroidetes and Bacillota, along with the archaeal phylum Methanobacteriota, were the most abundant taxa observed. Prevotella was the dominant bacterial genus, showing a higher relative abundance in the rumen of steers from the AS4 group. Methanobrevibacter was the predominant methanogenic genus, accounting for approximately 13% of the rumen metagenome, and its relative abundance was significantly higher in steers supplemented with Asparagopsis-based feed additives. Six classes of carbohydrate-active enzymes (CAZymes), AA, CBM, CE, GH, GT, and PL, were identified in the metagenome, with GH and GT being the most abundant, accounting for approximately 85% of the total CAZymes. AS supplementation increased the abundance of GH13, GH3, GH31, CBM48, GH5, GT35, GH9, GH77, GT51, CE10, GH43, and GH95 compared to the CON group. Notably, GH3 and GH95 were enriched in the AS7 group, while CE10 levels were higher in both AS4 and AS7 ($p < 0.05$). KEGG pathway analysis revealed that the functions of the rumen microbiota were associated with carbohydrate, amino acid, energy, and nucleotide metabolism. The relative abundance of the CH4 metabolism pathway (ko00680) was lower in the AS4 group compared with the CON and AS7 groups. Overall, supplementation with Asparagopsis-based feed additives at 0.5% inclusion level effectively reduced CH4 emissions in Hanwoo steers by up to 45%. These reductions were accompanied by shifts toward higher Prevotella abundance and lower CH4 metabolism pathway activity. These findings highlight the potential of Asparagopsis as a practical CH4 mitigation strategy for Hanwoo production without compromising rumen microbial diversity or key functional profiles.

Seasonal variability in the response of enteric methane emissions to 3-nitrooxypropanol in dairy cattle

M. Omirou[1], K. Kaikiti[1], J. Rodosthenous[1], G. Hadjipavlou[2], D. Sparaggis[2]
[1] Agricultural Research Institute, Agrobiotechnology, P.O.Box 22016, 1516 Lefkosia, Cyprus, [2] Agricultural Research Institute, Animal Production, P.O.Box 22016, 1516 Lefkosia, Cyprus

Mitigation of enteric methane (CH_4) emissions through inhibition of ruminal methanogenesis is a promising strategy to reduce the climate footprint of ruminant production. This study evaluated the seasonal response of methane emissions, hydrogen dynamics and metabolic indicators to 3-nitrooxypropanol (3-NOP) in dairy cattle. Gas exchange was measured using GreenFeed systems (C-Lock) in 24 animals (Control n = 12; 3-NOP n = 12) during two experimental periods (winter and summer). Emissions of CH_4, CO_2, O_2 and H_2 were recorded and used to derive methane yield (Ym), respiratory quotient (RQ) and heat production (HP). During winter, 3-NOP significantly reduced methane emissions by 27.7% (465 vs 336 g CH_4 d^{-1}; p = 0.00022). Hydrogen emissions increased markedly (0.84 vs 2.85 g d^{-1}; +239%; $p < 10^{-128}$), while CO_2 (10.7 kg d^{-1}) and O_2 consumption (~7.7 kg d^{-1}) were not affected. Metabolic indicators remained stable, with RQ close to unity (1.01 vs 1.02; p = 0.53) and heat production approximately 27 Mcal d^{-1} (p = 0.75), indicating that overall metabolic rate and substrate oxidation were unchanged. Methane intensity metrics decreased significantly, including CH_4/CO_2 (p = 0.00085), CH_4/O_2 (p = 0.0013) and CH_4/heat production (p = 0.00116). Methane yield (Ym) declined from ~7.1% to ~5.1% of gross energy intake, representing an approximate 28% mitigation. In contrast, during summer, methane emissions were higher in the 3-NOP group (367 vs 283 g CH_4 d^{-1}; +30%; p = 0.0037) and hydrogen emissions also increased (0.997 vs 1.43 g d^{-1}; $p = 3.1 \times 10^{-8}$). Methane intensity indicators, including CH_4/CO_2, CH_4/heat production and Ym, were also higher in the treated animals. Metabolic indicators showed a different pattern compared with winter, with lower heat production (p = 0.00052) and higher respiratory quotient (p = 0.00022), suggesting a shift toward carbohydrate-derived fermentation pathways. Methane production remained strongly coupled with CO_2 emissions ($R^2 = 0.77$; p = 0.005), indicating that methanogenesis continued to function as the dominant hydrogen sink. Hydrogen balance calculations further highlighted the seasonal contrast. In winter, methane reduction (−129 g CH_4 d^{-1}) corresponded to approximately 65 g H_2 equivalents, of which only ~3.1% appeared as molecular hydrogen while ~96.9% were redirected to alternative metabolic pathways. In summer, the additional hydrogen produced was almost entirely captured by methanogenesis, with only ~1% emitted as H2 gas. Overall, the study demonstrates effective methane inhibition by 3-NOP during winter without changes in host metabolic rate, whereas the summer period showed higher methane production and increased methane intensity, suggesting a potential seasonal modulation of rumen hydrogen metabolism. Because this response contrasts with the expected inhibitory effect of 3-NOP, additional summer measurements are required to confirm the observed seasonal pattern and identify the underlying mechanisms regulating hydrogen partitioning in the rumen.

Bovaer separation by feed particle size at two inclusion doses in dairy cows mixed rations

G. Giagnoni[1], M. Maigaard[1], C. Ohlsson[2], N. Walker[2], M. B. Jensen[1], M. R. Weisbjerg[1], P. Lund[1], G. A. Franchi[1]
[1] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Alle 20, 8830 Tjele, Denmark, [2] dsm-firmenich, Animal Nutrition & Health, postbox 2676, 4002 Basel, Switzerland

The additive Bovaer can be used to reduce enteric methane from cattle at a dose of min. 60 mg 3-nitrooxypropanol (3-NOP) per kg DM. This study investigated whether Bovaer can separate by feed particle size, which might result in sorting for or against the additive when the mixed ration is fed. During a trial two partial mixed rations (PMR) with either 62 or 93 mg 3-NOP/kg of DM were fed to lactating dairy cows (60BOV and 90BOV, respectively). The PMR were formulated at 54:46 forage to concentrate ratio (on DM basis) and included maize silage (70% DM of forage), grass-clover silage, barley, rapeseed cake, dried beet pulp (crushed pellets), and ingredients for micronutrients. Samples of the PMR were taken on Tuesdays on week 3, 6, and 9 during the trial. On each day, the samples were mixed and further split in 3 sub-samples. Each sub-sample was processed in a Penn State Particle Separator (PSPS) with sieves of 19, 8, and 1.18 mm, where each sub-sample had its own run in the PSPS. The PSPS was mounted on a rotary shaker set at 200 rpm for 20 s. In each run, the weight of the sub-sample before sieving and then for each sieve fraction were recorded. The fractions obtained by the PSPS were pooled between the 3 runs by sieve and Bovaer dose. Then, the pooled sample was split in 2 and used for DM analysis in a forced air oven at 60°C or transferred to a 500 mL HDPE container, and frozen for shipment and analysis of 3-NOP by high performance liquid chromatography. The average weight fraction of the original feed samples recovered in each sieve were calculated. Statistical analyses were performed in R using GLMMs. The first model tested the difference in DM concentration (DM%) between fractions, with DM% by particle size as a dependent variable, particle size as fixed effect, and week as random effect. One outlier was dropped from this model. The second model tested the difference in 3-NOP concentration by particle size, and it was similar to the previous model, but it included the additional effect of 3-NOP dose (60BOV or 90BOV), and its interaction with the particle size. The particle size effect consisted of 4 levels: >19 mm, ≤19 and >8 mm, ≤8 and >1.18 mm, and ≤1.18 mm. Across the 3 weeks, the average fresh weight of the starting feed sample for a single run in the PSPS was 693±62.1 g for 60BOV and 728±60.8 for 90BOV. The DM concentration was 38.8, 40.0, 44.5, 46.6% from largest to smallest particles size, with max SEM of 1.28%. The 3-NOP concentration in DM was unaffected by the feed particle size and no interaction was found between particle size and 3-NOP concentration. The concentration of 3-NOP was different between the 2 treatments ($P<0.001$) with estimated means and SEM of 57.2±10.3 (60BOV) and 84.9±15.3 (90BOV) mg 3-NOP/kg DM. The SEM based CV for 3-NOP concentration was over 15%, against the SEM based CV for DM% below 5%. The estimated means concentration of 3-NOP was 58.8, 57.6, 55.1, and 57.6 mg 3-NOP/kg DM for 60BOV, and 84.8, 73.8, 83.2, and 99.7 mg 3-NOP/kg DM for 90BOV. Overall, the distribution of 3-NOP between particle size was homogeneous. Also, the numeric difference in 3-NOP concentration between particle sizes at 60 mg 3-NOP/kg DM, which is the legally allowed minimum dose in the EU, was negligible. In conclusion, no differences in concentration of 3-NOP in different particle size fractions of a mixed ration were found when 3-NOP was dosed at either 63 or 92 mg 3-NOP/kg DM, indicating that the risk for animal variation in 3-NOP uptake due to sorting is minor.

In vitro evaluation of the effect of plant extracts on methane production and fiber degradation in a rumen ecosystem

G. Desrousseaux[1], V. Noirot[1], A. Froidurot[2], P. Grimm[2], S. Julliand[2]
[1] Phodé, ZI Albipôle, 81150 Terssac, France, [2] Lab To Field, 26 bd Petitjean, 21000 Dijon, France

Methane (CH4) emitted by ruminants is the main cause of greenhouse gas emissions from livestock farming. Methanogenesis by Archaea depends on H2 and CO_2 production by rumen microbiota, which is intricately linked to the degradation of plant fibers in the rumen. Reducing methanogenesis without impairing fibrolysis is crucial to maintain production and health of cattle. A growing body of evidence suggests that certain plant extracts (PE) can modulate rumen fermentation and mitigate enteric CH_4 emissions (Arndt et al, 2022). The first objective of this in vitro trial was to compare the effects of 2 new mustard extracts (ME) differing in composition to other plant extracts documented to alter CH_4 production in the bovine rumen ecosystem at the tested concentrations (Honan et al. 2020). The second objective was to evaluate the impact of these treatments on fiber disappearance. Rumen fluid was collected from three lactating cows fed a total mixed diet based on corn silage, soybean meal, linseed meal, barley, wheat, hay and minerals. 200 ml bottles were prepared under anaerobic conditions, with 90 ml of culture medium, 10 ml of rumen juice as inoculum, 2 g DM of substrate and one of the tested PE, or no product for control. The substrate was the diet of donor cows. All bottles were incubated in a water bath stirred at 39°C for 24 hours. Each treatment was tested in a triplicate. Gas production and composition were measured every 6 hours. Fiber disappearance (dFiber) and VFA production were measured after 24h fermentation from a pool of the triplicates. An analysis of variance (Mixed procedure, SAS) was used to evaluate the effect of PE. LS-Means were compared using the Tukey-Kramer method. The significance threshold was set at $p<0.05$. The highest CH_4 yield was measured for the control bottles without PE (Table 1). All the treatments containing PE significantly reduced gas and CH_4 production. Depending on the PE, disappearance of fibers and VFA production were numerically reduced to varying degrees. Calculating the volume of CH_4 produced per unit of fiber lost made the selection of the most promising treatments, i.e. those that did not inhibit fiber digestion and reduced CH_4 yield per g dFiber compared to the control. Among those, the treatment ME_1 50 ppm seemed the most favorable: while dFiber and VFA production were reduced by 18% and 25% respectively, CH_4 yield was decreased by 62%, suggesting a favorable shift in fermentations to mitigate CH4 emissions. This study confirmed the potential of PE to mitigate CH_4 emissions. Based on this approach combining measurements, the effect on fiber fermentation and methanogenesis appeared to vary deeply depending on the PE and the doses used. The treatments reducing CH_4 production more than fiber digestion could be selected for further tests.

Table 1: Fermentation modulation with plant extracts

Treatments	Total Gas_24h (ml)	CH4_24h (ml)	Total VFA (mmol/L)	dFiber (%)	CH4/g digested fiber (ml/g)	SEM
Mustard extract_2, 250 ppm	144.9e	0.0e	23.1	0.0	0.0	0.06

Metabolomic Profiling of Dairy Cows During the Transition Period: Associations with Reproductive Outcome

L. Zambianchi[1], E. Schievano[2], G. Campion[2], E. Giaretta[3], I. Fusaro[4], B. Merlo[1], R. Colleluori[1], A. Formigoni[1], L. Mammi[1]

[1] University of Bologna, Veterinary Medical Sciences, Via Tolara di Sopra 50, 40064 Ozzano Emilia, Italy, [2] University of Padova, Chemical Sciences, Via Marzolo 1, 35131 Padova, Italy, [3] University of Padova, Comparative Biomedicine and Food Science, Via Roma 34, 35020 Legnaro, Italy, [4] University of Teramo, Veterinary Medicine, Via Balzarini 1, 64100 Teramo, Italy

Improving reproductive efficiency in dairy cows remains a major challenge for the sustainability and profitability of modern dairy farming. The identification of behavioural patterns or physiological alterations associated with fertility loss could enable a more precise management of reproduction at the individual animal level. Aim of the present study is to identify metabolomic parameters that can explain subfertilty in dairy cows and to evaluate metabolic variations across key physiological stages of the transition period, in order to explain fertility variability among cows and support a more targeted reproductive management. The trial was conducted in two medium-sized commercial dairy farms where 137 multiparous Holstein cows were monitored from dry-off until the second artificial insemination (AI). Animals enrolled were managed using two different reproductive strategies: half underwent a Double-Ovsynch synchronization protocol and the other half were inseminated following a precision-based strategy relyng on natural heat detection through AMS. Metabolomic analyses were performed by retrospectively classifying animals according to reproductive outcome. Based on pregnancy diagnosis, cows were divided into Fertile (pregnant within the study period, n=63) and Subfertile (two consecutive negative pregnancy diagnoses, n=74) groups. For metabolomic analyses, blood samples were collected from the coccygeal vein into tubes without anticoagulant at 21 days pre-partum, 10 and 35 days post-partum, at 1°AI and at the eventual 2°AI. Samples were centrifuged at 3000 rpm for 15 minutes to obtain serum, which was stored at -80°C until analysis. Serum metabolomic profiling was performed using a $_1$H-NMR based approach. Low molecular weight metabolites were separated by ultrafiltration (3 kDa cut-off) to remove proteins and macromolecules; spectra were acquired at 600 MHz using a CPMG pulse sequence. After manual phase, spectra were binned and normalized to generate a data matrix for statistical analysis. Multivariate analyses were performed in SIMCA to explore metabolic differences between Fertile and Subfertile groups and across timepoints. Spectral regions contributing most to group separation were assigned to specific metabolites using Chenomx software, and metabolite identification was confirmed by 2D NMR (TOCSY). Based on the results, a targeted analysis of selected metabolites was conducted to improve biological interpretation of the metabolic changes observed. Multivariate models did not show a statistically significant metabolic discrimination between Fertile and Subfertile cows ($p>0.05$). Conversely, a consistent metabolic shift was observed across timepoints, particularly between late gestation (-21) and early lactation (+10, +35). The separation between pre- and post-partum samples reflects the metabolic imbalance that characterizes the transition period in dairy cows. Inter-individual biological variability and spectral complexity likely contributed to the limited separation between reproductive outcome groups. These findings suggest that reproductive failure may not be defined by a single metabolic signature, but future investigations focusing on key metabolic pathways could help differentiate between fertile and subfertile cows. Funded by European Union, Next Generation EU.

Lipidomic profile of dairy cows across key reproductive timepoints and association with fertility outcomes

P. Prasinou[1], V. Di Giandomenico[1], L. Zambianchi[2], H. Jalal[1], E. Giaretta[3], B. Merlo[2], M. Giammarco[1], L. M. E. Mammi[2], I. Fusaro[1]
[1] University of Teramo, Department of Veterinary Medicine, Loc. Piano D'Accio snc, 64100 Teramo (TE), Italy, [2] University of Bologna, Department of Veterinary Medical Sciences, Via Tolara di Sopra 50, 40064 Ozzano dell'Emilia (BO), Italy, [3] University of Padova, Department of Comparative Biomedicine and Food Science, Viale dell'Università 16, 35020 LEGNARO (PD), Italy

Improving reproductive efficiency in dairy cows is essential for the sustainability and profitability of modern dairy farming. Metabolic adaptations occurring around calving and during early lactation may influence reproductive performance and contribute to variability in fertility among animals. Lipidomic profiling provides a useful approach to investigate physiological changes in lipid metabolism associated with reproductive success. The aim of this study was to describe the lipidomic profile of dairy cows across key reproductive timepoints and to evaluate potential differences between cows with different fertility outcomes. The trial was conducted in two medium-sized dairy farms where 137 multiparous Holstein cows were monitored from dry-off until the second artificial insemination (AI). Blood samples for lipidomic analysis were collected at −21 days before calving, 10 and 35 days in milk (DIM), and at first AI. From each blood sample the membranes of the erythrocytes were isolated and by Gas-Chromatography a group of 10 FAs consisting of 2 saturated FA (SFA: stearic, palmitic), 3 mono-unsaturated FA (MUFA: palmitoleic, oleic, vaccenic), 3 polyunsaturated FA ω-6 (PUFA-ω6: linoleic, dihomo-gamma-linolenic [DGLA], arachidonic[ARA]) and 2 PUFA ω-3 (eicosapentaenoic [EPA], docosahexaenoic [DHA]) was determined, along with additional lipid parameters (SFA/MUFA, SFA/PUFA, ω6/ω3, PUFA balance, unsaturation [UI] and peroxidation [PI] indexes). Cows were retrospectively classified according to reproductive outcome as pregnant at first insemination (F1) or not pregnant after two inseminations (NF2). Fatty acid composition and lipid indices were compared between fertility groups at each sampling timepoint. Statistical analyses were performed using RStudio (version 2023.12.1). Overall, most lipid variables were similar between F1 and NF2 cows across the evaluated timepoints. However, a significantly higher concentration of vaccenic acid (18:1 11c) was observed in NF2 cows compared with F1 cows at 10 DIM ($P < 0.05$). Conversely, docosahexaenoic acid (DHA) levels at the time of first AI were significantly higher in F1 cows than in NF2 cows ($P < 0.05$). No other significant differences were detected between fertility groups for the remaining fatty acids or lipid indices at the investigated timepoints. These findings indicate that the overall erythrocyte membrane lipidomic profile was largely comparable between cows with different fertility outcomes. Nevertheless, specific fatty acids, particularly vaccenic acid in early lactation and DHA at the time of insemination, may reflect subtle metabolic differences associated with reproductive success. Further studies are warranted to clarify the potential role of these lipid biomarkers in supporting reproductive efficiency in dairy cows.

Tail hair $\delta^{15}N$ identifies cows with lower calf loss and greater liveweight production in extensive beef systems

L. Prada E Silva[1], K. Eyre[1], K. Mccosker[1], G. Somerset[1]
[1] The University of Queensland, 306 Carmody Road, 4072 Brisbane, Australia

Low protein availability constrains productivity in extensive beef systems. When cattle consume the same diet, the natural abundance of the stable isotope ^{15}N in tail hair ($\delta^{15}N$) reflects nitrogen retention relative to excretion and provides an integrated indicator of nitrogen use efficiency, with lower $\delta^{15}N$ values associated with reduced urinary nitrogen loss. This study evaluated whether $\delta^{15}N$ measured early in the production year could identify cows and heifers with lower calf loss risk and higher liveweight production under protein-limited grazing conditions. Tail hair samples were collected from 4,573 cows and heifers across eight properties in 2022/23 and 12 properties in 2023/24. Tail hair $\delta^{15}N$ was quantified using an IsoPrime100 isotope-ratio mass spectrometer, with values expressed relative to the AIR international standard. Reproductive and productivity outcomes included calf survival to weaning, total reconception, pregnancy within four months post-partum, calf weaning weight, and annual liveweight production. Associations between $\delta^{15}N$ and performance outcomes were analysed using generalised linear mixed models for binary traits and linear mixed models for continuous traits, with $\delta^{15}N$ fitted as a fixed effect and property included as a random effect to account for environmental heterogeneity. Cows with lower $\delta^{15}N$ values had a significantly lower risk of calf loss ($P < 0.01$). Across the observed $\delta^{15}N$ range (approximately 4–12‰), the predicted probability of calf loss declined markedly. Although individual properties spanned narrower $\delta^{15}N$ ranges (typically 2–3‰), the association was consistent across herds. Each 1‰ decrease in $\delta^{15}N$ reduced the odds of calf loss by approximately 23%. Lower $\delta^{15}N$ values were also associated with higher calf weaning weight ($P < 0.01$), with a significant interaction with calf sex ($P = 0.01$). For every 1‰ reduction in $\delta^{15}N$, weaning weight increased by 2.5 kg in male calves and 4.2 kg in female calves. Annual liveweight production (calf weaning weight plus maternal liveweight change) increased by 9.6 kg per cow per 1‰ reduction in $\delta^{15}N$ ($P < 0.01$), and this effect did not differ between sexes. No association was detected between $\delta^{15}N$ and either reconception or pregnancy within four months post-partum ($P > 0.10$). This study provides the first large-scale evidence that $\delta^{15}N$ in tail hair is associated with calf survival and total cow–calf liveweight production in extensive beef systems. Lower $\delta^{15}N$ values likely reflect greater urea recycling to the rumen and reduced urinary nitrogen excretion, enabling increased retention of absorbed nitrogen for maternal maintenance and milk production. These findings position $\delta^{15}N$ as a practical phenotypic indicator of nitrogen efficiency with implications for both productivity and nitrogen-loss mitigation in grazing systems.

Serum microRNA Signatures Associated with Clinical and Subclinical Endometritis in Dairy Cows

S. Kreuzer-Redmer[1], L. Neubrand[2], H. Pothmann[2], M. Drillich[2,3], K. Wagener[2]
[1] University of Veterinary Medicine Vienna, Centre for Animal Nutrition and Welfare, Veterinärplatz 1, 1210 Vienna, Austria, [2] University of Veterinary Medicine Vienna, Clinical Centre for Ruminants, Camelids and Herd Health Management, Veterinärplatz 1, 1210 Vienna, Austria, [3] Freie Universität Berlin, Unit for Reproduction Medicine and Udder Health, Faculty of Veterinary Medicine, Königsweg 65, 14163 Berlin, Germany

Endometritis remains a major cause of subfertility and economic loss in dairy production, yet reliable biomarkers for early and specific diagnosis are still lacking. Circulating microRNAs (miRNAs) are attractive candidates due to their regulatory roles in inflammation, immunity, and tissue repair, and their stability in serum. This study aimed to identify serum miRNA signatures associated with clinical (CE) and subclinical (SE) endometritis at different postpartum stages, providing both mechanistic and diagnostic insights. Dairy cows were enrolled on the day of calving. At day 28 postpartum (pp), cows underwent a gynecological examination including vaginoscopy. Cows showing pus in the vaginal discharge were diagnosed with CE. Cytobrush samples were collected from cows with clear vaginal discharge to assess the proportion of polymorphonuclear neutrophils (PMN). Animals with ≥5% PMN were classified as having SE, while cows with <5% PMN were considered healthy (HE). In total, 18 cows were included (n = 6 per category: CE, SE, HE) in this study. Individual blood samples were collected longitudinally at 14, 28, and 56 days resulting in 18 serum samples per group (54 total) for global miRNA profiling, followed by Venn analyses to identify shared and unique expression patterns across groups and time points. Key miRNAs were assessed for their relevance to inflammation and epithelial repair. Distinct and time-dependent miRNA patterns were observed. At day 14 pp, 252 miRNAs were shared among all groups, whereas 30, 31, and 37 were unique to CE, SE, and HE, respectively. CE and SE shared 45 miRNAs not detected in HE, indicating early inflammatory overlap. Similar patterns persisted at day 28 pp (232 shared; 64 CE–SE overlap) and day 56 pp (225 shared; 33 CE–SE overlap). Across all time points, 293 miRNAs were consistently detected, representing a stable circulating core. Several miRNAs displayed dynamic, condition-specific profiles. Bta-miR-21-3p shifted from being CE & SE-shared at day 14 pp to SE-unique at day 28 pp and CE-unique at day 56 pp, suggesting a role in inflammatory activation and later tissue remodeling. Bta-miR-141 remained SE-unique across all time points, consistent with involvement in epithelial repair and barrier integrity. Bta-let-7a-3p was shared early but became CE-unique late postpartum, possibly reflecting persistent inflammatory processes. In contrast, bta-miR-146a/b, bta-miR-155, and bta-miR-223 were shared among all groups, indicating general immune regulation rather than disease specificity. Serum miRNA profiling revealed stable and disease-specific expression patterns that reflect the transition from inflammation to recovery in postpartum cows. Early overlap between CE and SE suggests common inflammatory origins, while later divergence indicates distinct regulatory pathways. Among the identified miRNAs, miR-21-3p and miR-141 emerge as promising biomarkers combining diagnostic potential with mechanistic relevance, supporting their inclusion in multi-miRNA panels for early, stage-specific detection of endometritis.

Selection for Developmental Speed Skews Sex Ratios and Molecular Profiles in Bovine IVP Embryos

V. S. Baddela[1], T. Fersterer[1], R. Pöhland[1], F. D. A. M. Sterza[3], C. Ludwig[1], D. Becker[1], C. Kühn[2], J. Vanselow[1]
[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [2] Federal Research Institute for Animal Health (FLI), Südufer 10, 17493 Greifswald - Insel Riems, Germany, [3] State University of Mato Grosso do Sul, Animal Science, 79200-000 Aquidauana, Brazil

The developmental pace of in vitro produced preimplantation embryos is widely used to select candidates for transfer, yet the molecular profiles captured by fast versus slow development and the potential impact of this selection on embryo physiology and sex ratio remain largely unclear. Here, we investigated whether bovine IVP blastocysts that hatch on Day 7 versus Day 8 differ in transcriptomic and metabolic features, and whether this selection window alters the sex ratio. Hatched blastocysts collected on Day 7 and Day 8 were profiled by RNA sequencing and complemented with measurements of lipid accumulation, mitochondrial activity and reactive oxygen species (ROS). Embryo sex was determined by Y-chromosome multiplex PCR, and selected transcripts were validated by qPCR in individually sexed embryos. RNA-seq revealed 256 differentially expressed genes (DEGs) between Day 7 and Day 8 hatched blastocysts. Among these, 79 transcripts showed higher and 177 showed lower abundance in fast developing embryos (Day 7) relative to slower developing embryos (Day 8). Notably, Day 8 blastocysts showed higher expression of so-called pregnancy recognition factors (IFNT2, IFNT3) and the trophoblast marker TKDP1, as well as genes associated with glycolysis, lipid transport, and endoplasmic reticulum stress. In contrast, Day 7 blastocysts displayed upregulation of a number of genes involved in oxidative phosphorylation. Consistently, Ingenuity Pathway Analysis identified Oxidative Phosphorylation, Estrogen Receptor Signaling, and IL-12 Signaling as highly upregulated canonical pathways in fast-developing embryos, whereas Unfolded Protein Response, Glycolysis I, Endoplasmic Reticulum Stress, and Sirtuin Signaling were upregulated in Day 8 embryos. Despite these transcriptomic differences, mitochondrial membrane potential and ROS levels were not significantly different between groups, whereas Day 7 hatched embryos contained significantly greater neutral lipid accumulation. Sexing analysis demonstrated a male-biased sex ratio among hatched embryos on Day 7 (66.7%) and Day 8 (58.5%), whereas embryos hatching on Day 9 did not show a significant male skew. qPCR validation identified sex dependent regulation of UQCRC2 and hatching day dependent regulation of ENO1, UQCRC2, HSP90B1, and APOA1, highlighting interactions between sex and developmental timing in pathways linked to energy metabolism and stress responses. Together, these data show that Day 7 and Day 8 hatched bovine IVP blastocysts represent separable molecular and metabolic states. Importantly, embryo selection based on rapid development can inadvertently shift both the sex ratio and the underlying molecular profile of transferred embryos, with potential consequences for pregnancy establishment and herd replacement strategies.

Extender-Specific Lipidomic Signatures in Buck Semen

R. Murray[1], M. Hitit[1], M. Bodu[1,2], O. Greenwood[1], Z. Erdogan[1], S. Woldesenbet[1], M. R. Ugur[3], A. P. Cervantes[1], E. Memili[1]

[1] Prairie View A&M University, College of Agriculture, Food and Natural Resources, Prairie View, TX, 77446 Prairie View, United States, [2] Selçuk University, Faculty of Veterinary Medicine, Department of Reproduction and Artificial Insemination, Konya, 42100 Konya, Turkey, [3] IVF Michigan Fertility Centers, 37000 Woodward Ave #350, 48304 Bloomfield Hills, MI, United States

Semen extenders play a central role in artificial insemination and sperm cryopreservation by providing structural protection and metabolic support to sperm cells. Sperm lipid composition is a critical determinant of membrane functionality, influencing capacitation, acrosomal stability, resistance to oxidative stress, and cryosurvival. The objective of this study was to compare the lipidomic profiles of different semen extenders used in buck semen cryopreservation. Sperm samples (n=10, bucks) were diluted with plant (AndroMed® and Bovifree) and animal (Oviplus, Steridyl, and Triadyl) based extenders. Following a 4h equilibration at +4 °C, samples with total motility above 70% were cryopreserved, cooled from +5 °C to liquid nitrogen vapours -100 °C for 15 min, and stored in liquid nitrogen until post-thaw evaluation. Sperm samples containing 200 × 106 sperm/mL were washed by centrifugation at 2500× g at 4 °C for 10 min. Then, supernatant (extender and seminal plasma) was discarded. Lipids were extracted using a chloroform–methanol (2:1) solution and dried lipids were stored at −20 °C until further analysis. Gas chromatography–mass spectrometry analysis was conducted using an Agilent 7890A GC System coupled to an Agilent 5975C inert XL MSD with the triple-axis mass detector. Principal Component Analysis (PCA) revealed a clear separation among semen extenders based on their lipid composition. The first principal component (PC1) accounted for 90.3% of the total variance, while the second principal component (PC2) explained 4.6%. Along PC1, plant-based extenders clustered together on the negative axis, whereas animal-based extenders clustered on the positive axis. We identified a total of 33 fatty acids across all semen extenders. Among these, eleven fatty acids, C14:1, C14:0, C15:0, C16:1, C16:0, C17:0, C18:2, C18:1 (cis-9), C18:0, C20:4, and C22:6 showed significant differences among the extenders ($p < 0.05$). In contrast, C22:0 did not differ significantly between extenders ($p > 0.05$). The findings indicate that semen extenders with different formulations are associated with distinct fatty acid profiles and differences may be considered when selecting extender formulations for semen processing and cryopreservation. Keywords: Sperm, buck, lipidomics, fatty acid, cryopreservation

Reproductive performance as a pillar of pig production: interaction between parity and barn environmental parameters

C. Cintra Rodrigues[1], I. Bez[1], C. Sevillano[2], M. Lopes[2], S. Weber[1], L. Costa[1]
[1] MonoHub – Research Group for Monogastric Animals; Graduate Program of Animal Science – Pontifícia Universidade Católica do Paraná, Rua Imaculada Conceição, 1155, 80215-901 Curitiba, Brazil, [2] Topigs Norsvin Research Center B.V, Meerendonkweg 25, 5216 TZ 's-Hertogenbosch, Netherlands

Seasonal infertility compromises reproductive efficiency in pig production by increasing biological losses and reducing the sustainability and profitability of livestock systems. Developing more adaptive production systems and sows requires understanding how environmental factors interact with reproductive performance under different climatic conditions. This study evaluated the associations between in-barn heat load (HL) and light variability (L) with the reproductive outcomes farrowing success (FS) and litter size (LS) in purebred Large White sows raised in Brazil under contrasting subtropical and tropical production systems. We hypothesized that higher HL and greater light variability could affect FS and LS, with effects differing according to farm location and climate. Reproductive records from 2021 were retrospectively analyzed from two commercial Brazilian farms: a subtropical system in the southern region (Farm 1) and a tropical system in the central-west region (Farm 2). Temperature (°C) and photoperiod (lx) in gestation facilities were monitored using data loggers. Heat load was calculated using a plateau-linear function considering 25 °C as the upper critical temperature, while light variability was quantified as deviations from the expected daylight illuminance profile. Associations with FS and LS were evaluated using logistic and linear regression models, respectively. Results were expressed as odds ratios (OR) for FS and regression coefficients (β) for LS, with statistical significance ($P < 0.05$). Overall, environmental effects on reproductive performance were modest but varied according to production context. In the combined analysis of both farms, HL was not associated with FS ($P > 0.05$) but showed a modest positive association with LS ($\beta = 0.281$; $P = 0.031$). Light variability was not associated with either FS ($P = 0.836$) or LS ($P = 0.728$). A farm effect was observed for FS, with higher odds of success in Farm 2 compared with Farm 1 (OR = 1.724; $P = 0.029$), suggesting the influence of farm-specific factors such as housing design, environmental control, or management practices. In the farm-specific analyses, HL was not associated with FS or LS in Farm 1 (subtropical system) ($P > 0.05$). However, light variability was positively associated with LS ($\beta = 0.355$; $P = 0.014$), without affecting FS. In contrast, in Farm 2 (tropical system), light variability was negatively associated with both FS (OR = 0.72; $P = 0.028$) and LS ($\beta = -0.59$; $P = 0.020$), while HL remained unrelated to the outcomes. These results suggest that instability in light conditions may represent a relevant challenge for reproductive stability in this production context. In summary, the findings indicate that the reproductive impact of in-barn environmental conditions is system-dependent rather than uniform across climatic contexts. While heat load showed limited associations with reproductive outcomes, light variability emerged as a relevant factor, particularly under tropical conditions. The differences observed between farms highlight that environmental stressors operate within the context of baseline climate and production structure, emphasizing the importance of farm-specific environmental monitoring and control strategies to improve reproductive efficiency.

Effect of dietary quercetin and genetic line in rabbit semi-intensive production system

D. Jordán-Rodríguez[1], J. Fernández-González[2], A. Vicente-Carrillo[2], P. L. Lorenzo[1], P. G. Rebollar[3], R. M. García-García[1], M. Arias-Álvarez[2]

[1] Complutense University of Madrid, Physiology Dpt., Av. Puerta de Hierro s/n, 28040 Madrid, Spain, [2] Complutense University of Madrid, Animal Production Dpt., Av. Puerta de Hierro s/n, 28040 Madrid, Spain, [3] Technical University of Madrid, Agrarian Production Dpt., Senda del Rey 18, 28040 Madrid, Spain

Rabbit production is a sustainable livestock system due to its low environmental impact. The semi-intensive production system overlaps gestation and lactation, leading to negative energy balance and increased oxidative stress, which impairs reproductive performance and shortens lifespan, affecting productivity. Management strategies that improve circularity such as antioxidant supplementation with quercetin (Q) and the use of resilient genetic lines (GL) may help to optimise reproductive and productive efficiency. Does of two GL: V line (selected for litter size at weaning; group V) and LP line (selected for productive longevity, group LP) were fed a supplemented diet with 4g/kg Q (group Q) or not (group C) during rearing and the first four reproductive cycles under a semi-intensive system. Effect of Q and GL on body composition (BC) (fat and energy content), fertility, prolificacy and milk yield (MY) along cycles was evaluated. Results showed that Q did not affect BC, fertility, prolificacy or MY. LP line showed lower body fat and energy reserves compared with V line (fat:11.93±0.3 vs 10.94 ± 0.3%; p=0.03, and energy:982.18±13.9 vs 941.40±13.7kJ/100g; p=0.04, respectively), but higher MY (LP:5.6±0.1 vs V:5.2±0.1kg, p<0.01). LP does were able to maintain fertility in cycle 2 (55.5±7.5%). Similar number of liveborn kits was found between lines (LP:10.0±0.5 and V:10.6±0.5). The lowest BC was reached at first weaning (fat:7.6±0.4% and energy:769.46±21.4kJ/100g, p<0.0001), and the fertility decreased at second parturition (48.3±5.4%, p<0.001). Prolificacy and MY increased with the number of reproductive cycles (p<0.0001). In conclusion, Q had limited effects on the parameters studied. However, LP line demonstrated its functional robustness with better mobilization of reserves and higher milk production. Parity order affected reproductive performance, being particularly challenging for primiparous does, which has higher energetic demands. This work was supported by Grant PID2022-138223OB-I00 (funded by MCIN /AEI /10.13039/501100011033 [Spain], FSE, FEDER [EU] and, Next Generation EU/PTR)

Assessment of Securidaca longipedunculata (violet tree) effect on Semen Quality and Blood Sex Hormone Levels in Indigenous Goats

K. Shai[1], N. A. Sebola[1], S. Lebelo[1], M. Mabelebele[1], F. Manyeula[1]
[1] university of south africa, Agriculture and Animal Health, Florida Campus, 0709 Johanessburg, South Africa

Assessment of Securidaca longipedunculata (violet tree) effect on Semen Quality and Blood Sex Hormone Levels in Indigenous Goats Kamogelo. Shai, Segolo L. Lebelo, Freddy. Manyeula, Monnye. Mabelebele, Amenda N. Sebola a Department of Agriculture and Animal Health, College of Agriculture and Environmental Sciences, University of South Africa, Florida, 1710, South Africa bDepartment of Life and Consumer Sciences, College of Agriculture and Environmental Sciences, University of South Africa, Florida, 1710, South Africa Presenting author Dr K Shai: E-mail address. shaik@unisa.ac.za Abstract Semen quality and endocrine function are critical determinants of reproductive efficiency in indigenous goat bucks (IGB). Securidaca longepedunculata contains bioactive phytochemicals such as flavonoids, saponins, and alkaloids with antioxidant and potential androgen-modulating properties. It was hypothesised that supplementation with S. longepedunculata leaf extract (SLLE) would enhance semen quality and influence reproductive hormone concentrations in IGB. Sixteen (16) pubertal bucks (12–18 months) were randomly allocated to four treatment groups (n = 4 per treatment) receiving 0, 50, 100, and 125 mg/kg body weight of SLLE. Semen characteristics and serum hormones were analysed using a completely randomized design in SAS (PROC GLM). Data were pooled across time and subjected to one-way ANOVA, with mean separation using PDIFF at $P < 0.05$. SLLE significantly affected semen characteristics. Semen volume increased ($P = 0.01$) from 0.26 mL (control) to 0.42 and 0.38 mL at 50 and 100 mg/kg, respectively, but declined to 0.15 mL at 125 mg/kg. Sperm concentration improved ($P = 0.001$) from 267.3 $\times 10^6$/mL (control) to 441.5 and 455.6 $\times 10^6$/mL at 50 and 100 mg/kg, respectively, before decreasing to 169.3 $\times 10^6$/mL at 125 mg/kg. Total sperm motility increased ($P = 0.015$) from 29.0% (control) to 67.8% and 63.5% at 50 and 100 mg/kg, respectively. Similarly, progressive motility improved ($P = 0.02$) from 17.4% (control) to 49.8% and 45.4%, while rapid motility increased ($P = 0.02$) from 15.4% to 45.3% and 40.0% at 50 and 100 mg/kg, respectively. Sperm membrane integrity was higher ($P = 0.015$) at 50 (63.8%) and 100 mg/kg (60.9%) compared to the control (39.2%) and 125 mg/kg (36.3%). Live sperm percentage increased ($P = 0.005$) from 35.8% (control) to 78.8% at 100 mg/kg and 79.0% at 125 mg/kg. In contrast, serum testosterone (6.63 vs. 5.1–5.9 ng/mL) and oestrogen (0.83 vs. 0.60–0.88 ng/mL) were not affected ($P > 0.05$) by SLLE supplementation. In conclusion, moderate SLLE supplementation (50–100 mg/kg) significantly improves semen quality and sperm motility parameters in IGB, likely through antioxidant-mediated mechanisms, while higher doses may exert detrimental effects on certain traits. The lack of hormonal response suggests that improvements in semen quality are not mediated through endocrine changes. However, the small sample size (n = 4 per treatment) may limit statistical power for highly variable reproductive traits, and further studies with larger cohorts are recommended. Effects of maternal undernutrition on splenic white pulp morphology and immune-related metabolomic profiles in Japanese Black (Wagyu) fetuses

T. Haginouchi[1], Y. Suzuki[1], T. Gotoh[1]
[1] Hokkaido University, Field Science Center for Northern Biosphere, N11W10, 060-0811 Sapporo, Japan

Fetal underdevelopment increases the risk of neonatal disease and may adversely affect subsequent growth and fattening performance. Therefore, appropriate development of immune organs during early life is essential. The spleen is a secondary lymphoid organ and plays a key role in immune responses. Maternal nutrition is known to influence fetal development, and maternal undernutrition has been shown to reduce fetal body, thymus, and spleen weights. Splenic transcriptome analyses have further suggested altered inflammatory signaling and compensatory hematopoiesis under maternal undernutrition. In the present study, we evaluated splenic white pulp morphology and performed metabolomic profiling to clarify the effects of maternal undernutrition on the fetal spleen. Twelve multiparous Japanese Black cows were assigned from conception to day 260 of gestation to either a control group (CON, n = 6) receiving 120% of the Japanese Feeding Standard or a maternal undernutrition group (MUN, n = 6) receiving 60%. At day 260, fetuses were harvested and fetal spleens were collected. Hematoxylin and eosin staining was performed, and the white pulp area was quantified. Splenic metabolites were analyzed using LC-TOFMS. Differential metabolites were identified using Welch's t-test ($p < 0.1$), followed by pathway enrichment analysis. Maternal undernutrition significantly reduced white pulp area in the fetal spleen ($p < 0.01$). Metabolomic analysis detected 338 metabolites and identified 28 altered metabolites ($p < 0.1$). Notably, taurine, adenine, cytidine, 2′-deoxycytidine, 5-methylcytidine, GMP, phosphorylcholine, CDP-choline, dopamine-related compounds, and serotonin were reduced in the MUN group. Pathway analysis indicated enrichment of broad metabolic pathways and neuroactive ligand–receptor interaction pathway. Many altered metabolites are involved in nucleotide and choline metabolism, essential for cell proliferation and membrane synthesis. Their coordinated reduction, together with decreased white pulp area, suggests limited substrate availability for lymphoid cell development under maternal undernutrition. Reduced monoamine-related metabolites may reflect alterations in the splenic neuroimmune microenvironment. In conclusion, maternal undernutrition induces morphological and metabolic alterations in the fetal spleen, characterized by reduced white pulp development and metabolic downregulation. These findings indicate that maternal nutritional status influences immune organ development during gestation and may affect postnatal immune function.

Computer-Assisted Evaluation of Different Diluents on Kinematic Parameters of Ram Semen During Liquid Storage up to 72 h at 4 °C and after 2 h of Incubation

L. Mara[1], F. Chessa[1], I. Cossu[1], O. Todde[2], C. Nassif[1,2]
[1] Agricultural Research Agency of Sardinia (Agris Sardegna), Department of Animal Science, Bonassai, 07100 Sassari, Italy, [2] Associazione Allevatori della Regione Sardegna (AARS), Piazzale Segni, 1, 07100 Sassari, Italy

The preservation of ram semen quality during liquid storage is strongly influenced by diluent composition and sperm resistance to thermal stress after warming. This study evaluated the effects of different diluent formulations on ram semen quality during storage and after a 2 h incubation at 38 °C. Semen pools from six rams were diluted using eight extender formulations containing combinations of dimethylformamide (DMF) at 1.5%, Tempol (T) at 0.34 mg/mL, and hyaluronic acid (HA) at 0.06 mg/mL, with OviXcell® as reference. Samples were stored in liquid form at 4 °C and evaluated by CASA at 0, 24, 48 and 72 h after dilution. At each time, sperm quality was assessed immediately after warming to 38 °C and again after an additional 2 h incubation. Parameters included total motility, progressive motility and kinematic parameters included curvilinear velocity (VCL), straight-line velocity (VSL), average path velocity (VAP), linearity (LIN), straightness (STR), and amplitude of lateral head displacement (ALH). Data were analyzed using linear mixed-effects models with diluent, storage time and incubation as fixed effects and semen pool as a random effect. Storage time and incubation significantly affected all semen quality parameters. Total motility was influenced by storage time ($F = 6.55$, $p = 0.0004$) and incubation ($F = 24.10$, $p < 0.001$), while progressive motility showed strong effects of storage ($F = 8.21$, $p < 0.001$) and incubation ($F = 76.49$, $p < 0.001$). Significant storage × incubation interactions were observed for total motility ($p = 0.025$) and progressive motility ($p = 0.010$), indicating that incubation effects increased with storage duration. Velocity parameters were strongly affected by both factors. Motile VCL, VSL and VAP were significantly influenced by storage (VCL: $F = 59.19$; VSL: $F = 155.92$; VAP: $F = 172.40$; all $p < 0.001$) and incubation (VCL: $F = 82.45$; VSL: $F = 343.29$; VAP: $F = 139.53$; all $p < 0.001$). Significant storage × incubation interactions ($p \leq 0.005$) showed that velocity declined more markedly after incubation at longer storage times. Diluent had limited effects on total motility but significantly affected several kinematic parameters, including motile VSL ($F = 3.33$, $p = 0.003$), motile LIN ($F = 4.69$, $p < 0.001$), motile STR ($F = 2.29$, $p = 0.031$), progressive VSL ($F = 2.48$, $p = 0.020$), progressive LIN ($F = 5.89$, $p < 0.001$) and progressive STR ($F = 2.09$, $p = 0.049$). Significant diluent × storage interactions were detected for total motility ($p = 0.028$), progressive motility ($p = 0.020$), motile LIN ($p = 0.013$) and progressive LIN ($p = 0.006$). Diluent × incubation interactions were also observed for motile VCL ($p = 0.018$), motile LIN ($p < 0.001$), motile STR ($p = 0.038$), motile ALH ($p = 0.040$), progressive VCL ($p = 0.019$) and progressive LIN ($p < 0.001$), indicating differences in sperm resistance to thermal stress. Pairwise comparisons showed that 1.5 DMF + T + HA maintained among the highest progressive motility and kinematic values after prolonged storage and incubation. Storage duration and incubation at physiological temperature strongly affect ram semen quality, while diluent composition modulates sperm resistance to incubation stress. Extenders combining DMF with Tempol and HA improved preservation of sperm motility and kinematic characteristics during storage and subsequent incubation.

Effects of egg yolk and goat milk extenders on cryopreserved semen quality of West African Dwarf goats

N. A. Muhammed[1], T. O. Idowu[1], O. S. Ogundele[1], E. O. Adekunle[1], A. B. Kolade[1], F. A. Bello[1], A. A. Omoloye[1], M. A. Agbanimu[1], R. A. Ahmed[1], O. C. Olaniyi[1], V. T. Atanda[1], J. O. Daramola[1]

[1] Federal University of Agriculture Abeokuta, Animal physiology, Alabata road, Abeokuta, 111101 Abeokuta, Nigeria

Abstract Egg yolk and goat milk are widely used as cryoprotective extenders to enhance sperm motility, plasma membrane functionality, acrosome integrity and fertilizing ability in farm animals. However, their comparative effectiveness in preserving semen quality of West African Dwarf (WAD) goat bucks during cryopreservation has not been well established. This study evaluated the effects of Tris-based egg yolk and goat milk extenders on motility and functional integrity of WAD goat spermatozoa incubated at different temperatures. Pooled semen samples were collected from two mature bucks across five ejaculates (n = 5 replicates) and diluted in Tris egg yolk or Tris goat milk extender. Diluted semen samples were divided into five aliquots and incubated at 20, 16, 12, 8 and 4 °C. Samples were gradually cooled from 20 °C to 4 °C at a rate of 0.25 °C/min, equilibrated, and subsequently cryopreserved in liquid nitrogen (−196 °C) for 24 hours. Following thawing, sperm motility, acrosome integrity, membrane integrity, livability and morphological abnormalities were evaluated. Data were analysed using analysis of variance in a 5 × 2 factorial arrangement within a completely randomized design, and means were separated using Duncan's Multiple Range Test at $P < 0.05$. Results showed that higher sperm motility was obtained at 4 °C in the Tris egg yolk extender and at 16 °C in the Tris goat milk extender compared with other incubation temperatures. Membrane integrity was comparable between both extenders. Egg yolk extender maintained higher motility at lower temperature (4 °C), while the highest acrosome integrity was observed in semen extended with Tris egg yolk and incubated at 16 °C. These findings demonstrate that both extender type and incubation temperature significantly influence cryosurvival of WAD goat spermatozoa, with egg yolk extender showing superior performance in maintaining sperm motility at lower temperatures. Keywords: Cryopreservation; cryoprotectants; sperm motility; cooling temperature; extenders; West African Dwarf goat.

Policy to practice: Driving farm-level change with carbon accounting and transparent Scope 3

J. Gilliland[1]
[1] *Harper Adams University, Sustainable Farm Networks, Edgmond, TF10 8NB Telford, United Kingdom*

The need for accurate, cost-effective carbon accounting in agriculture has intensified as policy and markets demand robust measurement, reporting and verification (MRV) of both emissions and removals. Tier 1 factors have proven insufficient for capturing farm-level realities or tracking genuine progress towards net zero. This has driven efforts to develop Tier 2 (and eventually Tier 3) factors, particularly for carbon removals in productive landscapes where complexity arises from diverse soils, management practices and livestock systems. John Gilliland, a practitioner and farmer, with long-standing involvement in UK and international agricultural climate policy has contributed to this challenge through progressively scaled projects that combine accredited farm carbon calculators (initially with Tier 1 removals modules) with site-specific measurement techniques. The ARC Zero project (EIP-Operational Group, Northern Ireland, 2020–2023) serves as a concrete early example. Working with seven diverse farms (~930 ha, covering varied soil types and enterprises), the project established whole-farm baselines using Agrecalc. It integrated high-resolution aerial LiDAR surveys (40 scans per m²) for above-ground biomass quantification and deeper soil organic carbon sampling (to 1 m) to better capture contributions from livestock manure, multi-species swards and complex root systems. Preliminary results showed that 97% of total carbon stocks resided in the soil rather than in trees or above-ground biomass. Across the seven farms, combined carbon stocks totalled 515,166 t CO_2e, with soil carbon accounting for 494,438 t CO_2e (top 30 cm, conservative bulk density). Two farms were already at net zero status (gross emissions minus sequestration) at the outset. On the five farms with follow-up data, emission intensity reductions ranged from 4% to 53% through changes such as reduced nitrogen fertiliser, clover introduction and multi-species swards. These outcomes highlighted farms as significant carbon custodians while exposing limitations of standardised Tier 1 approaches in heterogeneous landscapes. This work has scaled to the AHDB-led Environment Baselining Pilot (supported by Quality Meat Scotland), now in its second year of a five-year programme involving 178 farms and over 36,000 ha across Great Britain. Initial baselines are complete, with early observations indicating that 14% of participating farms (more than half with livestock) are already beyond net zero on a net carbon basis. Soil carbon again comprises around 95% of measured stocks. Full peer-reviewed publication of results from this larger programme is still pending. John now advises the EU-funded CAFAMORE project, developing a cost-effective hybrid MRV solution (Earth Observation, Tier 3 modelling and ground truthing) for the EU Carbon Removals Certification Framework, and contributes to the UK Carbon Removals Taskforce on the GHG Protocol's Land Sector Removals Standards for Scope 3 declarations. These projects illustrate the tension between standardised, scalable carbon accounting and the need to reflect site-specific biophysical realities. Early findings emphasise the dominance of soil carbon, the value of hybrid methods (LiDAR + deep soil sampling), and the potential for data-driven management to deliver mitigation alongside co-benefits such as improved soil health. They also underscore the importance of transparent, cost-effective MRV for credible carbon removals claims in food-producing landscapes.

Carbon footprint as a key indicator of structural diversity in extensive dehesa livestock farms

A. Horrillo[1], P. Gaspar[2], A. Rodríguez-Ledesma[2], M. Escribano[1]
[1] Universidad de Extremadura, Producción Animal y Ciencia de los Alimentos, Av. de la Universidad, s/n, 10003 Cáceres, Spain, [2] Universidad de Extremadura, Producción Animal y Ciencia de los Alimentos, Avda. Adolfo Suárez s/n, 06007 Badajaoz, Spain

Extensive livestock farming systems are typically analysed from different perspectives, such as breed type, economic performance and environmental impact. This fragmented approach makes it difficult to gain a full understanding of the diversity of these systems, particularly in a context of increasing climate uncertainty. A more integrated assessment is required in order to better characterise how these farms function. This study evaluated 52 dehesa farms using technical, economic and environmental indicators during 2021–2022. Principal Component Analysis was followed by Cluster Analysis to identify the main structural characteristics. Three key factors were identified: (i) the level of intensification and greenhouse gas emissions; (ii) land tenure and labour; and (iii) dependence on Common Agricultural Policy (CAP) subsidies. These three factors explained 67.63% of the total variance, enabling the classification of four farm groups. The results showed that farms with lower levels of intensification (clusters 1, 2 and 3) had a lower environmental impact (991.99, 727.20 and 1,049.87 kg CO2eq per hectare per year, respectively) and were less reliant on external inputs. In contrast, the most intensive cluster (cluster 4) had an environmental impact of 2,183.58 kg CO2eq per hectare per year, though it achieved better economic performance. Of the identified groups, cluster 3 was the most balanced, combining good technical and economic results with regenerative management practices. This typology highlights the importance of incorporating greenhouse gas emissions into analyses of extensive livestock farms. It provides a basis for developing management strategies aimed at enhancing sustainability and resilience under climate uncertainty.

A combined nutritional-genetic modeling approach to predict enteric methane emissions in individual and groups of dairy cows

P. Mwangi[1], C. Richardson[2], K. Grant[2], N. Howes[2], R. Jahnel[1], C. Baes[1], F. Miglior[1,3], A. Fleming[3], E. Kebreab[4], J. Ellis[1]
[1] Department of Animal Biosciences, University of Guelph, 50 Stone Road E, N1G 2W1 Guelph, Canada, [2] AbacusBio International Ltd, Roslin Innovation Centre, Easter Bush Campus, University of Edinburgh, EH25 9RG Edinburgh, United Kingdom, [3] Lactanet Canada, 660 Speedvale Ave W, N1K 1E5 Guelph, Canada, [4] Department of Animal Science, University of California, Davis, Davis, 95616 CA, United States

Both nutrition and genetic selection for lower enteric methane (CH4) emissions can deliver permanent and cumulative strategies to lower CH4 production from dairy cattle. In 2023, Canada released CH4 breeding values derived from mid-infrared spectral data of milk samples and rigorous CH4 measurements collected using GreenFeed (C-Lock Inc., USA) in Holstein cows. Previous studies reported moderate heritability for daily CH4 production, CH4 yield, and CH4 intensity (ranging from 0.16 to 0.40), with a strong genetic correlation between CH4 production and intensity (rg = 0.94), supporting the inclusion of a CH4 trait in selection programs. Concurrently, numerous animal trials have demonstrated that nutritional manipulation can reduce enteric CH4 emissions in dairy cows, and both empirical and mechanistic models have been developed to predict CH4 emission responses to these dietary strategies. To quantify reductions achieved by combined mitigation measures, integration of genetic and nutritional mitigation strategies into carbon accounting tools are required. Currently, no model integrates both methane estimated breeding values (EBVs) and predicted CH4 emissions from nutritional models for concurrent use in dairy cows. Therefore, this study aimed to develop models that combine empirical prediction of CH4 based on nutritional variables with CH4 breeding values to predict enteric CH4emissions from individual dairy cows. Observed data was provided by the consolidated database of Net-zero Dairy Genome Project (www.ndgp.ca) collected from the Ontario Dairy Research Centre, Elora, ON, Canada (ODRC). The dataset included 627 genotyped first parity Holstein cows encompassing 2,974 records for CH4 production, DMI and dietary nutrient composition. Individual CH4 measurements were collected mid-lactation (day 120-185 DIM) using a GreenFeed system. Cows were moved in groups of 2 to 4 into a tie-stall area and acclimatized for 2-days, followed by a 5-day CH4 measurement period (3 to 4 visits a day of 8-10 min each). During this period, cows were fed a total mixed ration ad libitum and had free access to water. Twenty-five published empirical CH4 prediction models were identified and their predictive performance evaluated using the reported CH4, DMI and nutrient composition records from the ODRC herd. Models incorporating DMI, NDF, and fatty acid content of the diet outperformed equations that used only DMI or omitted fibre and fat content of the diet. The top eight performing models, based on the Root Mean Square Prediction Error (RMSPE) and concordance correlation coefficient (CCC), were then combined with CH4 EBVs from selected genotyped herds. Integrating EBVs with the empirical models moderately improved CH4 emission prediction accuracy, reflected by lower RMSPE and higher CCC. These results demonstrate the potential of combining genetic and nutritional models to predict individual CH4 emissions, and supports application in national inventories and life cycle assessment analysis.

Bridging the Climate-Corporate Gap: Utilizing GWP* with GWP100 for Livestock Companies' Greenhouse Gas Inventories

S. Klopatek[1], L. Thompson[2], M. Beck[3], S. Place[4]
[1] University of Wisconsin, Nelson Institute of Environmental Studies, 500 Lincoln Dr, 53706 Madison, United States, [2] Kansas State Univeristy, Animal Science, 919 Mid-Campus Drive North, 66506 Manhattan, United States, [3] Texas A&M University, Animal Science, 400 Bizzell St, 77840 College Station, United States, [4] Colorado State University, Animal Science, 350 W Pitkin St, Fort Collins 80521, United States

The global warming potential (GWP) metric on a 100 year basis (GWP100) is currently the most common metric implemented by corporations in their greenhouse gas (GHG) inventories. However, GWP100 cannot adequately account for the short atmospheric lifespan of some GHG, such as CH4 which has a 12-yr atmospheric lifespan. As such, GWP100 is unable to adequately translate GHG emissions to climate warming contributions. More recently, GWP-star (GWP*) has been developed to resolve this issue. The GWP* and GWP100 result in different estimates of climate warming contributions by CH4. With the emergence of GWP* there has been increasing interest in adopting this metric into corporate reporting. However, the 20-year baseline data required to calculate GWP* has limited companies' ability to incorporate GWP* into their current GHG reporting inventories. To bridge the gap between GWP* and corporate accounting we developed a straightforward methodology to enable companies to dual report both GWP* and GWP100 within their inventories. Specifically, the methodology developed a "shadow company" technique that will allow GWP* to be This is a provisional file, not the final typeset article calculated from a specified baseline reporting year and onwards. To realistically model a corporate inventory we developed a mock beef company, titled the Global Beef Company that operated in Brazil, Australia, and the United States. Emission reduction and growth scenarios were modeled over an 80-year timescale. To evaluate the cumulative effect of warming over time, GHG were modeled using cumulative sum of GWP* and GWP100 values. With many companies reporting GHG on an intensity basis, a new metric was formulated entitled Intensity Cumulative where GWP* and GWP100 were both reported on intensity basis. Overall, the paper provides a step-by-step template for dual reporting GWP* and GWP100 on an absolute and intensity basis for GHG corporate accounting.

Dynamic Life Cycle Assessment of Greenhouse Gas Emissions of Live Animals in Beef Cattle Production

M. Ryynänen[1], S. Hietala[2], A. Stygar[3], J. Niemi[3], M. Pastell[1]
[1] Natural Resources Institute Finland, Production systems, Latokartanonkaari 9, 00790 Helsinki, Finland, [2] Natural Resources Institute Finland, Bioeconomy and environment, Latokartanonkaari 9, 00790 Helsinki, Finland, [3] Natural Resources Institute Finland, Business economics, Latokartanonkaari 9, 00790 Helsinki, Finland

The major sources of greenhouse gas (GHG) emissions in ruminant livestock systems are enteric methane and excreta methane and nitrous oxide emissions. Since emission mitigation potential of these emissions is realised at farm through decisions made at herd and individual animal levels, dynamic tools are needed to quantify emissions and to identify high-emitting animals at these operational scales. Although existing Life Cycle Assessment (LCA) frameworks, such as the Product Environmental Footprint Category Rules (PEFCR) for Dairy Products, the IDF global Carbon Footprint standard for the dairy sector, and the Finnish Food-LCA guidelines, provide general methodologies for quantifying livestock emissions, they are mainly designed for dairy systems and farm- or product-level assessments. Consequently, they require systematic adaptation before they can be applied to animal-level calculations in beef cattle during the growing period. This gap limits stakeholders in developing and evaluating effective mitigation and management strategies. The aim of this work is to develop a dynamic approach for estimating GHG emissions of live animals during the fattening stage at farm. Following the principles laid down in PEFCR Dairy for climate change impact assessment, we developed an animal-level emission calculation model for Finnish beef production systems. The model integrates IPCC Tier 2/3 equations for enteric methane and manure methane emissions, Tier 1/2 approaches for direct and indirect nitrous oxide emissions, and upstream LCA data for feed. Primary data includes daily diet composition, feed composition, live weight, and manure management system. Secondary data is used for emissions from feed production. Capital goods and housing energy are excluded. The model outputs the total GHG emissions from enteric fermentation and manure management per animal per day and per kilogram of live weight, allowing comparability with farm and product level indicators. Application of the model in Finnish beef herds reveals variability in methane intensity, driven mainly by differences in growth rate, diet composition and manure management conditions. These results show that aggregated farm-level metrics can mask significant individual variation and highlight the potential for targeted interventions. The developed model provides stakeholders such as producers, advisors, processors, breeding companies, environmental agencies and researchers with a practical, new tool for evaluating mitigation options, optimising feeding strategies, benchmarking animals, and reporting climate performance using traceable and reproducible calculations. In conclusion, this work demonstrates that existing LCA standards can be systematically adapted to dynamic animal-level assessments of live beef cattle without compromising methodological consistency. The resulting framework contributes a novel approach to integrating individualized GHG emission data into management, breeding and sustainability reporting, supporting the transition toward more climate smart beef production in Europe. Authors received financial support from the European Union's Horizon Europe Coordination and Support Action under grant agreement no. 101134866 (project Digi4Live, https://digi4live.eu/).

Dietary carbon use efficiency, emissions, and losses in growing-finishing pigs

G. Shurson[1], B. Kerr[2], S. Trabue[3], D. Humphrey[4]
[1] University of Minnesota, Animal Science, 1988 Fitch Ave., 55108 St. Paul, MN, United States, [2] USDA-ARS, National Laboratory for Agriculture and the Environment, 1015 N. University Blvd., 50011 Ames, IA, United States, [3] USDA-ARS, National Laboratory for Agriculture and the Environment, 1015 N. University Blvd., 50011 Ames, IA, United States, [4] Iowa State University, Animal Science, 806 Stange Rd., 50011 Ames, IA, United States

Carbon (C) accounting is a process of quantifying direct and indirect carbon use, losses, and emissions of agriculture and food supply chains, and is typically measured in carbon dioxide equivalents (CO2e). It is a framework to measure, track, and report emissions to identify hotspots, set reduction targets, meet sustainability goals, reduce operational costs, and ensure regulatory compliance. Livestock and poultry production contributes about 12% to the total global anthropogenic emissions of CO2, CH4, and N2O. Although pigs emit less CO2 and CH4 than ruminants, accurate assessment of the C mass balance and emissions in swine production systems is needed for developing of feeding strategies that improve C use efficiency of pork production to minimize C losses to the environment, spare unnecessary use of natural resources, enhance food security, and reduce the cost of production. Previous estimates of the C footprint of pork production chains are highly variable and range from 0.6 to 6.75 kg CO2e per kg live weight and 2.25 to 4.52 kg CO2e per kg pork products. As a result, the current review is the first to systematically summarize, synthesize, and evaluate empirical published and unpublished data to quantify C mass balance, emissions, and losses in growing-finishing pigs. Thermal combustion analysis is the most common standardized method for determining total C concentrations in a wide variety of matrices including feed ingredients. Analytical results of the C concentration of 80 feed ingredients were highly variable (0.02 to 77% C) within and among classification categories which included: crystalline amino acids (30 to 64% C); animal by-products (38 to 55% C); fats and oils (~ 77% C); inorganic macro- and microminerals (0.02 to 12% C); grains and plant-based by-products (44 to 60% C); and organic trace minerals and choline chloride (1 to 34% C). There was a strong positive association between fecal ($r = 0.998$; $P < 0.001$) and urinary ($r = 0.998$; $P < 0.001$) C and gross energy (GE) excretion, where daily fecal C excretion corresponded to a loss of 10.55 kcal GE per g of C, and urinary C excretion corresponded to a daily loss of 11.91 kcal GE per g of C. Overall, about 13% of dietary C intake is excreted in feces, 3% is excreted in urine, while only about 25% of dietary C intake is retained in whole body protein and fat. Depending on the methods and assumptions used, exhaled C represents the greatest C loss and represents about 55% to 61% of dietary C intake. On a GE basis, 25% of dietary net energy C is retained (10% in body protein, 15% in body fat), 30% of energy is lost from fasting heat production, 29% is lost from heat production from activity and thermic effect of feed, and 13% and 3% of GE is lost in feces and urine, respectively. These results indicate that dietary C use efficiency in growing-finishing pigs is relatively poor (~25%) with more than 55% of dietary C lost from enteric C emissions. Studies are needed to quantify C utilization associated with the physiological and metabolic changes caused by heat stress and immune challenges in pigs. In addition to diets and feeding programs, manure management is the other major contributor to CO2, CH4, and N2O emissions from swine production systems. Type and time period of manure storage affects variability in CO2, CH4, and N2O emissions under commercial conditions which need to be quantified and better characterized.

Economic and greenhouse gas emissions assessment of grass silage under different management scenarios in Irish grassland systems

G. Don[1], M. Mcgee[2], L. Gallo[1], E. Sturaro[1], M. Berton[1], P. Crosson[2]
[1] Università di Padova, DAFNAE, Viale Dell'Università, 16, 35020 Legnaro, Italy, [2] Teagasc, Animal & Grassland Research and Innovation Centre, Grange, Dunsany, A85 VP65 Co. Meath, Ireland

Feed provision is the principal variable cost and a key source of greenhouse gas emissions (GHGE) on Irish grassland farms. Grass silage is the predominant conserved forage in Irish livestock systems and management choices such as cutting frequency, conservation method and fertilisation strategy affect both costs and emissions. The Grange Feed Cost Model (GFCM), developed by Teagasc, is a simulation model which integrates agronomic outputs and resource use to calculate total feed cost from crop establishment to feeding; however, it does not include environmental indicators. The objective of this study was to augment the existing model with a GHGE module enabling scenario-based assessment. The economic module accounts for variable and fixed costs and reports results per hectare (ha), per tonne (t) of dry matter fed (DM) and per GJ of metabolisable energy fed (ME). To implement the GHGE module, ISO 14040/44 principles were followed using an inventory-based cradle-to-feeding boundary. The global warming potential (GWP) was calculated using IPCC (AR6) 100-year characterisation factors for carbon dioxide (CO_2), methane and nitrous oxide. Emission factors for upstream inputs were derived from established Life Cycle Inventory databases (Ecoinvent and Agri-footprint) or the literature. Forage production scenarios included perennial ryegrass only (PRG), harvested once or twice, and PRG plus red clover (RC) harvested twice or three times, annually. In terms of management, two conservation methods (pit or baled silage) and two fertilisation strategies (inorganic fertiliser with slurry (WS) or without slurry (WO)) were evaluated. Under the one-cut PRG pit scenario, GHGE were 1.53 t CO_2-eq/ha (31.6 g CO_2-eq/MJ ME) for WS and 1.55 t CO_2-eq/ha (31.9 g CO_2-eq/MJ ME) for WO. Total costs were 307 €/t DM (28.9 €/GJ ME) and 325 €/t DM (30.6 €/GJ ME), respectively. In the two-cut PRG pit scenario, GHGE increased to 2.59 t CO_2-eq/ha (32.4 g CO_2-eq/MJ ME) under WS and 2.70 t CO_2-eq/ha (33.8 g CO_2-eq/MJ ME) under WO, with total costs of 339 €/t DM (32.2 €/GJ ME) and 354 €/t DM (33.6 €/GJ ME), respectively. Baled silage increased GHGE and cost per ha by approximately 7% but reduced GHGE and cost per MJ of ME fed by 3% compared with pit conservation. Across PRG scenarios, slurry use reduced GHGE by 3% and total costs by 4%. RC swards exhibited markedly lower GHGE. Two-cut RC pit silage produced 1.36 t CO_2-eq/ha (16.2 g CO_2-eq/MJ ME fed), while baled silage produced 1.42 t CO_2-eq/ha (14.4 g CO_2-eq/MJ ME fed). Total costs were 251 €/t DM (23.8 €/GJ ME fed) for pit and 252 €/t DM (23.7 €/GJ ME fed) for baled silage. Three-cut RC produced 1.69 t CO_2-eq/ha for pit and 1.74 t CO_2-eq/ha for baled silage, at a total cost of 267 €/t DM and 258 €/t DM, corresponding to 24.5 and 25.4 €/GJ ME fed, respectively. For the conditions considered, the most favourable combined economic and environmental performance was observed for RC two-cut pit silage WS. The least favourable economic performance was associated with PRG two-cut baled silage WO, which showed the highest costs per hectare and per unit of energy fed. The highest GHGE per MJ ME fed was observed for PRG two-cut pit silage WO. Compared with PRG, RC reduced GWP by over 50%, while maintaining competitive or lower costs per unit of energy. Overall, systems with higher harvest frequency and greater input use increased GHGE and costs per hectare, while differences per ME fed remained limited. Integrating economic and GHGE metrics highlights how functional unit selection shapes mitigation assessment in grassland systems.

Constraints on greenhouse gas emission mitigation options of dairy cow farms in Switzerland through production systems and agro-climatic zones

D. Stucki[1], S. Ineichen[1], B. Reidy[1], J. Grenz[1]
[1] BFH-HAFL, Agriculture, Laenggasse 85, 3052 Zollikofen, Switzerland

Reducing greenhouse gas (GHG) emissions of ruminant production systems is relevant for agricultural research and policy in Europe. However, most farm level mitigation measures do not exhibit strong effects and not all measures are applicable on all farms. Within the framework of the KlimaStaR Milch project, dairy farms in Switzerland are being paid primes for reducing their GHG emission intensity (GEI; kg CO2e/kg FPCM). Here, we assess their achievements over four years and discuss possible constraints by production systems and agro-climatic zones. In total, 216 farms were classified into three groups according to production system and zone: conventional valley/hill (C-VH; 109 farms), conventional mountain (C-M; 78 farms) and organic-all zones (ORG; 30 farms). Differences in GEI between the baseline (aggregated values 2019-2021) and the year 2025 were calculated using the Swiss GHG-calculation model KLIR. Separate Spearman rank correlations between the change in input variables (covering production, herd management, feeding, farm manure storage and land use) and the change in GEI for each system-zone group was used to assess the most relevant input variables. After four years, C-VH farms reduced their GEI by -0.064±0.052 kg CO2e/kg FPCM as compared to the baseline. This decline was significantly greater than for C-M (-0.044±0.059; p=0.014) and O-AZ farms (- 0.037±0.049; p=0.015), respectively. No difference was observed in GEI between C-M and O-AZ (p=0.53) farms. C-VH farms featured ten variables significantly associated with the decline in GEI: allocation factor (AF) milk (ρ = -0.34), annual milk yield/cow (ρ = -0.54), first calving age (ρ = 0.24), total milk production/farm (ρ = -0.38), proportion of specialized dairy-breed (-0.32), feeding of 3-NOP (ρ = -0.40), MJ NEL/kg DM pasture feed (ρ = -0.23), g CP/kg DM of roughage other than grass (ρ = -0.21), proportion of covered slurry pits (ρ = -0.22), total hours on pasture per year (ρ = -0.26). C-M farms shared four of these: AF milk (ρ = -0.52), annual milk yield/ cow (ρ = -0.68), first calving age (ρ = 0.39) and total milk production/farm (ρ = -0.55). Four variables were associated with a reduction of GEI only for C-M farms: total farm size (ρ = -0.26), proportion of slurry in biogas digesters (ρ = -0.35), proportion of slurry in covered pits (ρ = 0.23) and the proportion of manure in biogas digesters (ρ = -0.27). Only three variables were associated with a reduction of GEI for O-AZ farms. The AF milk (ρ = -0.75) and annual milk yield/cow (ρ = -0.50) were significant for both other farm groups, too, whereas productive lifespan (ρ = -0.44) was only significant for O-AZ farms. As C-VH farms have the least constraints by regulations, climate and topography, their potential to intensify dairy production is the highest. Variables explicitly linked to dairy production intensity were hence strongly associated with GEI. Up to now, the feeding of 3-NOP is only promoted for farms feeding total mixed rations and prohibited in organic farming. Increasing the proportion of farm manure fermented in biogas digesters and covering slurry pits were relevant for all conventional farms. Surprisingly, these measures were not associated with a reduction of GEI on organic farms. As the potential for intensification is limited on organic farms, increasing the productive lifespan of dairy cows appears to be a more frequent strategy. There is not necessarily a causal relationship between the input variables and the reduction in GEI. Nevertheless, our results highlight a set of potential GHG mitigation measures on dairy farms. Some are more applicable to specific agro-climatic zones or production systems than others.

Exploring scenarios for integral sustainability of Dutch dairy farms towards 2030

M. De Vries[1], A. Evers[1], G. Doornewaard[2], M. De Haan[1], J. Reijs[2], S. Jebbink[1], G. Migchels[1], P. Galama[1]
[1] Wageningen Livestock Research, Animal Farming Systems, De Elst 1, 6708 WD Wageningen, Netherlands, [2] Wageningen Social & Economic Research, Agricultural Policy and Data Management, Droevendaalsesteeg 4, 6708 PB Wageningen, Netherlands

The Dutch dairy sector faces multiple sustainability targets, including targets for greenhouse gas emissions (GHG), ammonia emissions (NH3), water quality, and biodiversity. This study estimated effects of alternative development pathways and management interventions on technical, environmental and economic performance of Dutch dairy farms towards 2030. Six farm types representative of the Dutch dairy sector were modeled with DairyWise for a 2022 reference situation (R22). Three pathways for 2030 were explored: business as usual (B30); higher productivity with advanced techniques and land-sparing (Hi30); and lower productivity with a larger land base and land-sharing (Lo30). All pathways included a similar increase in herd size per farm, genetic progress, regulatory measures (e.g., ending derogation), increased drought and heat, and a national herd reduction. Environmental impacts were quantified using the Annual Nutrient Cycling Assessment (ANCA) model. In B30, N soil surplus, NH3 emissions, and GHG emissions (per kg FPCM) decreased by 16–46%, 17-37%, and 2-21%, mainly due to planned and implemented regulation and agreements towards 2030. Access to pasture, manure export, and energy use increased; permanent grassland area declined; and land use per kg milk remained stable. Relative to B30, NH3 and GHG emissions decreased further in Hi30, by an additional 4-27% and 2-29%, and in Lo30 by 5-25% and 2-29%. Both Hi30 and Lo30 reduced manure export relative to B30 and increased green-blue infrastructure and measures under the Dutch agri-environment scheme (ANLb). Lo30 provided additional benefits on most farm types for N soil surplus, energy use, home-grown protein, access to pasture, and permanent grassland; Hi30 showed predominantly unfavorable effects for these variables, except for a lower land use per kg milk. Relative to B30, labor income declined on 3 of 6 farm types in Hi30, and 4 of 6 in Lo30. At national scale, assuming equal national herd size, B30, Hi30 and Lo30 resulted in 32%, 48% and 37% lower NH3; 13%, 28% and 23% lower direct non-CO2 GHG; and 11%, 14% and -2% less domestic land use. Milk volume would change by -6%, 1% and -21%. A mixed implementation of pathways seems most promising for meeting national targets and improving the integral sustainability of the Dutch dairy sector towards 2030.

Relevance, Variability, Availability – Evaluation of German dairy farm data for GHG accounting

K. Agethen[1], K. Bretschneider[1], L. M. Hollmann[1]
[1] Thünen Institute, Institute of Farm Economics, Bundesallee 63, 38116 Braunschweig, Germany

On-farm greenhouse gas (GHG) accounting faces a variety of requirements. It should be complete within defined farm-level system boundaries and consistent with the national inventory. For reliability purposes, regarding e.g. legally compliant reporting along the value chain, input data should have sufficient data quality and must be verifiable. Yet, to reduce data collection effort, GHG accounting ideally makes best use of suitable, already existing farm-level data. Last but not least, the input data needs to be sufficiently specific to allow a mapping of possible mitigation measures. The majority of German dairy farms are already obliged to regularly record a substantial number of variables, e.g. animal numbers and movements, fertilisation and cultivation planning as well as farm accounting. More data might be available at farm level for operational management. The more relevant these data are to the GHG balance and its variability across farms, the more important it is to ensure good data quality for these variables at the farm level. Based on the national inventory methodology and common farm-level GHG accounting tools, we identify GHG accounting-relevant variables for dairy farms. We investigate their variability and assess its impact on the GHG emissions. Following this, we explore the availability of the identified variables across farms, considering regular mandatory data collections, e.g. for accounting, traceability and inventory data management as well as quality and performance analysis. The availability of further voluntary data across dairy farms is also assessed. We map our findings in order a) to outline potential farm-data integration in GHG accounting tools b) to inform about potential needs for robust secondary data, and c) to derive recommendations for on-farm data collection for reliable, feasible and verifiable carbon accounting at the farm-level.

Environmental assessment of french rainbow trout production : a regional analysis

S. De Montmorillon[1], J. Aubin[2], A. Tocqueville[3], C. Van Cuyck[4], J. Bonneau[1], M. Dupont-Nivet[1], S. Pouil[1]

ENVIRONMENTAL ASSESSMENT OF FRENCH RAINBOW TROUT PRODUCTION: A REGIONAL ANALYSIS De Montmorillon Sophie*1, Aubin Joël2, Tocqueville Aurélien3, Van Cuyck Claire4, Bonneau Jeanne1, Dupont-Nivet Mathilde1, Pouil Simon1 1Université Paris-Saclay, INRAE, AgroParisTech, GABI, Jouy-en-Josas, France 2UMR SAS, INRAE, Institut Agro Rennes-Angers, 35042 Rennes, France 3ITAVI, F-75009 Paris, France 4CIPA, F-75010 Paris, France *Presenting author: sophie.de-montmorillon@inrae.fr Rainbow trout (Oncorhynchus mykiss) is the main farmed fish species in France (29,000 tons in 2023). Production is traditionally based on freshwater flow-through systems. Farms are widely distributed across the country, with major producing regions including Hauts-de-France, Nouvelle-Aquitaine, Bretagne and Normandie. Production objectives vary according to market outlets: restocking and recreational fishing (10% of volumes), export (17%), and domestic human consumption (73%). Although these orientations are primarily driven by economic factors, environmental performance has become an increasing societal concern. Life Cycle Assessment (LCA) is a holistic and standardized method for environmental assessment. It has been applied to trout production to estimate impacts under various zootechnical and geographical conditions (Aubin et al., 2009; Chen et al., 2015; Maiolo et al., 2021). A previous environmental assessment of French rainbow trout farming was conducted by Chen et al. (2015). The present study provides an updated assessment of the environmental performance of French rainbow trout production, with a focus on regional differences among the main producing areas. Twenty-six surveys were conducted between March and November 2025 on conventional freshwater flow-through trout farms. Representativeness was evaluated by comparing the geographical distribution of surveyed farms with national aquaculture inventories from 2020 and 2022 (Agreste). Data collection covered all inputs and outputs required over one reference production year. For each farm, an LCA was performed to quantify environmental impacts per ton of live-weight trout at the farm gate. Principal component analysis and inferential statistics were applied to LCA results to assess whether the production region influences farm-level environmental impacts of trout production. Feed production was identified as the dominant contributor across most impact categories. Significant regional differences were observed for Net Primary Production use and Water Consumption, reflecting distinct feed compositions and sourcing strategies among regions, together with regional river characteristics. Environmental impact values were significantly correlated with zootechnical performance, particularly feed conversion ratio. Overall, inter-farm variability in environmental impacts appears largely explained by zootechnical characteristics which appear to reflect region-specific commercial strategies and rearing practices. To investigate the influence of market orientation on environmental performance, future assessments should extend system boundaries beyond the farm gate to include post-farm operations. Advancing Harmonised Data Collection and Product-Based Greenhouse Gas Accounting in Dairy Production

F. Fenger[1], T. Krebs[1], H. Knopp[1], H. M. Paulsen[1]
[1] Johann Heinrich von Thuenen Institute, Institute of Organic Farming, Trenthorst 32, 23847 Westerau, Germany

Farm-level greenhouse gas (GHG) accounting is becoming increasingly important in dairy production due to policy requirements, climate targets and market-driven sustainability standards. Within the RindforNet-SH network, we evaluated potential for standardized and digital data collection on German dairy farms and calculated product carbon footprints (PCF) for four German Holstein dairy research farms (conventional and organic; differing in housing, feeding intensity and herd structure) over the years 2022–2024. Emissions were calculated using the calculation standard for individual farm-level GHG accounting (BEK) from 2021 (KTBL 2021, 2nd ed. [1]). The calculation sheets and procedures are completely transparent and thus allow traceable calculations and adaptations. Digital interfaces (e.g., HIT (Animal traceability and information system), LKV (national milk inspection data) and on-farm weighing systems) were combined with equal pre-calculations to generate comparable datasets across farms. Farm-specific PCFs were calculated where possible, e.g. on farm forage production, while for other parameters standardized KTBL default values were used, e.g., imported concentrate feed. Average carbon footprints for milk ranged from 0.6 to 1.0 kg CO_2eq per kg ECM between farms. Year-to-year variation within farms was considerable and mainly driven by fluctuations in milk yields and forage yields. Higher milk yield per cow was associated with lower emissions per kg ECM, reflecting dilution of maintenance emissions. However, differences in forage quality and composition, replacement rate and manure management influenced total and product-based emissions. The BEK substitution approach for allocation of GHG emissions to milk and meat generated notable emission credits for culled cows and calves, resulting in considerably lower PCFs compared to using a biophysical allocation method. While the use of standard emission factors improves practicability and comparability, it reduces sensitivity to farm-specific mitigation strategies, particularly in forage production and youngstock rearing. Data quality proved to be a central determinant of robustness. Relevant uncertainties arose from discrepancies between produced and marketed milk, estimation of milk fed to calves (especially in cow–calf systems), and the reliance on default emission factors. Particularly forage production (yields and quality) emerged as key leverage point for mitigation and for farm specific improvements on data quality. This was especially important when grazing was involved due to large uncertainties in assessing the amount of feed intake during grazing in mixed systems including indoor feeding. This underlines the need for precise, farm-individual data and the need for further research into practical and precise assessment of forage yields and feed intake during grazing on farms. Digital data interfaces substantially reduced workload in data generation but revealed structural gaps, particularly regarding feed intake documentation, internal material flows and consistent recording across software systems. In conclusion, standardized yet flexible data frameworks combined with digital interfaces enable comparable and robust PCF calculation for dairy farms. However, methodological assumptions and data quality strongly influence results and mitigation assessment. Farm-individualized forage and herd data are essential to unlock reliable reduction potentials while maintaining practical feasibility for widespread application. V. 2021.

The carbon footprint of Bonsmara cattle grazing Sourish mixed bushveld in South Africa

S. M. Grobler[3], M. Kidson[1], H. T. Pule[2], M. M. Scholtz[3,4]
[1] Agricultural Research Council, Soil Climate and Water, Belvedere str, 0083 Arcadia, South Africa, [2] Agricultural Research Council, Range and Forage, Old Olifantsfontein weg, Irene, 0062 Pretoria, South Africa, [3] Agricultural Research Council, Animal Production, Old Olifantsfontein weg, Irene, 0062 Pretoria, South Africa, [4] University of the Free State, Animal Science, 205 Nelson Mandela Drive, Park West, 9300 Bloemfontein, South Africa

The perception that beef production carries a larger carbon footprint compared with other foods, has a negative impact on the sector. It is therefore essential to obtain local data of the whole system to shed light on the soil-plant-animal interactions relating to the carbon balance of the system. The aim of the study was to establish a realistic baseline carbon footprint for extensive beef production under natural grazing conditions by taking into account enteric methane emissions as well as the grassland and soil carbon components. The study was conducted using 10 multiparous Bonsmara cows grazing approximately 50 ha of undisturbed rangeland in the Sourish mixed bushveld of South Africa. Stocking density was maintained at 0.2 LSU ha^{-1}. Methane emissions were estimated based on the enteric methane emission factor for commercial beef cattle in South Africa (78.9 kg CH_4 LSU^{-1} $year^{-1}$). Annual methane emissions per cow were converted to carbon dioxide equivalents (CO_2-eq) using the 100-year global warming potential (GWP^{100}). Gross seasonal carbon input from the rangeland was determined from above-ground dry matter production measured over the three growing seasons. Veld evaluation was done by both the step-point and quadrant veld evaluation methods. Above- and below-ground carbon stocks were derived using weighted root-to-shoot ratios for grass species, calculated according to their relative abundance in the veld. A carbon fraction of 0.45 was assumed for dry biomass. Dry-season contributions were considered negligible due to minimal plant growth. Net seasonal vegetation carbon was calculated as the difference between gross carbon input and estimated decomposition losses. Soil organic carbon (SOC) stocks were determined to a depth of 60 cm from measured SOC concentration and bulk density. Soil respiration was measured during the growing season to quantify CO_2 release from soil. The seasonal carbon emission fraction (f-emission) was calculated as the ratio of measured soil respiration C-flux to total estimated decomposed carbon, estimating the proportion of decomposed biomass carbon released to the atmosphere. Net seasonal carbon balance (soil + vegetation) was converted to CO_2-equivalents using the IPCC (2006) molecular mass ratio (44/12). Total system CO_2-eq per hectare, including cattle methane emissions combined with soil and vegetation carbon fluxes over a 12-month period, was then calculated. All procedures involving animals were approved by the ARC-API Ethics Committee (APIEC21/12) and conducted under Section 20 authorisation of the Animals Protection Act No. 71 of 1962 (Ref nr 12/11/1/1/15 (2167JD)). The total carbon footprint of the system, including enteric methane emissions from the animals and measured soil and vegetation carbon losses, was approximately 20.5 kg CO_2eq kg^{-1} live weight per year. The total system CO_2eq per ha over a 12-month period is calculated at 244kg CO2eq ha^{-1}. The carbon footprint measured in this study is therefore in line with published values for extensive, low-input rangeland systems under semi-arid conditions. The results show that under semi-arid South African conditions, an extensive beef production system can maintain near carbon-neutral dynamics within the rangeland.

Pre- and post-weaning management and nutritional strategies to increase piglet growth and health

P. G. Lawlor[1]
[1] Teagasc, Pig and Poultry Research and Knowledge Transfer Department, AGRIP, Moorepark, P61 C996 Fermoy, Co. Cork, Ireland

At weaning piglets are confronted with abrupt changes to their physical and social environment. This is accompanied by a growth check and frequently by post-weaning diarrhoea in piglets. Increasing litter size has increased within-litter piglet weight disparity and reduced mean piglet weaning weight, thereby exacerbating the challenge. A number of management and nutritional strategies to increase pre- and post-weaning piglet growth and health and consequently improve post-weaning (PW) outcomes have been proposed. These are particularly important considering recent bans on the use of pharmacological levels of ZnO and in-feed antibiotics. Pre-weaning strategies such as improved pen hygiene, split-suckling, provision of pain relief to sows and creep feeding (in dry pellet and liquid form) can help to reduce mortality, increase weaning weight and improve PW outcomes. Immediately PW, strategies including improved pen hygiene, liquid feeding, increased floor and feeder space allowance and feeding diets with reduced acid binding capacity (ABC) can help to increase PW growth, survival and lifetime growth. These pre- and post-weaning strategies have been evaluated by our group and are reported here. Implementation of an optimized farrowing house hygiene routine reduced the bacterial load in farrowing pens, which led to reduced diarrhoea prevalence and clinical cases of disease, as well as antibiotic and anti-inflammatory usage; all culminating in increased piglet weaning weight. However, intensive split-suckling reduced pre- and post-weaning average daily gain (ADG) and did not impact medication usage. Postpartum administration of the non-steroidal anti-inflammatory drug, meloxicam, to sows is an inexpensive and easily implemented strategy. It reduced clinical cases of disease and medication usage and increased ADG during the first two weeks of life and early PW, culminating in increased final carcass weight. Pre-weaning, liquid feeding increased weaning weight and reduced pre-weaning mortality but had no residual effect on PW growth. Provision of supplemental milk replacer for 10 days PW dramatically increased average daily feed intake and ADG and final carcass weight. However, milk replacer is expensive and its use must be economically justified. Good pen hygiene is considered essential during the PW period; however, optimising PW pen hygiene over that achieved with a basic hygiene protocol conferred no additional growth or health benefits. Doubling the legal floor space allowance during the PW period increased piglet growth by 7.3% to 45 days PW and at this floor space allowance increasing feeder space allowance improved feed conversion efficiency (FCE) by 6.3% between day 27 and 45 PW. Feeding diets without limestone flour for 14 days PW so that their ABC-4 was reduced by 130 meq/kg to ~300 meq/kg increased ADG and improved FCE. Reducing dietary ABC-4 by 230meq/kg to ~ 200meq/kg via dietary inclusion of fumaric acid, during the same period, also improved FCE. In summary, a number of successful management and nutritional strategies exist to improve pre- and post-weaning piglet growth and health. However, strategies should be selected to suit individual production systems and must always be cost-beneficial.

Delayed weaning impacts on piglet gut physiology and metabolism

C. Knudsen[1], S. Ferchaud[2], M. Despeyroux[1], C. Lencina[1], N. Marty-Gasset[1], L. Cauquil[1], A. Juppeau[1], G. Payros[3], Y. Lippi[3], S. Combes[1], M. Beaumont[1]
[1] Université de Toulouse, INRAE, ENVT, GenPhySE, 29 Chemin de Borde Rouge, 31320 Castanet Tolosan, France, [2] INRAE, GenESI, La Gouvanière, 86480 Rouillé, France, [3] Université de Toulouse, INRAE, ENVT, EI-Purpan, Toxalim, 180 Chemin de Tournefeuille, 31300 Toulouse, France

Weaning is defined as the transition from milk to solid feed intake. Under free-range conditions, this transition is gradual from the initiation of solid feed intake between 2 and 3 weeks of age until milk intake ceases completely between 10 and 17 weeks of age. This contrasts with usual practices in conventional pig farming, where weaning is carried out much earlier, between 3 and 4 weeks of age. At this stage, voluntary solid feed intake is very low and the digestive system still immature, making this feed transition to exclusive solid feed very abrupt. This period is often associated with digestive disorders that adversely affect piglet health, leading to increased medication use and a decline in technical and economic performance. The impact of weaning age has been extensively studied in the literature up until 35 days of age, but the effects of delayed weaning in pig farming (>40 days of age), closer to the conditions observed in free-range situations, have been poorly documented, although this practice is becoming more widespread, mainly in organic farming, where specifications require weaning at over 40/42 days of age in the EU. Thus, our study aimed to assess impacts of delayed weaning (49 vs 21 days of age) on the gut physiological and metabolic adaptations of piglets. (Large White x Landrace) x (Pietrain x Duroc) piglets from 10 litters were studied. Within each litter, at 21 days of age, piglets were separated into two groups: conventional weaning at 21 days of age (n=3 per litter, W21, fed exclusively with solid feed) vs delayed weaning at 49 days of age (W49, remaining litter with access to maternal milk until 49 days of age and solid feed). In order to evaluate early and delayed impact of weaning age, 9 piglets per group (sex ratio 50:50, paired within litter with equivalent weight at 21 days of age) were euthanized at 28 and 56 days of age and colon tissue and content were sampled. Microbial response was evaluated through metabolomic analyses by NMR and metagenomic analyses by 16S rDNA sequencing. Host response was evaluated through IgA level measurements and transcriptional analyses by RNA sequencing (RNA-seq). Suckling piglets (W49) were heavier with a shorter colon than weaned piglets (W21) at 28 days of age, while no differences persisted at 56 days of age once all piglets were weaned. The composition and activity of the colon microbiota were altered by weaning age. Colon pH was higher in suckling piglets (W49) associated with a higher level of amino acids and branched chained fatty acids, while short chain fatty acid levels were unaffected by weaning age at 28 days of age. At 56 days of age, no impact of weaning age on pH was observed and modulations of microbial metabolic activity were weak. When looking into the host response to weaning, no impact was observed on IgA levels regardless of age. RNA-seq data evidenced 243 genes that were modulated by weaning age at 28 days of age while solely one was modulated at 56 days of age. Genes involved in mitochondria metabolism, BCAA degradation and absorptive cell differentiation were differentially expressed between suckling and weaned piglets at day 28. Our study showed that weaning age had strong early impacts on gut physiology and metabolism but only weak impacts persisted in later stages of life. These results will be integrated with behavioral evaluations of the piglets and the sows in order to have a global view of the impact of delayed weaning in pig farming.

A fresh start: The effect of hygiene routine in the farrowing room on piglet faecal consistency, performance, and tail damage prevalence

A. Middelkoop[1], J. Boekhorst[2], M. Kleerebezem[2], F. Molist[1]
[1] Schothorst Feed Research, R&D, Meerkoetenweg 26, 8218 NA Lelystad, Netherlands, [2] Wageningen University & Research, Host-Microbe Interactomics Group, De Elst 1, 6708 WD Wageningen, Netherlands

Poor hygiene practices in pig production can lead to reduced growth and an increased risk for disease and damaging behaviour. On the other hand, early-life exposure to sow faeces may support piglet gut microbiome maturation and growth. The objective of the current trial was to evaluate the effects of three hygiene routines in the farrowing room: 1) An incomplete hygiene protocol (water wash) + removal of sow faeces (W); 2) A complete hygiene protocol including washing and disinfection + removal of sow faeces (D); 3) Complete hygiene protocol + no removal of sow faeces (F). Sow faeces was removed twice daily (except for treatment F) for the first 2 weeks post-farrowing. Floor swabs were collected from each farrowing pen before the sows entered the farrowing room to verify differences in hygiene status between hygiene protocols. Each treatment consisted of 16 litters with intact tails (15 piglets/litter), divided over two batches. Piglets were weaned at 29 ± 0.1 days of age, weighing on average 8.4 ± 0.11 kg. All weaner pens were cleaned according to the complete hygiene protocol. After weaning, piglets were mixed within pre-weaning treatment and all pigs were housed and managed similarly, with 18 pens (6 piglets/pen) per treatment group. Pig performance and faecal consistency were analysed using a mixed model with pen as experimental unit. Diarrhoea occurrence and tail damage were scored on individual level and analysed according to a GLM using a multinomial distribution and logit transformed data. Floor swabs showed higher adenosine triphosphate (ATP) levels (W: 1.9 vs. D: 1.1 log10 reflective light units/cm_2; P<0.001), a higher aerobic total bacterial count (W: 931 vs. D: 42; P<0.001) and higher enterococci levels (W: 40.3 vs. D: 7.6; P = 0.01) for the farrowing pens cleaned according to the incomplete versus complete hygiene protocol. These results indicate reduced cleaning efficacy as a result of the incomplete protocol, reflected by increased organic residue and higher bacterial and faecal contamination. No differences were found between the three treatment groups in the farrowing room in terms of faecal consistency, diarrhoea prevalence, litter size at weaning, growth or weaning weight. W-piglets had a higher pre-weaning intake of solid feed than F-piglets (17 vs. 11 g/piglet/d; P=0.04) and a higher prevalence of tail damage at 2 weeks of age (2.6 vs. 0.4%; P = 0.02). Post-weaning morbidity (6 piglets) and mortality (1 piglet) was low. After weaning, W-piglets ate and grew faster than D-piglets in weaner phase I and II, as well as the total period (ADFI: 563 vs. 523, P<0.01; ADG: 445 vs. 404; P<0.001). F-piglets performed similarly as D-piglets in phase I, grew similarly as W-piglets in phase II, and had intermediate growth in the total period. At D28 post-weaning, W- (+1.1 kg) and F-piglets (+0.7 kg) weighed more than D-piglets (P<0.01). No significant effects on feed efficiency or faecal score were observed after weaning (P>0.05). At 2 weeks post-weaning, W-piglets had the highest prevalence of tail damage (W: 7%, D: 4%, F: 0%; P<0.001). Results of the current study suggest that early microbial exposure may influence both behavioural development and post-weaning performance. Analysis of the piglets' microbiome from rectal swabs remains to be conducted, and may help to explain the observed differences among the experimental groups. This research is part of PPP-project Gut2Go, which receives 50% of its funding from public sources through the TKI Agri & Food programme (Top Consortium for Knowledge and Innovation in Agri & Food).

Pre-Weaning Supplementary Milk Enhances Post-Weaning Feeding Behaviour and Growth Performance in Piglets

F. González-Solé[1], L. Sobrevia[1], L. Blavi[1], A. Koppenol[1], S. Tibble[1]
[1] AB Neo, PL Fraga, C/ Comunidad de Murcia, parc. LIE-1-03, 22520 Fraga, Spain

Early feed intake after weaning is critical for piglet health and performance, yet heavier piglets often show delayed adaptation to solid feed. This study evaluated the effects of pre-weaning supplementation with a complementary milk on post-weaning feeding behaviour and growth. Twenty-six sows were assigned to either a control group or a group whose litters received complementary milk replacer (Danmilk Supreme® via the Pump'n'Grow cup system, AB Neo) from day 7 to 18 of lactation. All litters received a prestarter diet from d14 of lactation to weaning. From each litter, the two smallest (S; excluding stunted/IUGR pigs) and two heaviest (H) piglets were selected and eart-agged the day before weaning, resulting in a 2 × 2 design: small vs. heavy piglets and complementary milk (Milk) vs. control (Con). At weaning (day 24), piglets were transported to an experimental facility equipped with an electronic feeding system that continuously recorded individual feed intake, water intake, and body weight. Each group was assigned to a single pen and all pigs had ad libitum access to the same prestarter diet offered in the farrowing house. However, unequal group sizes and body weights occurred because some ear-tagged piglets could not be located within the full batch after transport to the nursery site, particularly in the small-weight category (S+Milk: 13 pigs, 6.1 ± 0.81 kg of body weight (BW); S+Con: 21 pigs, 4.9 ± 1.04 kg BW; H+Milk: 25 pigs, 8.25 ± 0.83 kg BW; H+Con: 22 pigs 8.8 ± 1.21 kg BW). During days 0–14 post-weaning, milk-supplemented pigs displayed numerically higher average daily gain (ADG) than their respective controls, with S+Milk outperforming both S+Con and H+Con groups (S+Milk: 184 g/d^{a}; S+Con: 98 g/d^{b}; H+Milk: 151 g/d^{ab}; H+Con: 108 g/d^{b}; $p = 0.002$). During this period, average daily feed intake (ADFI) was also higher in Milk-supplemented pigs than in controls (S+Milk: 222 g/d^{a}; S+Con: 157 g/d^{b}; H+Milk: 219 g/d^{a}; H+Con: 152 g/d^{b}; $p = 0.047$). Across the 42-day post-weaning period, S+Milk pigs showed greater ADFI ($p = 0.017$) than S+Con pigs (603g/d vs 461g/d) and both Milk-supplemented groups showed a tendency for improved growth compared with their respective control groups (S+Milk: 407 g/d^{x}; S+Con: 334 g/d^{y}; H+Milk: 398 g/d^{x}; H+Con: 352 g/d^{y}; $p = 0.066$). Marked differences in early feeding behaviour were observed. Small pigs receiving DanMilk exhibited the shortest latency to first feed (mean= 7.7 h), compared with S+Con (12.3 h), H+Milk (15.9 h), and H+Con (27.6 h). The time-to-event analysis confirmed that H+Con pigs required more time to initiate feeding than both small pig groups ($p < 0.05$). During the 24-hour period following each pig's first feeding event, S+Milk pigs consumed more feed (S+Milk 213g^{a}, S+Con 153g^{ab}, H+Milk 127g ^{ab}, H+Con 78g ^{b}; $p = 0.003$) and performed more feeder visits involving feed consumption (S+Milk: 10.8^{a}, S+Con 6.5^{ab}, H+Milk 6.6^{ab}, H+Con 4.4^{b}; $p = 0.006$) than H+Con pigs. Overall, pre-weaning milk supplementation (Danmilk Supreme®, AB Neo) improved early post-weaning feeding behaviour and supported enhanced growth in both small and heavy pigs. Small pigs consistently demonstrated faster adaptation to solid feed than heavy pigs, with the greatest benefits observed in Milk-supplemented small pigs. Interpretation should, however, consider confounding effects from unequal starting body weights and group sizes, particularly within the small – milk supplemented group.

Dietary supplementation with sodium butyrate and plant extracts to optimize the weaning process and productive outcome in piglets

J. Muñoz-Grein[1], A. H. Checkikene[1], M. Á. Latorre[1], A. Belanche[1]
[1] University of Zaragoza, Department of Animal Production and Food Science, Miguel Servet 177, 50013 Zaragoza, Spain

The post-weaning period in piglets is characterized by gastrointestinal immaturity, microbial instability and inflammatory responses, which may impair nutrient utilization and intestinal homeostasis. Following the ban of antibiotic growth promoters and zinc oxide, alternative nutritional strategies are needed. Several nutritional approaches, such as butyrate or plant extracts, have shown promising results when used individually, however their potential combined effects remain largely unexplored. The objective of this study was to investigate the effects of dietary supplementation with sodium butyrate (BU), a plant extract blend (PE) containing turmeric, green tea, Scutellaria baicalensis and sodium gluconate, and their combination as strategies to optimize the post-weaning in piglets. A total of 120 male piglets (22–25 d of age; 6.8±1.2 kg) were randomly allocated to four dietary treatments in a 2×2 factorial design: control (BU−PE−), sodium butyrate (BU+PE−), plant extract (BU−PE+), and their combination (BU+PE+), with five pens per treatment with homogeneous animal size. Additives were included at 3 g/kg in the pre-starter diet (day 1-14 post-weaning) and 2 g/kg in the starter diet (d 15–44). Growth performance, diarrhoea incidence and morbidity were recorded weekly. Feed digestibility, blood biochemical and cytokine profiles, gastrointestinal fermentation parameters, and ileal histomorphology were assessed at the end of each phase. Results showed that during the pre-starter phase, PE supplementation increased nutrient digestibility (+1.2% for DM, +1.7% for CP, + 3.0% for EE and +12% for NDF, $P < 0.05$). Supplementation with BU reduced blood concentration of pro-inflammatory cytokines such as IL-8, GM-CSF and IFNγ. The combination of both additives tended to decrease the concentration of IL-6, suggesting a superior intestinal health. Regarding gut fermentation, BU supplementation increased total VFA concentration in the stomach, particularly butyrate. Supplementation with either additive alone increased ileal ammonia-N concentration ($P = 0.025$), whereas PE supplementation increased total VFA concentration in the ileum ($P = 0.024$) and decreased the proportion of branched-chain fatty acids in the cecum (-42%). Histologically, PE supplementation increased the villus height and papilla surface area in the ileum. During the starter period, most of the previously observed effects tended to disappear. Piglets supplemented with BU alone had higher nutrient digestibility (+3.0% for DM, +3.6% for CP, +14.7% for EE a +10.2% for NDF, $P < 0.05$) compared with their un-supplemented counterparts. Moreover, BU supplementation increased blood glucose concentration (+11%), whereas PE supplementation increased total proteins and albumin concentrations, indicating improved energy and protein uptakes, respectively. Blood inflammatory markers, ileal histology and gut fermentation parameters remained largely unaffected during the starter period. Piglets supplemented with BU tended to have a higher VFA concentration in the cecum (+19.8%, $P = 0.080$), which may explain the improved digestibility. In conclusion, this study demonstrated that post-weaning adaptation can be optimized through nutritional interventions. Supplementation with BU reduced inflammatory markers, whereas PE enhanced intestinal epithelium morphology and feed digestibility during the first two weeks after weaning. The combination of both additives did not result in additional improvements, contrary to the initial hypothesis. Further studies are warranted to explore the productive implications under more challenging conditions.

Propionic acid–preserved grain enhances growth performance more effectively than combined butyric acid and resistant starch supplementation in weaned pigs

K. R. Connolly[1], T. Sweeney[2], J. V. O'Doherty[1]
[1] University College Dublin, School of Agriculture and Food Science, Belfied, Dublin 4, D04 V1W8 Dublin, Ireland, [2] University College Dublin, School of Veterinary Medicine, Belfield, Dublin 4, D04 W6Y8 Dublin, Ireland

Weaning represents a critical transition in commercial pig production and is commonly associated with reduced feed intake, immature digestive capacity and instability of the intestinal microbiota, predisposing piglets to post-weaning diarrhoea and impaired growth performance. Nutritional interventions capable of supporting gut function and maintaining performance during this period are therefore of considerable interest. Preservation of grain using organic acids such as propionic acid (PA) may improve feed hygiene, nutrient utilisation and intestinal function. Alternatively, dietary supplementation strategies targeting butyrate supply may enhance epithelial health, either directly through butyric acid (BA) inclusion or indirectly through microbial fermentation of resistant potato starch (PS). The present study evaluated the independent and combined effects of PA-preserved grain and BA + PS supplementation on growth performance, intestinal microbiota composition and hindgut fermentation characteristics in weaned pigs. A total of 144 piglets (28 days of age) were allocated to one of four dietary treatments in a 2 × 2 factorial arrangement consisting of dried grain or PA-preserved grain (4 g PA/kg grain) with or without supplementation of BA (1.5%) and PS (1%). Growth performance was monitored throughout the post-weaning period through measurements of average daily feed intake (ADFI), average daily gain (ADG) and gain-to-feed ratio (G:F). Faecal consistency was assessed twice daily using a 1–5 scoring system to evaluate diarrhoea incidence. On day 8 post-weaning, intestinal tissue and digesta samples (n = 12) were collected for assessment of intestinal morphology, microbial composition and volatile fatty acid (VFA) concentrations. Feeding PA-preserved grain increased ADFI, ADG and final body weight compared with dried grain diets ($P < 0.05$), despite higher dietary deoxynivalenol concentrations. PA-preserved grain also altered hindgut microbial composition, increasing the relative abundance of several fibre-fermenting and butyrate-associated bacterial genera, alongside increases in proteolytic bacterial taxa and colonic branched-chain fatty acid concentrations ($P < 0.05$). These changes were accompanied by a higher incidence of diarrhoea compared with pigs offered dried grain diets ($P < 0.05$). Across grain types, BA + PS supplementation increased the abundance of butyrate-producing bacteria, including Roseburia and Faecalibacterium, and increased total VFA concentrations in caecal digesta ($P < 0.05$). However, BA + PS supplementation did not influence growth performance or faecal scores ($P > 0.05$). A significant grain × supplementation interaction was observed for G:F ($P < 0.05$), whereby BA + PS improved feed efficiency in pigs fed dried grain but not in those receiving PA-preserved grain. In conclusion, PA-preserved grain exerted the strongest overall effects on post-weaning growth performance and hindgut fermentation, indicating its potential as an effective nutritional strategy to support piglet performance after weaning. Supplementation with BA + PS may provide complementary benefits in conventional dried grain diets through enhancement of butyrate-producing microbial populations and improved feed efficiency, although additive effects were not observed when combined with PA-preserved grain.

Berry Good for the Gut: The effect of Aronia melanocarpa and Ribes nigrum Pomace Mix on Oxidative Stress and Gut Health in Weaned Pigs Challenged with Enterotoxigenic Escherichia coli F18

A. P. Rasmussen[1], S. K. Jensen[1], A. R. Williams[2], K. Jerez-Bogota[1], C. Lauridsen[1]
[1] Aarhus University, Blichers Alle 20, 8830 Tjele, Denmark, [2] University of Copenhagen, Grønnegårdsvej 7, 1870 Frederiksberg, Denmark

During the weaning transition, pigs face multiple stressors, such as abrupt dietary changes, housing transitions, and infections with enteric pathogens such as enterotoxigenic Escherichia coli (ETEC), which collectively cause oxidative stress and increase the risk of developing postweaning diarrhea (PWD). To control PWD, pigs are often treated with antibiotics, however reducing antibiotic use is essential given the globally growing problem of antimicrobial resistance (AMR). Dietary antioxidant supplementation may mitigate oxidative damage and enhance endogenous antioxidant enzymes. Berry pomace, a by-product of juice production, is rich in bioactive compounds with antioxidative, anti-inflammatory, and antimicrobial properties, making it a promising nutritional strategy to support pig health and oxidative status during this critical transition. This study aimed to investigate the effect of supplementation with a mixed berry pomace derived from Ribes nigrum and Aronia melanocarpa on the oxidative status and gut health of pigs postweaning. 72 newly weaned 26-day-old pigs (body weight (BW) = 6.3 ± 1.48 kg) were randomly assigned to four dietary treatments: standard weaner diet (CON), CON + berry pomace (50 g/kg feed; MIX), CON + challenged with ETEC F18 (CON_ETEC), and MIX + challenged with ETEC F18 (MIX_ETEC). The experiment was conducted in two blocks, each lasting 17 days postweaning. Pigs were housed in mixed-litter, mixed-sex pens of three. On days 4 and 5 postweaning, piglets in MIX_ETEC and CON_ETEC received an ETEC inoculum orally (5 ml of 10^9 CFU/ml; strain O138 F18-ETEC 9910297-2STM), while CON and MIX received phosphate-buffered saline. Feed intake was recorded daily, BW weekly to calculate average daily feed intake (ADFI), average daily gain (ADG), and gain to feed ratio (G:F). Fecal samples were collected every second day to assess diarrhea occurrence. On day 10 postweaning, one pig from each pen was euthanized, and tissue samples from the small intestine (SI; at 50% length) were collected for analysis of oxidative stress biomarkers (malondialdehyde (MDA) and superoxide dismutase (SOD)). The remaining two pigs in each pen were euthanized on day 17 postweaning, and SI samples were collected for MDA and SOD. Pigs from groups supplemented with berry pomace (MIX and MIX_ETEC) had a higher BW on day 17 ($p < 0.05$) compared to CON and CON_ETEC. MIX tended to have a higher ADFI from day 11 to 17 postweaning ($p = 0.09$) compared to CON. MIX tended to have a lower G:F from day 11 to 17 postweaning ($p = 0.06$) compared to CON, but had no statistical difference in ADG. No statistical differences in ADFI, ADG, or G:F were observed between CON_ETEC and MIX_ETEC. MIX_ETEC tended to have a higher fecal DM from days 10 to 14 postweaning ($p = 0.097$) compared to CON_ETEC. MDA concentrations in SI tissue did not differ between MIX and CON on day 10 or 17 postweaning. MIX_ETEC had a lower MDA concentration in SI tissue on day 10 ($p = 0.01$) compared to CON_ETEC; however, no difference was observed on day 17 postweaning. Regardless of the ETEC challenge, no difference in SOD activity was observed in SI tissue on either day 10 or day 17 postweaning. In conclusion, diets supplemented with berry pomace mitigate oxidative stress biomarkers, shown by reduced SI tissue MDA concentration in challenged pigs compared to control pigs, and indicate faster post-ETEC recovery in pigs receiving berry pomace compared with controls. This project is part of the PIG-PARADIGM project, funded by the Novo Nordisk Foundation under grant number NNFSA210073688.

Impacts of encapsulated amino acids on growth performance, gut microbiota, and the caecal metabolome in weaned pigs

F. Correa[1], D. Luise[1], T. Chalvon-Demersay[3], D. Guillou[2], P. Trevisi[1]
[1] University of Bologna, Department of Agro-Food Sciences and Technologies, Viale Fanin 46, 40127 Bologna, Italy, [2] EUROLYSINE, Rue de Monceau 11, 75008 Paris, France, [3] METEX ANIMAL NUTRITION, Rue de Monceau 11, 75008 Paris, France

Piglets encounter post-weaning challenges that significantly affect growth performance and gut health. Amino acids (AAs) can be considered potential prebiotic able to modulate gut microbiota and serve as precursors for functional molecules potentially enhancing animals'robustness. Their encapsulation could increase their availability in the hindgut where microbes are abudant. This study evaluated the effects of encapsulated AAs on growth performance, cecal metabolome and metagenome of weaned pigs. A total of 168 weaned pigs (28 days old), housed in 56 pens, were assigned to seven dietary treatments: 1) a Control group (standard weaning diet) and six groups receiving encapsulated AAs: 2) lysine (Lys, 2 kg/t), 3) tryptophan (Trp, 2 kg/t), 4) branched-chain AAs (BCAA, 2 kg/t), 5) combination of Lys (1 kg/t) and Trp (1 kg/t) (Lys + Trp), 6) combination of Lys (1 kg/t) and BCAA (1 kg/t) (Lys + BCAA), 7) combination of Trp (1 kg/t) and BCAA (1 kg/t) (Trp + BCAA) on top to the basal diet. Body weight (BW), average daily gain (ADG), feed intake (FI), and feed-to-gain ratio (F:G) were recorded weekly. At d14 and d28, one piglet per pen was euthanized for collecting gut content in ileum, caecum and colon. Free AAs were quantified in ileum content and faeces at day 28 by HPLC. Cecal microbiota was analyzed using shotgun metagenomics, and cecal metabolomics was performed by UPLC-MS/MS (Metabolon Global Discovery Panel) at day 28. Although BW and FI did not differ among treatments, ADG and F:G improved during days 21–28 in the BCAA and Trp + BCAA groups compared with the Control ($P < 0.05$). Free Trp concentrations were higher in the ileum of the Trp group compared with the Control ($P < 0.05$). However, Trp disappearance (ileal Trp – faecal Trp) did not differ among groups, suggesting targeted release and utilization. Global microbial diversity indicators did not differ across treatments, however metagenomic analysis revealed an increased relative abundance of Kahnovirus in the Trp group, Flintibacter sp. KGMB00164 in the BCAA group, and Roseburia hominis in the Trp + BCAA group (LDA > 3, $P < 0.05$). For metabolomics, the two-component sparse partial least squares discriminant analysis (sPLS-DA) model (Balanced error rate = 0.78) showed clear separation of BCAA and Trp from the Control. Component 1 was mainly driven by lipid metabolites, particularly glycerophospholipids, discriminating the BCAA group. Pathway analysis confirmed significant enrichment of lysophospholipid and long-chain polyunsaturated fatty acid metabolism ($P < 0.001$). In contrast, Lys was associated with metabolites linked to glutathione metabolism ($P < 0.01$), indicating modulation of redox pathways. Component 2 primarily differentiated the Trp group through nitrogen-related metabolites, with enrichment of sphingomyelin and dinucleotide metabolism ($P < 0.05$). The Trp+BCAA group also showed shifts in lysophospholipid ($P < 0.01$) and pyrimidine metabolism ($P < 0.05$). Encapsulated AAs, particularly BCAA and Trp + BCAA, improved ADG and F:G during the last experimental week (d21–28). Beyond this period-specific effect, they modulated the gut microbial ecosystem and cecal metabolic environment, especially lipid, nitrogen, and redox pathways. These results suggest that encapsulated AA can influence microbial and metabolic functions in weaned pigs, potentially supporting post-weaning robustness.

Effect of increasing dietary lysine level on transcriptomic profile in pig longissimus thoracis muscle following a period with dietary protein restriction after weaning

R. Ruggeri[1], M. Sharma[2], M. Girard[3], P. Silacci[4], G. Bee[3], C. Larsen[2], A. R. Williams[2], J. G. Madsen[2]
[1] University of Bern, Vetsuisse Faculty, Bremgartenstrasse 109a, 3001 Bern, Switzerland, [2] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 15, 1870 Frederiksberg C, Denmark, [3] Agroscope, Swine Research Group, Route de la Tioleyre 4, 1725 Posieux, Switzerland, [4] Agroscope, Animal Biology Research Group, Route de la Tioleyre 4, 1725 Posieux, Switzerland

Lysine (Lys) is a building block for muscle protein synthesis and the most limiting amino acid (AA) in weaning diets. It is unclear how increasing dietary Lys levels affects molecular mechanisms in muscle, after dietary crude protein (CP) restriction during the early weaning period. Low protein (LP) pigs were fed a CP/essential AA (EAA)-restricted diet (−20% CP vs. standard (STD) CP level) during weeks 1–4 after weaning (W1–4). During weeks 5–8 after weaning (W5–8), pigs received diets with dietary Lys and other EAA increased by 10% (LP-STD10+, N = 12) or 20% (LP-STD20+, N = 12) above the standard level (LP-STD, N = 12) to evaluate the effect of increasing AA levels. A control group (STD-STD, N = 12) was not restricted in dietary CP during W1–4 and received a standard CP diet during W5–8. At the end of W8 all pigs were euthanized and tissue samples from the longissimus thoracis muscle were collected for transcriptomic profiling by RNA-seq. Differential gene expression was analysed using DESeq2 (R Project), and pathway enrichment evaluated using gene set enrichment analysis (GSEA; Broad Institute). Results were considered significant at adjusted $p < 0.05$ (DESeq2) and $q < 0.05$ (GSEA). In LP-STD vs. STD-STD pigs, the metabolic adaptation genes FGF21 and PDK4, alongside HABP2, were up-regulated ($P < 0.05$), and the metabolic, immune and nutrient regulating genes SSH3, ARG1 and STRA6, were down regulated ($P < 0.05$). A significant suppression ($P < 0.05$) of pathways related to general metabolism, steroid hormone biosynthesis, and AA metabolism was observed in LP-STD vs. STD-STD pigs. On the contrary, the oxoacid and organic acid metabolic process and apical plasma membrane pathways were relatively enriched ($P < 0.05$) in LP-STD vs. STD-STD pigs. In LP-STD10+ and LP-STD20+ vs. LP-STD pigs, the immune regulating genes TREM2, BTK and DOCK2, and CD14, CCR1 and NCF1 were up regulated ($P < 0.05$), and the AA metabolism genes ASNS, SLC7A5, and MIOX, and FGF6, ARG2 and PSAT1 were down regulated ($P < 0.05$). In LP-STD10+ and LP-STD20+ vs. LP-STD pigs, the cytokine-cytokine receptor interaction and chemokine signalling, and B cell receptor signalling pathways were activated ($P < 0.05$), while the regulation of immune system process pathway was relatively enriched ($P < 0.05$). On the contrary, biosynthesis of AA was suppressed ($P < 0.05$) in both LP-STD10+ and LP-STD20+ vs. LP-STD pigs. In LP-STD10+ and LP-STD20+ vs. STD-STD pigs, genes related to metabolic regulation and stress signaling (TXNIP, SOG3, PDK4) and to apoptotic/tissue-response pathways (ANXA8, DEDD2, DMRTA1) were upregulated ($P < 0.05$), while metabolic genes PSAT1, QPRT, PLPP4, and PAPPA, FGF6 and TOPAZ1 were down regulated ($P < 0.05$). In LP-STD10+ and LP-STD20+ vs. STD-STD pigs, GSEA analysis showed the inflammatory mediator regulation of transient receptor potential channels pathway, and chemokine signalling pathway was activated, while pathways involved in oxoacid and organic acid metabolic process, and icosanoid transmembrane transporter activity and xenobiotic transmembrane transporter activity were relatively enriched ($P < 0.05$). The results suggest that increasing the dietary Lys and other EAA levels after a dietary CP restriction modulates muscle metabolism, with potential implications for health and performance.

Supplementation of His and Arg during the nursery phase improves gut health in weaning piglets fed low crude protein diets.

A. J. Galindo[1,2], D. Solà-Oriol[2], M. Paniagua[1]
[1] Quimidroga SA, Technical Department, Tuset 26, 08006 Barcelona, Spain, [2] Universitat Autònoma de Barcelona, Department of Animal and Food Science, SNiBA, Travessera dels Turons, 08193 Bellaterra, Spain

Post-weaning diarrhea (PWD) is still a major challenge in the swine industry, causing mortality and growth retardation in piglets. In front of the recent ban of ZnO, reducing dietary crude protein (CP) level can be a useful strategy to control PWD. However, growth performance may be impaired despite balancing essential amino acids (AA). Histidine (His), an essential AA, and arginine (Arg), a conditionally essential AA, are involved in important metabolic pathways associated with immune response and intestinal health and may help to enhance gut function under low CP feeding conditions. Fecal calprotectin has been shown to be a non-invasive biomarker of intestinal inflammation in piglets. Therefore, it was hypothesized that providing His and Arg above nutrient requirements would benefit weaned piglets fed low CP diets. This study evaluated the effects of 38% SID His:Lys and 95% SID Arg:Lys ratios on growth performance and gut health parameters. Distributed in two batches, 552 weaning piglets (DanBred × Pietrain; initial BW 6.2 ± 0.67 kg) were randomly allocated into 23 mixed-sex pens (12 pigs/pen). Four diets were offered from 0 to 15 days (phase 1) and two from 16 to 42 days (phase 2). Dietary treatments of phase 1 were arranged in a 2×2 factorial design with CP level (14% vs 16%) and the addition or not of His and Arg (no vs FAA) as main factors. All diets were balanced with all essential crystalline AA according to the FEDNA (2013) guidelines. His and Arg were supplemented to achieve 38% SID His:Lysine (Lys) and 95% SID Arg:Lys ratios in FAA treatments. During phase 2, two diets of 18%CP with or without FAA were offered according to the previous treatments. BW and FI were assessed on days 0, 15, 28 and 42 of the trial. ADG, ADFI ang G:F ratios were calculated for each period. On day 15 blood and fecal samples were collected for analysis of serum urea nitrogen (SUN) and calprotectin. Fecal score was registered every 2 days according to Hu et al (2012). Data were analyzed using the lmer package of the R software considering CP level, FAA and their interaction as fixed effects and batch included as a random effect. No CP*FAA interaction was detected ($P>0.05$). When significant effects were observed, post hoc comparisons were performed using Tukey's test with R software. Increasing CP level positively affected growth performance parameters during phase 1, with higher BW ($P<0.05$), ADG ($P<0.01$) and G:F ratio ($P<0.01$). SUN concentrations tended to decrease with CP reduction ($P=0.080$), suggesting a limitation in nitrogen availability in 14%CP diets despite adequate AA balance. In contrast, the increased ratios of His and Arg did not markedly affect growth but tended to increase ADFI ($P=0.089$) and reduce diarrhea incidence during phase 1 ($P=0.073$) and the overall experimental period ($P=0.061$) which was supported by the lower concentrations of fecal calprotectin ($P<0.05$). In conclusion, SID 38% His:Lys and SID 95% Arg:Lys ratios showed beneficial effects on gut health parameters while maintaining growth performance in piglets fed low CP diets. These results highlight the functional roles of these amino acids in mitigating PWD under protein-restricted conditions.

Impact of a bioactive additive as an alternative to antibiotic growth promoters on growth performance, gut health, and inflammatory response in weaning piglets

A. J. C. Buzatto[1], G. Zigovski[1,4], I. C. C. Bez[1,4], M. R. R. Catoia[1,4], G. M. D. O. Júnior[2,4], P. L. D. O. Carvalho[3], L. B. Costa[1,4]

[1] Pontifícia Universidade Católica do Paraná, Grad. Program in Animal Science, Imac. Conceição St, 1155, 80215-901 Curitiba, Brazil, [2] Federal University of Sergipe, Dept. of Animal Science, Av Marcelo Deda Chagas, 49107-230 São Cristóvão, Brazil, [3] Western Paraná State University, Dept. of Animal Science, Pernambuco St, 1777, 85960-128 Marechal Cândido Rondon, Brazil, [4] MonoHub–Research Group for Monogastric Animals, Imac. Conceição St, 1155, 80215-901 Curitiba, Brazil

After weaning, piglets face physiological, nutritional, and immunological challenges, which often lead to impaired gut health and weight loss. To mitigate these adverse effects, antibiotic growth promoters (AGPs) were introduced into animal production; however, their use has stimulated bacterial resistance. The search for alternatives is constant, with acidifiers and essential oils emerging as promising possibilities due to their antimicrobial and immunomodulatory effects. Thus, this study aimed to evaluate a microencapsulated bioactive additive composed of acidifiers (citric, fumaric, malic, and phosphoric acids) and essential oils (thymol and carvacrol) as an alternative to AGPs on the performance, gut health, and inflammatory response of weaned piglets. We hypothesized that, due to its positive properties, the bioactive additive would show equal or superior effects compared to the AGP. The 43-day experiment involved 120 piglets blocked by initial weight and sex. Animals were randomly assigned to five treatments (8 replicates, 3 piglets/pen): negative control (NC, basal diet), positive control (PC, basal diet with 120 mg/kg chlorohydroxyquinoline), and the basal diet supplemented with the additive at 200, 400, and 800 mg/kg (NC200, NC400, and NC800, respectively). Piglets were weighed on days 1, 7, 14, 28, and 43 to determine body weight, average daily gain, average daily feed intake, and feed conversion ratio. On day 41, fecal samples were collected from piglets with body weights closest to the block average (8 animals per treatment; $n = 40$) to determine counts of total and thermotolerant Enterobacteriaceae and lactic acid bacteria. Blood samples were collected from the same animals to measure interleukin-6 (IL-6) and interleukin-10 (IL-10) concentrations. Data were analyzed via GLM for linear and quadratic effects, using Dunnett's test for PC comparisons. Cytokines were assessed by Kruskal–Wallis and Mann–Whitney tests. Significance was set at $p < 0.05$, with trends at $0.05 \leq p \leq 0.10$, using SPSS software. Results showed that additive levels were comparable to the PC in terms of growth performance ($p > 0.05$). Additionally, a positive linear effect was observed for lactic acid bacteria counts as inclusion levels increased ($p = 0.031$), while NC200, NC400, and NC800 tended to have higher counts compared to the PC group ($p = 0.061$). This finding may be related to the ability of the acidifiers to reduce luminal pH, favoring the establishment of beneficial populations. Regarding the inflammatory response, the two highest additive levels (NC400 and NC800) showed a trend toward reduced IL-6 levels compared to the PC ($p = 0.057$). This result demonstrates synergistic actions of the bioactive additive; besides positively modulating the microbiota, it suggests a potential to attenuate cytokines associated with increased intestinal permeability and bacterial translocation. In conclusion, the microencapsulated bioactive additive performs similarly to the AGP regarding growth performance, while exhibiting superior effects on gut health and inflammatory response by stimulating lactic acid bacteria proliferation and potentially reducing pro-inflammatory cytokines.

Late lactation represents the main time-window for sow-to-piglet transmission of persistent gut strains

M. Pomies[1,2], G. Agoutin[1], L. Auer[2], A. Castinel[3], O. Bouchez[3], C. Achard[4], H. Quesnel[5], G. Pascal[1], S. Combes[1]

The gut microbiota plays a key role in the health of piglets. Microbiota transmission from mother to offspring could be a relevant leverage to shape microbiota of piglets for preventing post-weaning digestive disorders. This study aims to better characterize the mother-to-offspring microbiota transmission and persistence by using a metabarcoding approach based on long-read sequencing of the 16S-ITS-23S region. Fecal samples were collected from 17 families, each including one sow and three piglets, sampled at different stages: 110 days of gestation, early (d6) and late lactation (d28) for the sow; early lactation (d6), late lactation (d28), and 5-day post-weaning for the piglets (n = 204 samples). Amplicons were generated following the PacBio Barcoded Overhang Adapters protocol. Sequencing was performed on a PacBio Sequel II system using HiFi long-read technology. Reads (n = 11,550,265) were analyzed using the FROGS 5.1 pipeline for long reads. To achieve near-strain-level resolution and analyze the temporal dynamics and vertical transmission of the microbiota, a putative strain (PS) reconstruction method was developed to group ASVs (Amplicon Sequence Variants, n = 6064) affiliated with the same bacterial species based on their covariance across the whole dataset ($r \geq 0.9$, n = 4857 PS). As expected, the diversity of the piglet microbiota, initially distinct, converged toward that of the sows by the end of lactation with a progressive diversification during lactation. Within individual sows, 27 ± 6% of the PS were persistent from late gestation until the end of lactation. In piglets, only 4.2 ± 2.5 % of PS were detected both at d6 and d28 and remained present until 5 days after weaning. Persistent PS in piglets were affiliated predominantly to Limosilactobacillus reuteri, Lactobacillus amylovorus, Holdemanella porci, Bifidobacterium pseudolongum, Limosilactobacillus mucosae, and Romboutsia ilealis. The PS shared between piglets and sows were significantly higher within the same family than between unrelated piglets and sows at all stages ($p < 0.05$), except when piglets were at the end of lactation (d28) and sows were at the end of gestation. The PS shared from the sow to its own piglets was the highest at the end of lactation (35 ± 7% and 29 ± 6% in piglets at d28 of lactation and 5 days after weaning). Finally, 2.7 ± 1.6% and 15.4 ± 5.6% of the PS transmitted by the sow persisted in piglets from day 6 of lactation to 5 days after weaning, and from day 28 of lactation to 5 days after weaning, respectively. For the latter window (day 28 of lactation to 5 days post-weaning), the species most frequently associated with transmitted and persistent PS across all pig families were Sodaliphilus sp004557565 (109 distinct PS), Sphaerochaeta globosa (20 PS), and Cryptobacteroides sp900316045 (40 PS). These results highlight the contribution of maternal transmission to the establishment of the post-weaning piglet gut microbiota and suggest late lactation as a key window for sow-to-piglet microbiota transfer.

Lactobacillus postbiotic in gestating and lactating sows: effects on sow microbiota, colostrum omics composition, litter growth and health

B. Polimeni[1], F. Correa[1], D. Luise[1], G. Rocchetti[2], A. Serra[3], P. Trevisi[1]
[1] University of Bologna, Department of Agricultural and Food Sciences, Viale G. Fanin 46, 40127 Bologna, Italy, [2] Università Cattolica del Sacro Cuore, Piacenza and Cremona Campus, Department of Animal Science, Food and Nutrition, Via Emilia Parmense 84, 29122 Piacenza, Italy, [3] University of Pisa, Department of Agriculture, Food and Environment, Via del Borghetto 80, 56124 Pisa, Italy

Nutritional management of the sow during late gestation and lactation plays a pivotal role in promoting both maternal and piglet performance. Targeted nutritional strategies during these critical phases can influence multiple parameters, including shift in the gut microbiota, colostrum composition and overall piglet growth and health. Among these, postbiotics have emerged as a promising intervention in swine. This study evaluated the effects of gestational and lactational supplementation with Lactobacillus postbiotic (heat-inactivated L. fermentum and L. delbrueckii) on sow and piglet performance, colostrum composition, and gut microbiota. Three weeks before farrowing, 210 sows were assigned to a control group (G0; 42 sows) or a postbiotic-supplemented group (G20; 20 g/t; 168 sows). At farrowing, G20 sows were further allocated to four groups (42 sows/group) receiving 0 (G20-L0), 10 (G20-L10), 20 (G20-L20), or 100 (G20-L100) g/t of postbiotic during lactation. Piglets were weighed at birth (d0), d6, d14, d28 (weaning), and d42 (post-weaning), while mortality and exclusion were daily recorded. Growth performance data were analysed using a linear model, including diet, parity order and batch as factors, litter size and initial body weight (BW) as covariates. Postbiotic supplementation during late gestation (G20) increased piglets' birth weight compared to G0 ($p<0.05$). All postbiotic groups had a higher piglets' BW at d6 compared to G0-L0 ($p<0.001$). At d28, G20-L10 had higher piglets BW than G20-L20 ($p<0.05$), but it did not differ from G0-L0. All postbiotic groups had a higher ADG at d0-d6 than G0-L0 ($p<0.001$). Cumulative mortality during lactation was significantly reduced in G20-L0 and G20-L100 compared with G0-L0 ($p<0.01$). Postbiotic supplementation did not affect immunoglobulins in colostrum. Colostrum fatty acid profiling showed no significant differences between gestation groups. However, a tendency toward a lower HPUFA n-6/n-3 was observed in G20 ($p=0.05$). Multivariate analysis (sPLS-DA) of colostrum miRNAs identified miR-28-5p as discriminative (PC1=0.78) for the G20 group. Metabolomic analysis characterised G20 colostrum with metabolites associated with branched-chain biosynthesis, arginine and proline metabolism, tyrosine metabolism, and glycerophospholipid metabolism. Gestational postbiotic supplementation enhanced sow's faecal microbial richness ($p=0.01$) and beta diversity ($p=0.01$, $R^2=0.06$). Differential abundance analysis highlighted enrichment of Lachnospiraceae, Firmicutes, and Enterococcus faecium in G20, while G0 was enriched in Firmicutes and Bifidobacterium thermophilum. Functional profiling revealed upregulation of pathways related to fermentation and energy metabolism in G20, contrasting with amino acid degradation and thiamine metabolism in G0. In conclusion, postbiotic supplementation in gestation modulated sow gut microbiota and colostrum metabolome, improved early piglet growth, and reduced pre-weaning mortality. The observed microbial and functional shifts suggest enhanced maternal fermentation and energy metabolism, likely involved in changes in colostrum amino acid and lipid pathways relevant for neonatal growth. Overall, these findings support a gut-mammary axis mechanism underlying improved early piglet performance.

Effect of Dietary Zinc Supplementation on Growth Performance and Health of Piglets during the Early Rearing Phase

D. Outor-Monteiro[1,2], T. Skau Nielsen[3], H. Maribo[4], M. Ramis[5], J. Paié-Ribeiro[1], V. Pinheiro[1,2]
[1] University of Trás-os-Montes and Alto Douro, Veterinary and Animal Research Centre (CECAV), Quinta de Prados, 5000-801 Vila Real, Portugal, [2] University of Trás-os-Montes and Alto Douro, AL4Animals, Quinta de Prados, 5000-801 Vila Real, Portugal, [3] Aarhus University, Nordre Ringgade 1, DK-8000 Aarhus, Denmark, [4] Danish Agriculture & Food Council Pig Research, Axeltorv 3, DK-1609 Copenhagen V, Denmark, [5] University of Murcia, C. Campus Universitario 11, 301000 Murcia, Spain

Zinc (Zn) plays a crucial role in immune competence, intestinal integrity and growth performance in piglets, particularly during the critical post-weaning period. Historically, pharmacological levels of zinc oxide (up to 1,500 ppm) were widely used to control post-weaning diarrhea, however, environmental concerns have led to a substantial reduction in the authorized inclusion levels (currently 150 ppm) in Europe. However, during the post-weaning period, piglets have a very low intake of feed, and the 150 ppm Zn may not meet their physiological needs. Recent Danish results suggest that newly weaned pigs have a Zn requirement around 1400 ppm for optimal production, blood Zn status and in terms of minimizing the risk of diarrhea. In contrast, 150 ppm Zn may oversupply older pigs relative to their requirement leading to unnecessary Zn excretion to the environment, without negative effects on production and health, which will reduce the Zn. In the present study, we compared assessed the negative effects of a very low level of zinc in the diet, which does not meet the animal's physiological needs, compromises its health, and may lead to additional antibiotic treatments. In this study, seventy-two weaned piglets (28 days of age) were allocated to two dietary treatments: a control diet containing 150 ppm Zn (CT) and a Zn-supplemented diet containing 1,400 ppm Zn from zinc oxide for two weeks post-weaning. Animals were housed in 12 pens per treatment, with three piglets per pen. Feed intake was recorded daily and body weight weekly. Diarrhea incidence was monitored daily using a 0–3 category fecal consistency score. Performance results were analyzed using a variance test with feed as the variance factor; for diarrhea occurrence results, the T-test was used. The JMP pro 17 program was used for statistical analysis. Average daily gain was significantly higher in the Zn-supplemented piglets during the first week (0.33 vs. 0.28 kg/day; $p = 0.0023$), but final body weight was not affected by treatment ($p > 0.05$). Weekly and overall average feed intake per pig did not differ between treatments ($p > 0.05$). Feed conversion ratio was not affected ($p > 0.05$) and the value obtained was 1.53 (1.58 and 1.47 in the CT and Zn-supplemented group, respectively). Zinc supplementation significantly reduced diarrhea incidence ($p < 0.001$), decreasing the number of affected piglets, the duration of clinical signs and their severity. Overall, for the two weeks of trial, the number of piglets experiencing diarrhea was 30 and 6 in the CT versus Zn-supplemented group, respectively. The increased dietary Zn supplementation during the early post-weaning phase improved short-term growth performance and markedly enhanced gut health by reducing diarrhoeal episodes. These findings suggest that strategic higher Zn supplementation right after weaning may support productive and health stability during this critical transition period. Keywords: Zinc supplementation, diarrhoea incidence, growth performance Acknowledgments: This work was supported by the projects UID/00772/2025, DOI https://doi.org/10.54499/UID/00772/2025 funded by the Portuguese Foundation for Science and Technology (FCT).

Effect of increasing the dietary valine-to-lysine ratio on growth performance of average and slow growing pigs during the weaner period

C. Larsen[1], D. A. Columbus[2], H. M. Hammon[3], J. G. Madsen[1]
[1] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 15, 1870 Frederiksberg C, Denmark, [2] Prairie Swine Centre, Inc., Box 21057, 2105-8 St. E., S7H 5N9 Saskatoon, Canada, [3] Research Institute for Farm Animal Biology (FBN), Metabolic Health Group, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

One fourth of the pig littermates exhibit a slow growth rate from the early weaning phase, resulting in a subset of slow growing (SG) pigs having poorer growth performance during their lifetime than their average growing (AG) counterparts. It has been suggested that increasing the dietary valine (Val) above recommended levels may modulate muscle metabolism leading to improved growth performance. Seventy-two German Large White × Landrace gilt piglets from 18 litters were used in the experiment, with four blocks (farrowing series) needed to complete the experiment. Pigs of average (AG; avg. 235 g/day) and slow (SG; avg. 191 g/day) growth rates were selected based on pre-weaning (day 1-28 of age) growth rates, thus, from each litter two AG and two SG piglets were selected. At weaning (28 days of age) the 36 AG (avg. 8.00 kg BW) and 36 SG (avg. 6.42 kg BW) pigs were, respectively, randomly allocated and evenly distributed (24 pigs per treatment) between three dietary treatments only differing in Val:Lysine-ratio; a control (CON, avg. 7.31 kg BW) with recommended ratio (64%), a treatment with a high ratio (Val-H; 74%, avg. 6.99 kg BW) and a treatment with a very high ratio (Val-VH; 84%, avg. 7.33 kg BW). A three-phase (day 28-35, day 35-49 and day 49-84) feeding regime was applied during the experimental period. Pigs were housed in pens of four animals (two AG and two SG per pen) with ad libitum access to feed and water. The data were analysed by applying ANOVA from the 'nlme' package in R (R Project) using a linear mixed-effects model to estimate BW and average daily gain (ADG). The model included growth category (AG or SG) and dietary treatment (CON, Val-H, or Val-VH) and their interaction as fixed effects, weaning weight as co-variate, and sow and block as random effects. As intended weaning weight differed (7.97 vs. 6.40 kg BW, $P < 0.0001$) between AG and SG pigs. Final body weight (day 84 of age) was greater for AG compared with SG pigs (38.7 vs. 33.5 kg BW; $P < 0.0001$), with similar differences observed at the starting points of the respective phases (days 28, 35, and 49; all $P < 0.0001$). As intended ADG was greater in AG than SG pigs from day 1–28 (235 vs. 191 g/day; $P < 0.0001$). During the second (day 35-49) and last phase (day 49–84) ADG, respectively, tended to be greater and was greater in AG compared with SG pigs (326 vs. 317 g/day; $P = 0.06$ and 640 vs. 601 g/day; $P = 0.02$). Over the entire experimental period (day 28–84) ADG was also greater in AG than SG pigs (525 vs. 443 g/day; $P = 0.027$). The dietary treatment had no effect on final BW or ADG in overall period, but tendencies were observed for ADG during the pre-weaning period (day 1–28) (CON; 216 g/day, Val-H; 201 g/day, Val-VH; 222 g/day, $P = 0.058$) and for BW day 28 (CON; 7.34 kg BW, Val-H; 6.81 kg BW, Val-VH; 7.41 kg BW, $P = 0.05$), had an effect on day 35 (CON; 8.42 kg BW, Val-H; 8.17 kg BW, Val-VH; 8.18 kg BW, $P = 0.0002$), and tendency day 49 (CON; 13.0 kg BW, Val-H; 13.0 kg BW, Val-VH; 13.1 kg BW, $P = 0.06$). No growth category × dietary treatment interaction effects were observed in any of the parameters. In conclusion, the difference in pre-weaning growth rate between AG and SG pigs persisted throughout the weaning period, resulting in greater BW and ADG. Although large numeric differences in final BW and overall ADG were observed between CON and Val-VH SG-pigs (data not shown), no effect of the dietary treatment was found.

Effect of increasing levels of linseed expeller in nursery pig diets containing Carob meal

N. Einhardt Manzke[1], A. Torres[2], A. Balfagon[2], C. Vanderhaeghe[3], G. Mantovani[1], L. Hackenhaar[1], J. De Laat[1]
[1] Cargill Animal Nutrition and Health, R&D, Veilingweg 23, 5334 LD Velddriel, Netherlands, [2] Cargill Animal Nutrition and Health, SMT, Poligono Industrial Riols, 50170 Mequinenza, Spain, [3] Cargill Animal Nutrition and Health, R&D, Bedrijvenlaan 9, 2800 Mechelen, Belgium

The immediate post-weaning period is characterized by reduced feed intake, immature digestive function, and elevated risk of gastrointestinal disturbance, making diet formulation a critical strategy to maintain gut integrity and growth performance. Among those strategies, feeding linseed expeller (LEX, a by-product of oil extraction) and carob meal (CM, from carob pods or germ) can be used as a source of functional compounds such as omega-3 fatty acids, fibers and polyphenols. Those components can increase digesta viscosity and supply substrates for microbial fermentation in the distal gut, potentially affecting colonization resistance and mucosal protection. The objective of this study was to evaluate increasing levels of LEX in diets containing 2% CM on nursery pig growth performance and fecal score during the first 3 weeks post weaning. The study was conducted at the Cargill Animal Nutrition and Health, Global Innovation Center in Velddriel (NL). A total of 288 pigs (23 d; 7.1 ± 0.7 kg BW) were assigned to six treatments (8 pens/treatment; 6 pigs/pen) in a randomized complete block design (block = initial BW; pen = experimental unit). From day 0 to day 21 post weaning, pigs were fed with the following dietary treatments: negative control (NC, 0% carob, 0% linseed), positive control (PC, 2% carob, 0% linseed), or diets with 2% carob and increasing levels of LEX at 1.0, 2.5, 3.5, or 5.0% partially replacing corn and SBM. From day 21 to 39 post weaning all pigs received a common diet without LEX and CM to evaluate any potential carry-over effect. Diets were formulated to provide similar levels of crude protein (21%) and 1.40% SID Lys (NE 2,565–2,587 kcal/kg). Response variables evaluated included ADG, ADFI, G:F, and BW (days 0, 7, 14, 21, 39 post weaning). Fecal consistency was scored at pen level on d 0, 4, 7, 14, 21, 29 on a 4-point scale (from 1 = normal to 4 = watery). Data were analyzed using linear mixed-effects models (lme4 in R; treatment fixed, block random; $\alpha = 0.05$); ordinal mixed models were fitted for scores. During the first week post weaning, pigs fed PC showed greater ADG (0.189 kg, P=0.07) and ADFI (0.189 kg, P=0.09) compared with NC (0.146 kg and 0.155 kg, respectively), and ADG was also greater (+19%, P = 0.08) compared with pigs fed diets containing LEX (0.156 kg). During d0–21, G:F ratio decreased linearly (P=0.01), representing a 3.5% reduction between 1% and 5% of LEX inclusion, while ADG and ADFI did not differ among treatments. During d21–39, ADG (P=0.08) and ADFI (P=0.06) showed quadratic responses to increasing LEX levels, peaking at 2.5% inclusion (0.697 kg and 1.046 kg, respectively) and declining at 5% (0.670 kg and 1.014 kg, respectively). During d0–39, G:F declined linearly in those pigs that received LEX (P=0.03); ADG and ADFI were unaffected. Fecal consistency did not differ; no diarrhea occurred. Given that feed intake during the first week is a key determinant of subsequent piglet growth, early improvements in feed intake with CM suggest that it may stimulate intake and support initial adaptation to weaning. The health status in this trial was high, with low mortality and good fecal scores across treatments. In conclusion, under these high-health conditions, increasing LEX inclusion reduced feed efficiency in a dose-dependent manner and provided no additional benefit beyond CM.

Multi-omics characterization of sow colostrum and faecal microbiota reveals signatures associated with parity, piglet survival and growth

B. Polimeni[1], D. Luise[1], F. Correa[1], G. Rocchetti[2], M. Errico[2], A. Gallo[2], F. Bonelli[3], A. Serra[4], M. Mele[4], P. Trevisi[1]

Fanin 46, 40127 Bologna, Italy, [2] Università Cattolica del Sacro Cuore, Piacenza and Cremona Campus, Department of Animal Science, Food and Nutrition, Via Emilia Parmense 84, 29122 Piacenza, Italy, [3] University of Pisa, Department of Veterinary Sciences, via Livornese snc, 56122 Pisa, Italy, [4] University of Pisa, Department of Agriculture, Food and Environment, Via del Borghetto 80, 56124 Pisa, Italy

Colostrum is essential for neonatal piglet survival and growth, yet its bioactive composition and its relationship with parity and early-life outcomes remain poorly defined. This study aims to characterise the colostrum composition of sows with different parity orders and to identify, using a multiomics approach, the main pathways and bioactive compounds that, together with the microbiota can improve the piglet's survival and average daily gain (ADG) during suckling. Colostrum from 20 sows (7 gilts, 7 second-parity, 6 multiparous) was analysed for proximal composition, immunoglobulins, oligosaccharides, fatty acids (FAs; GC-FID) and untargeted metabolomics (UHPLC-HRMS). Piglet mortality and ADG were recorded until d24, and faecal microbiota (d6, d24) was assessed by 16S rRNA sequencing. Multivariate analyses (sPLS-DA, OPLS-DA) and integrative DIABLO models were applied. Parity did not affect colostrum proximal composition or immunoglobulins, but significantly influenced metabolomic (OPLS-DA: $R^2Y = 0.97$; $Q^2 = 0.52$) and FAs profile (22 discriminated FAs). Gilts had higher abundance of branched-chain FAs, several amino acids (AAs) and peptides (e.g., lysine derivatives), suggesting altered metabolic status. Piglet mortality differed by parity ($P < 0.001$), with second-parity sows showing higher losses. Mortality classes at d 6 were discriminated by 177 metabolites and 2 FAs, and 248 metabolites and 21 FAs at d 24. Both at d 6 and d24 a higher abundance of C18:2 8 trans,10cis discriminated for lower mortality (importance = 1 for d 6 and 0.34 for d 24), whereas increased C22:5n6 characterized higher mortality. Metabolomics pathway analysis indicate arginine biosynthesis and alpha-linolenic acid metabolism as key routes linked to survivability both at d6 and d24. Integrative multi-omics analysis associated lower mortality with higher colostrum C18:2 8trans,10cis, C18:1 5trans, salicylic acid, and increased abundance of Holdemania and Roseburia in piglet faeces. For ADG d0–d24, 151 metabolites and 33 FAs discriminated classes. Higher ADG (>240 g/d) was associated with colostrum vitamin E, histidine, branched-chain AAs and specific anteiso FAs (VIP score > 1). Conversely, L-kynurenine and gamma-aminobutyric acid were linked to lower ADG, suggesting maternal inflammatory or stress-related imprinting. Integrated models (accuracy 55–64%) identified combined metabolic–microbial signatures of higher ADG, involving histidine-related metabolites, anteiso FAs and enrichment of gut taxa Lachnospiraceae UCG-009 and Akkermansia. This study confirms the importance of parity order in shaping colostrum composition and identifies several bioactive compounds, some parity-dependent and others parity-independent, that may be associated with improved piglet survival and growth and gut microbiota maturation. These findings support precision nutritional strategies in sows and provide targets for next-generation artificial colostrum supplements for piglets. FundingResearch was supported by BOOSTcolostrum project (P2022Z-TYLS—CUP J53D23018670001) – NextGenerationEU—Piano Nazionale di Ripresa e Resilienza (PNRR) – DD N. 1409 del 14/09/2022.

Semi-targeted metabolomics to explore potential blood biomarkers of oxidative stress in pigs using an E. coli LPS model

P. A. Madsen[1], K. Jerez-Bogotá[1], D. Vodolazska[1], M. S. Hedemann[1], C. Lauridsen[1]
[1] Aarhus University, AU Viborg, Animal and Veterinary Sciences, Blichers Alle 20, 8830 Tjele, Denmark

Post-weaning diarrhea caused by enterotoxigenic E. coli remains a major challenge in pig production and is a key driver of antibiotic use. Following the ban on therapeutic zinc oxide and increased antimicrobial restrictions in the EU, new solutions have become essential. Infection with E. coli is associated with systemic inflammation and oxidative stress, which can impair intestinal integrity and exacerbate diarrhea. Biomarker-based approaches may support evaluation of nutritional and management interventions to mitigate oxidative stress, improve post-weaning robustness, and reduce antibiotic use. Lipid metabolites have been associated with immune responses and thus may be potential biomarkers for inflammation as well as oxidative stress. The objective of this study was to explore potential lipid oxidative stress biomarkers via semi-targeted metabolomics using a controlled lipopolysaccharide (LPS) challenge model as a proxy for bacterial-induced systemic inflammation observed during post-weaning enteric disorders. Ten healthy juvenile female pigs (3 months old, 25 ± 1 kg) were selected to ensure uniformity and avoid gender-related effects. Serial blood samples were collected from pre-infusion up to 72 h post-LPS challenge. Two concentrations of LPS (0.75 and 1.50 µg/kg BW) from E. coli O111:B4 were administered. A semi-targeted lipid-focused metabolomics approach was applied to explore potential oxidative stress biomarkers. Data were analyzed using multivariate methods to identify metabolites that discriminated across time independently of the LPS dosage. Cortisol was identified at level 1 with a standard and showed a clear response following LPS infusion ($P < 0.001$), peaking at 2 h post-challenge. Plasma cortisol was strongly correlated with rectal temperature across both LPS doses ($r \approx 0.65$, $P < 0.001$), consistent with its role in the inflammatory response. Linoleic acid and arachidonic acid, and the lipid peroxidation marker 8-iso-$PGF_2\alpha$, were identified at level 1, however, they did not show a clear response to LPS. The absence of a clear 8-iso-$PGF_2\alpha$ response may reflect methodological constraints, as omission of alkaline hydrolysis likely limited quantification to free rather than total F_2-isoprostanes. A serotonin-related metabolite, glutamine and an oxylipin 10-HOME were tentatively identified at level 3. A pronounced response was observed for the serotonin-related metabolite at 3 h post-challenge ($P < 0.01$) and for glutamine at 8 h post-challenge ($P < 0.01$), whereas the oxylipin 10-HOME exhibited a rapid but less distinct response at 0.5 h after LPS infusion ($P < 0.01$). Serotonin has been suggested to influence immune cells, while glutamine may serve as a metabolic substrate for lymphocytes and a modulator of pro-inflammatory cytokines. The rapid increase in 10-HOME may indicate involvement in the early inflammatory response to LPS. However, further research is needed to confirm the identity of the tentative metabolites, clarify their role in inflammation and oxidative stress, and to assess their suitability as potential biomarkers during post-weaning enteric challenges. As pigs are particularly vulnerable during the pre- and post-weaning periods, early application of potential biomarkers may serve as an opportunity to maintain gut resilience and avoid the onset of diarrhea by early nutritional intervention. This work is part of the PIG-PARADIGM project, funded by the Novo Nordisk Foundation (NNFSA210073688).

Effect of tannin of Chestnut and MGM-P on early weaning stage of piglets

Z. Yang[1], P. Shi[1], K. Wang[1], M. Ma[2], Y. Enomoto[1], T. Suda[1], J. Li[1]
[1] The University of Tokyo, Graduate School of Agricultural and Life Sciences, Animal Resource Science Center, 319-0206 Kasama, IBARAKI, Japan, [2] The University of Tokyo, Graduate School of Agriculture and Life Science, Veterinary Pathophysiology and Animal Health, 113-8657 Tokyo, Japan

Background In our laboratory has found condensed tannins MGM-P that from Quebracho not only effects on post-weaning diarrhea also improve growth performance of piglets (Ma et al., 2021). The results showed that adding 0.3% concentration of MGM-P demonstrated a better effect in alleviating post-weaning diarrhea than 0.2%. When compere the concentration of MGM-P 0.5% and 1.0% (Ma et al., 2024) found that the 0.5% concentration group had better effects to improve the growth-promoting properties. However, the 1.0% concentration group showed severe anti-nutritional effects, reducing feed conversion efficiency and daily weight gain. Objectives To find the optimal tannin as a feed additive for growth promotion and anti-diarrhea effects and to expect synergistically effect on prevention diarrhea and growth performance the two tannins has conducted. Addition of 0.75% chestnut tannin and combined 0.5% MGM-P and 0.75% chestnut tannin has conducted. Results 1. Growth Performance There are no fatalities occurred during the experimental period. The ADG in 0.75N group was lower than that in the C group. The ADG of the MN group was much lower than that of the C group, but the difference was not statistically significant. Although the ADFI and FCR among the three groups did not show significant differences, the 0.75N and MN groups were showed tendency lower compared to the C group. 2. Blood Hematology Analysis, the RBC levels in both in 0.75N and MN groups at w6 and w7 were significantly lower than those in C group that showed anemia phenomena. 3. The result of WBC levels was significantly lower in 0.75N and MN groups than that in C group at w6. 4. Diarrhea incidence The diarrhea incidence in C group was 41.7%, and 25% in MN group. However, no diarrhea occurred in 0.75N group, significantly lower than that in C group. Discussion & conclusion The present study showed that Chestnut tannin addition level when 0.75% and combined with 0.5% MGM-P showing the tendency negatively affect growth performance. The weekly ADG changes is also showing tendency decrease even if was no significant. The RBC levels from third week, in two tannin-treated group were significantly lower than those of the control group. Ma, Min, et al. (2021,2024) demonstrated that MGM-P even if added from 0.3% to 1.0% there is no anemia phenomena had happened in piglets. Thus, these results might be caused by 0.75% chestnut tannin addition. The WBC showed higher in control group, it might be related with diarrhea, that the incidence of diarrhea in the C group was higher compared to the MN group, and no diarrhea occurred in the 0.75N group, indicating 0.75% chestnut tannin significantly suppresses post-weaning diarrhea. Our study showed Tannins, as a primary component in anti-diarrheal drugs, are known for their astringent and anti-inflammatory properties. This aligns with our findings where the tannin-treated groups, particularly the 0.75% Chestnut group, had dark, harder solid feces, consistent with the fecal moisture measurements showing the lowest moisture content in the 0.75N group. Therefore, the strong anti-diarrheal effect of 0.75% Chestnut tannins in this study is likely due to its astringent properties. The discrepancies between the 0.75% Chestnut results and previous 0.75% MGM-P experiments may be attributed to differences in tannin type, purity, chemical structure, and the timing of creep feed.

The aWISH vision: Improving welfare of pigs and chickens by automated monitoring of animal welfare indicators at slaughter

N. Van Noten[1], F. Tuyttens[1], Awish Consortium[1], J. Maselyne[1]
[1] Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Burg. Van Gansberghelaan 92 bus 1, 9090 Merelbeke-Melle, Belgium

aWISH (Animal Welfare Indicators at the Slaughterhouse) is a four-year Horizon Europe Research & Innovation Action (Grant number 101060818) that started in October 2022. The project responded to a call aiming to support policy makers and other actors, such as business operators, in monitoring and improving the welfare of farm animals, with special attention to automated data collection and exploitation at different levels, ranging from individual farms to regional/national and EU-level. The project focuses on automated monitoring of animal-based welfare indicators at the slaughterhouse with the goal to document and ultimately improve the welfare of broiler chickens and fattening pigs during each production phase (farm, transport and slaughter). This approach was developed in close collaboration with all actors involved, from primary producers up to policy makers and citizens through several workshops, interviews and surveys. Now that the project is nearing completion, an overview of the main achievements, lessons learned and way forward is presented. At the heart of the project are six pilots spread across Europe, where a total of sixteen new sensor technologies were developed, tested and validated. Each pilot consists of a slaughterhouse with a local research partner, associated farms and various technology providers. The four pig pilots are located in the Netherlands, Spain, Austria and Serbia, while the two broiler pilots are situated in France and Poland. For pigs, technologies were developed to measure ear lesions, skin lesions, tail length, tail lesions, blood stress parameters, stress vocalisations, tear staining, stunning effectiveness, environmental parameters, body weight, lung lesions and coughs. The broiler technologies document hock burn, footpad lesions, catching lesions, back scratches, stress vocalisations, activity, environmental parameters, heat stress prediction and an app for on-farm welfare self-assessment. These technologies are mainly installed in slaughterhouses, although some are also installed on-farm. For the new sensor systems, TRL levels currently range from 2 to 7, with an average of 6. To support future implementation, an interactive catalogue of both commercially available technologies and research developments for the routine assessment of pig and chicken welfare indicators, covering the five animal welfare domains, has been developed and is updated half-yearly. Furthermore, two methodologies were developed to aggregate welfare indicator outcomes using expert elicitation: an indicator-based aggregation model and a situation-based model. Sensor data complemented by metadata from focal farms and socio-economic and environmental metrics are stored and processed on a custom-made aWISH data platform. The different actors in the production chain receive feedback on relevant individual and aggregated indicator scores through multiple interactive visualisations and dashboards, allowing, for example, time-series monitoring and benchmarking. The interface also provides users with access to best practice guides to address specific animal welfare problems. The platform is further used to document the welfare status at operator and regional/national level, identify risk and success factors, and investigate the effect of the feedback loop on pig and broiler welfare. Finally, the impact of several welfare-improving initiatives on welfare outcomes and socio-economic metrics was assessed. Further expansion and development of the aWISH approach holds promise for cost-effective monitoring and improvement of the welfare of meat-producing livestock throughout Europe.

Monitoring on-farm welfare by using animal-based indicators at slaughter – past and future

C. Berg[1]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, PO Box 234, 532 23 Skara, Sweden

On-farm animal welfare (AW) inspections can be very useful and is a necessary tool for checking the resources and management provided to the animals, with a focus on prevention of AW related problems, and the state of the animals during different phases of rearing. Nevertheless, in-farm inspections can only provide an instant snapshot, and because such inspections are not carried out that frequently – e.g. for reasons related to resources at the competent authorities – there is an obvious risk that AW problems may go undetected. However, most farm animals will sooner or later end up at the slaughterhouse. This means that animal-based indicators reflecting the on-farm conditions can be assessed at the slaughterhouse, and incorporated into the overall AW control system, in addition to on-farm inspections. One such example is the foot-pad dermatitis (FPD) programme for broilers, which was developed in Sweden in the mid-1990s, and has since been implemented – with or without modifications – in several other countries, by legislation or as part of a private standard. The use of food-pad status as an indicator is also mentioned in the EU Broiler Directive. In Sweden, participation in the foot-pad programme, which is part of a larger animal care programme for broilers, is a legal prerequisite for applying higher stocking densities, and this indicator is used for almost all broiler flocks slaughtered in Sweden each year. The foot-pad status is a relevant indicator of the environment and management of the birds, as it is closely linked to the status of the litter material, reflecting factors such as heating and ventilation management, feed composition, hygiene, water quality and litter management. These factors are highly relevant for the welfare of the birds during a production cycle, and in addition to this severe FPD, i.e. the presence of ulcers on the soles of the feet of the birds, is assumed to be a painful condition. A total of 100 feet (one foot per bird, 50 in the beginning of the batch and 50 at the end) are collected from the slaughter line after bleeding and scored by designated slaughterhouse staff under the supervision of the official veterinarian. Each foot given a score of 0 (no lesion), 1 (mild lesion) or 2 (severe lesion), and by weighing these scores in accordance with a pre-set equation, a total flock score between 0 and 200 is achieved. Depending on this score, it can be concluded that everything is fine, or the producer will receive advice within a set advisory programme. In case of repeated flocks with high total scores, the maximum stocking density for the farm in question may be decreased until the problems have been solved. In very severe cases, the competent authorities may be contacted. When the programme was initiated in 1994, the average FPD flock score was 43. In year 2000, the average score had been decreased to 24. Further efforts were made to optimize litter management, feed composition, genetics and other factors, and in 2005, the average flock score was 28, and then as follows: 2010: 34 (median 21), 2015: 21 (median: 11), 2020: 6 (median 0,5) and 2025 (median 0). Some between-year variation is evident, but the general trend, in particular since year 2014, is clearly decreasing. From this, we can learn that it is possible to identify animal-based indicators at slaughter that reflect the on-farm situation in some respects. The next step is to identify indicators that can be assessed automatically, possibly with the help of AI. This still poses some technical challenges, and it is also important to remember that such a system must be regarded by the competent authorities as trustworthy and non-manipulable, to be accepted for replacing a manual system.

An Integrated Welfare Intelligence Platform Across the Animal Production Chain

G. Mandilaras[1], K. Perakis[1]
[1] UBITECH, DEA, Thessalias 8 & Etolias 10 Chalandri, 15231 Athens, Greece

Animal welfare indicators are routinely generated at multiple stages of the production chain, including farm management, transport, and slaughter. However, these data are typically fragmented across stakeholders and analysed independently, limiting their capacity to support systemic interpretation. The increasing availability of welfare-related data calls for structured approaches that enable cross-stage exploration while respecting data ownership and confidentiality. Within the framework of the aWISH project, an integrated welfare intelligence platform was developed to serve as the central environment for concentrating, interlinking, and analysing welfare data generated across the production chain. The objective of the platform is to support structured batch-level analysis across production phases and stakeholder groups. The system ingests welfare indicators as recorded in practice. For fattening pigs, examples include environmental parameters (temperature, humidity, CO_2), drinking and feeding behaviour, tail length, lameness, skin/tail/ear lesions, bruises, and pneumonia findings. For broiler chickens, indicators include foot pad dermatitis, hock burns, bruising, dead-on-arrival rates, and human-animal relationship assessments. These heterogeneous datasets are processed and modelled into an analysis-ready structure. Data are interlinked at stakeholder level, batch level, temporally, and based on contextual properties, enabling coherent cross-stage tracking and exploration. Analytical outputs are delivered through interactive dashboards that allow users to monitor batch performance, explore historical trends, and investigate potential associations between management conditions and downstream outcomes. A fine-grained access control mechanism ensures that stakeholders access only data related to their own operations and animals, while enabling comparison against aggregated and anonymised peer benchmarks. In addition, configurable warning mechanisms allow users to define threshold-based conditions and receive alerts when extreme or critical cases are detected. The platform also integrates curated best-practice guidance linked to specific welfare indicators, supporting informed interpretation and management reflection. By bringing together welfare data from different production stages into a single analytical environment, the platform enables stakeholders to examine their results in context rather than in isolation. This integrated perspective supports more consistent interpretation of welfare indicators and encourages coordinated approaches to welfare management across the production chain.

Roadmap for a Prototype Knowledge Platform to Track European Animal Welfare Data.

J. Zemzmi[1], E. Caro[2], C. Reverté[3], S. Ashe[2], L. Amato[2], Y. P. Van Der Stede[2], A. Velarde[1]
[1] IRTA, Animal Welfare, Veïnat de Sies, 17121 Monells, Spain, [2] European Food Safety Authority (EFSA), Animal Welfare Team, Unit Biological Hazards, Animal Health and Welfare (BIOHAW), Via Carlo Magno, 43126 Parma, Italy, [3] IRTA, Research Data Management, Crta: Poble Nou, Km 5,5, 43540 La Ràpita, Spain

Monitoring animal welfare across Europe is a challenge due to the heterogeneous data, the use of multiple indicators for the same welfare concern, and variation in assessment methodologies. To address these challenges, the SOA09 project has developed a prototype Knowledge Platform designed to collect, harmonize, and analyse animal welfare data, providing reliable and comparable information to support policymakers, researchers, and other stakeholders. The platform is being developed following a structured roadmap: first, a network of stakeholders was established to identify requirements, priorities, and available data sources; second, welfare indicators were mapped and harmonized with widely used assessment methods; third, key animal-based "iceberg" indicators were selected to capture multiple welfare outcomes; fourth, standardized data collection templates were created to capture these indicators alongside relevant contextual variables; fifth, templates and indicator selections undergo expert review and pilot validation; sixth, the platform architecture, data management protocols, and governance guidelines were defined; seventh, platform content is developed, and a functional prototype is tested using sample datasets; eighth, user accessibility and role-based permissions are configured; ninth, the platform is launched with training, user manuals, and ongoing support; and finally, a maintenance and update plan is implemented to ensure long-term sustainability. By following this roadmap, the platform aims to enable standardised, high-quality data collection, support and facilitate evidence-based decision-making, and provide a scalable model for future European-wide implementation of animal welfare monitoring.

Experiences and expectations of pig processing plants in the aWISH project to monitor animal welfare using sensor technologies

R. Klont[1], M. Bouwknegt[1], E. Kurt[1], N. Kajari[2], J. Reixach[3], C. Pfeiffer[4], M. Lindinger[5], E. Klont[1]
[1] Vion Food, Boseind 15, 5281RM Boxtel, Netherlands, [2] Carnex DOO, Kulski put 26, 21460 Vrbas, Serbia, [3] Selección Batallé, Avinguda dels Segadors, 17421 Riudarenes, Spain, [4] University of Veterinary Medicine, Animal Welfare Science Unit, Veterinärplatz 1, 1210 Vienna, Austria, [5] Rudolf Großfurtner GmbH, Hofmark 1, 4972 Utzenaich, Austria

The aWISH project is aimed at developing automated systems for monitoring animal-based welfare indicators throughout the pig production chain—from farm through transport to slaughter. As the project approaches completion, this paper provides an overview of the experiences, technological developments, and lessons learned from integrating sensor-, vision-, and AI-based systems in commercial slaughterhouses across Europe. The overarching goal is to enable slaughterhouses to optimize animal welfare, transparency, and product quality by digitally capturing key indicators. Multiple sensor technologies were deployed at partnering farms and slaughterhouses. At farm level, climate sensors continuously measured CO_2, ammonia, indoor and outdoor relative humidity and temperature. Image-based sensors have been used for continuous prediction of liveweight and pig behaviour. Data were visualized in dashboards to support improved farm management. At slaughterhouse level, camera systems and AI algorithms monitored animal handling during unloading and lairage. Sound and motion sensors were piloted as objective welfare indicators. Assessment of effectiveness of stunning process were determined using automatic image collection and use of AI algorithms. Debleeding quality was assessed during exsanguination, complemented by lactate and stress-related blood analyses. An automated tear staining assessment system was implemented in order to test and validate this novel indicator of pig welfare. Ultrasound and fibre-optic probes provided real-time carcass composition data. Newly developed in-line tail-length measurements, including automatic detection of tail damage, were implemented and results fed back to farmers via an online data platform. An automated image-analysis tool was tested and validated for identifying and scoring gross lung lesions associated to respiratory diseases. Integrating sensor and AI technologies demonstrated strong potential for objective, continuous welfare assessment. Preliminary findings indicate that connecting farm-to-slaughter data streams supports predictive modelling and early detection of welfare risks. Automated indicators such as tail damage scoring, environmental measurements, and behavioral data were particularly promising for scalable adoption. Lessons Learned were: (1) Successful implementation requires strong commitment from plant management and IT departments, (2) Reliable on-site IT infrastructure and edge-computing capacity are required for real-time processing, (3) Algorithm training and validation take more time than expected and often require site-specific tuning, (4) Equipment durability must match harsh slaughterhouse cleaning conditions, (5) Integrating data feedback loops to farmers creates new opportunities for chain-wide improvement and for supporting future welfare certification systems. The aWISH project shows that combining sensor, imaging, and AI systems across the pig production chain enables new ways to enhance predictability, welfare assessment, and operational efficiency. Digitalization at slaughterhouses not only supports higher welfare and processing standards but also strengthens transparency and sustainability throughout the livestock chain.

The Eyes & Ears project: automatic on-farm monitoring of animal health and welfare

T. B. Rodenburg[1], P. Llonch[2], E. Mainau[2], W. Wang[3], M. Coutant[4], S. Ntalampiras[5], L. Büttgen[6], E. D. Ellen[6], M. Giacobini[7], O. Guzhva[8], N. Högberg[8], C. Gaillard[9], M. Majewski[10], M. F. Giersberg[1]

Both for indicators of animal welfare and of animal health, monitoring (groups of) animals over time is becoming increasingly important. Modern animal welfare concepts focus more on positive and dynamic aspects of welfare and on supporting the adaptive capacity of animals. Therefore, relevant animal-based measures of health and welfare indicators need to be monitored over time to come to a meaningful assessment at individual or group level. The technical possibilities for automatic monitoring of farm animal health and welfare are developing rapidly. Approaches where vision and/or sound monitoring systems are used hold great promise, as they provide a non-invasive way to monitor health, welfare, specific behaviours and potentially even affective state of farm animals. To date, however, development of practical tools for health and welfare monitoring on commercial farms is still limited. The newly started Eyes & Ears project, an internal project of the European Partnership on Animal Health and Welfare, aims to facilitate the identification, development and validation of such on-farm surveillance tools. The project includes 20 partners from 11 EU countries and will start by reviewing and describing the current technologies that are available for both vision and sound monitoring systems and collecting existing and new datasets. For both vision and sound, we will work on well-defined cases across animal species (including ruminants, pigs, poultry and fish). Here, we also plan to make use of the wealth of approaches and data in some species (for instance: computer vision in cattle) to apply these approaches in other species. In the next step of the project, we plan to develop a dedicated pipeline for analysis of the data coming from the vision and sound monitoring systems, translating the data into relevant information for the farmer. This will be done by applying machine learning techniques. Farmers and other stakeholders will be invited to participate in the decision process about information needed. At this stage, we will focus on a limited number of cases (across species) that are already closer to commercial application. Finally, the project also plans to develop education and training materials that can be used by a wide range of stakeholders interested in developing tools for automatic on-farm monitoring of animal health and welfare. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW.

Using continuous sensor data on barn climate to evaluate the effect of barn climate advice on pig welfare: a Dutch case-study

K. Van Langeveld[1,2], N. Van Staaveren[3,4], N. Van Noten[1], T. B. Rodenburg[3], M. F. Giersberg[3], R. Klont[5], K. Mulder[6], F. A. Tuyttens[1,2]

[1] ILVO (Flanders Research Institute for Agriculture, Fisheries and Food), Animal Sciences, Burg. van Gansberghelaan 119, 9090 Merelbeke-Melle, Belgium, [2] Ghent University, Faculty of Veterinary Medicine, Salisburylaan 133, 9090 Merelbeke-Melle, Belgium, [3] Utrecht University, Faculty of Veterinary Medicine, Yalelaan 2, 3584 CM Utrecht, Netherlands, [4] University of Guelph, 50 Stone Road E, N1G 2W1 Guelph, Canada, [5] Vion Food Group, Boseind 15, 5281 RM Boxtel, Netherlands, [6] Connecting Agri & Food, Oostwijk 5, 5400 AM Uden, Netherlands

Automated barn climate (BC) monitoring is a widely used tool in precision livestock farming. However, poor sensor maintenance and farmers' hesitation to modify BC settings can result in inadequate air quality for pigs, which has been associated with poor pig health and detrimental behaviour. This highlights the need for expertise in managing BC and the importance of air quality to pig welfare. Therefore, this study aimed to evaluate whether professional BC advice based on continuous barn climate monitoring resulted in improved finisher pig welfare in the Netherlands. Nine pig farms with the Better Life label (1 star) were equipped with the Slimme Stal barn climate sensor (Eng. Intelligent Barn; Connecting Agri & Food) in one finisher unit and followed for two consecutive rounds. In one round, an expert provided BC advice (ADV), whereas this was not the case in the other round (CON). Advice implementation was voluntary (5/9 ADV rounds with uptake of the advice). The rounds were blocked by their starting date (four-week window), and treatment (ADV or CON) was randomly assigned within each block. Pig welfare was assessed twice each round (two weeks after arrival in the finisher barn and in the week before slaughter) using a modified Welfare Quality® protocol for growing pigs. The change in criterion scores and three qualitative behaviour assessment (QBA) PCA component scores between visits were analysed using linear mixed modelling, with treatment as a fixed effect and farm and blocking factors as random effects. Specifically, the criterion scores for Comfort around resting, Thermal comfort, Absence of injuries, Absence of disease, Expression of social behaviours, Expression of other behaviours, and Good human-animal relationship could be analysed, due to proper variation between visits and rounds. Treatment did not affect any of the between-visit changes in criterion scores ($p > 0.05$), nor the first two principal QBA component delta scores representing calm-positive and active-engaged mental states, respectively. The third component, however, showed a tendency for pigs becoming more agitated-distressed during the ADV rounds compared to the CON rounds (LS means [95% CI]: 0.11 [-0.90, 1.11] vs. -0.75 [-1.80, 0.30]; $\Delta = 0.86 \pm 0.34$; $p = 0.054$). In our study, expert BC advice did not improve aggregated pig welfare outcomes. However, effects on non-aggregated welfare indicators are still to be analysed. Further, future analyses will assess whether ADV improved barn climate and how specific air quality parameters relate to (aggregated) pig welfare indicators. This study was part of the aWISH project, which has received funding from the Horizon Europe Research and Innovation Program under grant agreement No. 101060818.

Development of a computer vision system for the assessment of swine welfare from indicators on carcasses.

The measurement of welfare indicators on pig carcasses offers a cost-effective approach for surveillance of animal welfare on-farm and in pre-slaughter handling. With application of computer vision system (CVS) technologies the evaluation of welfare indicators on carcasses can become continuous, standardized and objective, producing quantifiable data on all animals processed. System development should consider implementation in different abattoir environments, flexibility to integrate with other on-site technologies and be sufficiently comprehensive to provide a strong evaluation of animal welfare from which stakeholders can make informed decisions. This work describes the development of a real-time CVS for the automated assessment of swine carcasses that presently measures four key welfare indicators. For practical installment and operation in a variety of abattoir environments, the CVS uses one, 2D IP camera (H.264 compression) positioned opposite a turn in the conveyer rail after carcasses have received initial dehairing. The CVS was developed with multiple distinct modules that are combined for the total system, with the ability to process on edge hardware within the abattoir, on a cloud system, or a hybrid of the two. A tracking and image acquisition feature identifies individual pigs, the carcass position, captures and stores images of the lateral and dorsal side of each carcass as it passes the camera. Using object detection and neural networks, the CVS divides the carcass into different anatomical regions of relevance to pig welfare and carcass quality assessment; the head and shoulder, mid-section, hindquarters and tail (lateral side), and the back of the pig, tail, left and right ear (dorsal side). Welfare measures are then taken relevant to each anatomical area. Lesion detection modules identify lesions as absent or present, thereafter classifying them into levels of severity; mild, moderate and severe (skin), mild and severe (tail lesions, hernias) and tail length (undocked, or ¾, ½ or ¼ docked tail). The severity of skin and tail lesions is calculated from the ratio of skin surface presenting lesions to the total visible skin surface (per body area), from which the carcass is classified based on the ratio threshold. For tail lesions a secondary colorimetric analysis is applied to characterise red and black (necrotic) tissue, improving the accuracy of assessment. System evaluation was performed using videos of carcasses taken from one abattoir, in which carcasses had been assessed by human observers and classified into severity. Videos were spliced together to provide a range of lesion severity per welfare indicator for the CVS to evaluate (120 carcasses). In the current stage of development, our system achieves correct classification of welfare indicators with accuracies of 93.0% for hernias, 86.3% and 90.4% for dorsal and lateral skin lesions, respectively, and 86.8% for tail lesions. Tail length can be estimated with a magnitude of error of 19.82 px^2 (represented by mean square error) by geometric analysis with an image pixel to cm conversion factor for the tail area. Operating at 30.31 frames per second, this modular framework offers a scalable method for real-time extraction of multiple welfare indicators in industrial settings with the flexibility to add modules. An update on work in progress will be given: the external validation of this CVS in different abattoir environments and development of batch identification for processing data by farm.

Interactive catalogue of sensor technologies for automated welfare assessment at pig slaughterhouses

A. Ramon-Perez[1], B. Forkman[2], X. Manteca[1], P. Llonch[1]
[1] Autonomous University of Barcelona, Department of Animal and Food Science, Building V, Travessera dels Turons, 08193 Cerdanyola del Vallès, Barcelona, Spain, [2] University of Copenhagen, Section of Animal Welfare and Disease Control, Department of Veterinary and Animal Sciences, Groennegaardsvej 8, 1870 Frederiksberg C, Denmark

Because of increasing public concern for animal welfare, it is necessary to find methods for its assessment that are valid and can be implemented routinely. Welfare assessment should rely mainly on animal-based measures due to their higher validity and relevance compared with environment-based measures. Recent technological advances in sensor technologies enable us to monitor animal-based measures in a continuous and systematic way. Assessing animal welfare at the slaughterhouse through technological implementation allows an objective and continuous evaluation of large numbers of animals. Within the European project aWISH (101060818), a catalogue of sensor technologies was developed to measure welfare indicators in pigs for automated welfare assessment at slaughter. A systematic literature search across three databases identified the most relevant pig welfare indicators, followed by a commercial search to detect technologies currently available or at the prototype stage. Subsequently, 39 experts in technology and animal welfare were consulted to verify and complement the compiled information. As a result, an interactive catalogue comprising 64 technologies was created, of which 14 correspond to prototypes, including computer vision systems (n=38), weighing scales (n=9), flow meters (n=5), acoustic sensors (n=5), thermal (n=5) and infrared cameras (n=2). Technologies are classified according to assessment stage (antemortem, stunning, postmortem), welfare domain (nutrition, environment, health, behaviour or mental state), specific indicator and technology type. Antemortem technologies cover all five welfare domains, whereas stunning and postmortem sensors are restricted to the health domain. During the antemortem phase, tools monitor body weight and water consumption within the nutrition domain; cough within the health domain; tail-biting and activity within the behaviour domain; vocalisations and human–animal interactions within the mental domain; and noise, body temperature and pen space estimation within the environmental domain. Stunning sensors assess stunning effectiveness and killing efficacy, while postmortem technologies evaluate tail and lung lesions. The catalogue is presented as an online interactive tool that enables the selection of the most appropriate technologies for monitoring welfare indicators at the slaughterhouse level and is updated every six months to incorporate emerging technologies.

Ensemble Machine Learning Framework for Automated Cough Detection in Pigs

K. Mladenović[1], M. Tomić[2], J. Stanojević[3], D. Dramićanin[4], B. Karaklajić[4], V. Vujačić[5], J. Sudar[5], N. Kajari[5], D. Pavlović[6]

The monitoring system for livestock cough detection is essential factor for early warning of respiratory diseases in pig farming and is vital for effective animal welfare and productivity management. Respiratory diseases are one of the most frequently occurring in swine production facilities and may reduce the feed conversion and growth rates, lower pork quality, and increase treatment costs. Therefore, detection of coughing, as the most common symptom of respiratory diseases in pigs, is crucial for the early identification of disease onset. However, complex acoustic conditions in such facilities comprising a range of animal sounds such as screams and sneezes that share similar acoustic properties with coughs, make this problem considerably challenging. The aim of the study was to determine the feasibility of enhancing the accuracy of cough classification based on the sound derived from microphones installed in two separate pig pens utilizing both conventional machine learning and deep learning approaches. The recordings were made at a sampling rate of 8 kHz and comprised of various environmental sounds, including animal vocalization such as coughing, screaming, sneezing and eating. To address the cough classification problem, two distinct approaches were employed in this study: the first utilized time-domain acoustic features with a Support Vector Machine (SVM) algorithm, while the second leveraged frequency-domain features in the form of spectrograms with a ResNet-18 model. The first approach relies on domain knowledge to extract features known to be effective for cough detection, whereas deep learning approach allows features to be learned automatically, eliminating the burden of feature engineering process. Initially, each audio signal was pre-processed and 60 second intervals containing at least one coughing instance were selected for further analyses. Each interval was then divided into 1-second windows and further represented with a total of 21 acoustic features followed with backward feature elimination process and SVM algorithm to identify the most discriminative set for cough classification task. Alternatively, the 1-second windows were transformed into spectrograms and used as input to a neural network model. Instead of using discrete class predictions, the class probabilities from each window produced by the individual models were combined, and the final predictions were obtained as a weighted sum of the probability scores from the two approaches. In order to fill the instantaneous gaps in coughing and non-coughing segments, an additional post-processing step was applied using stacked median filters. The window sizes of the filters, as well as class probability weights for each model, and the class discrimination threshold were optimized on the training/validation dataset and subsequently evaluated on the test set. The proposed methodology accurately detected coughing instances, achieving an overall score of 0.78 F1 score on the test set, thus outperforming the individual approaches by 5% compared to the post-processed SVM approach with acoustic features and 7% compared to the post-processed predictions of ResNet-18 using spectrograms.

Validation of a Computer Vision–Based Tail-Length Measurement Algorithm for Finishing Pigs at the Slaughterhouse

C. Pfeiffer[1], K. Maschat[1], S. Kalburgi[2], A. Voss[2], C. Bonk[2], J. Baumgartner[1]
[1] Animal Welfare Science Unit, University of Veterinary Medicine, Vienna, Veterinärplatz 1, 1210 Vienna, Austria, [2] CLK GmbH - Bildverarbeitung & Robotik, Zur Steinkuhle 3, 48341 Altenberge, Germany

Tail-biting in fattening pigs is a multifactorial behavioural disorder caused by an interaction of internal and external risk factors. A common procedure to reduce the risk of tail-biting is tail-docking. Routine tail docking is prohibited in the EU; however, it can be assumed that a high percentage of finishing pigs are still tail-docked. The risk of injuries from tail-biting is higher in pigs with intact tails. Hence, tail length, along with tail lesions can be considered as iceberg indicators when assessing animal welfare, but objective, cost-efficient, large-scale on-farm monitoring is currently not feasible. Therefore, a computer vision-based algorithm to measure tail length at the slaughter chain was developed and validated in a slaughterhouse in Austria. A stereo 3D camera setup with pattern projection and auxiliary illumination, capturing five images per carcass, was installed on the slaughter line upstream of the decontamination area. To enable individual animal recognition, an OCR algorithm was applied to identify individual slaughter numbers on both lateral sides of the carcass. Tail length was measured using a two-step approach. First, tails were segmented from the carcass using a retrained YOLOv8 segmentation model applied to the 3D images. Altogether 1,252 3D images were annotated in CVAT and split into a training (876), validation (188) and test (188) datasets. Precision-recall curve showed high precision maintained across the full recall range; the resulting average precision of all classes yielded mAP@0.5 = 0.993. Second, geometric length estimation was performed by applying a classical image-processing pipeline to the predicted tail masks. To evaluate the developed tail length algorithm, 1,102 tails were manually measured on the slaughter line by means of a 'TailSizer' and were defined as the reference data. For statistical analysis, 688 measurements remained. The average measured tail length was 20.3 ± 2.56 cm, ranging from 2.00 to 40.0 cm, and the computer-based tail length 20.3 ± 7.12 cm, ranging from 2.10 to 39.2 cm, respectively. A simple linear regression model ($R^2 = 0.991$, $p < 0.001$) was fitted, showing a strong linear association between computer-based algorithm and measured tail length. Spearman rank correlation coefficient was 0.955 ($p < 0.001$), and the RMSE 2.13 cm. Results demonstrate a small systematic difference between the tail length algorithm and the reference data. Implementing a computer vision–based tail length measurement system at the slaughterhouse can support improvements in on-farm animal health and welfare while providing objective metrics for monitoring legal compliance and enabling welfare-based subsidy schemes in the pig industry.

Automated real-time monitoring of corneal reflex using computer vision to assess stunning effectiveness in a commercial pig slaughterhouse

J. Sanchez-Cañadó[1], A. Ramon-Perez[2], V. Garcia-Vera[1], J. Plà-Claver[1], J. Reixach[3], J. Canet[4], S. Gol[3], X. Manteca[2], P. Llonch[2]

Mossèn Jaume Soler, 56, Local A, 43820 Calafell, Tarragona, Spain, [2] Autonomous University of Barcelona, Department of Animal and Food Science, School of Veterinary Science, Building V, Travessera dels Turons, 08193 Cerdanyola del Vallès, Barcelona, Spain, [3] Selección Batallé S.A, Genetics and R&D, Avinguda dels Segadors, s/n, 17421 Riudarenes, Girona, Spain, [4] Frigoríficos del Nordeste S.A, N-2, Km.707, 5, 17181 Riudellots de la Selva, Girona, Spain

Ensuring effective stunning during slaughter is an ethical, legal, and social requirement in livestock production. In commercial slaughterhouses, the assessment of consciousness is largely based on evaluations performed by trained operators. Specifically, in pigs, the corneal reflex is widely used due to its sensitivity and because it is the first reflex to appear when an animal regains consciousness. However, its evaluation remains labour-intensive, which limits its feasibility for continuous assessment. As a potential solution, the use of technologies in slaughterhouses is gaining more interest, as it enables individual, continuous, real-time and objective assessments. This study presents the results of a field implementation program of an artificial intelligence-based system designed to automatically detect the corneal reflex in pigs stunned with CO_2 under commercial conditions. The system combines a high-resolution industrial camera and an air stimulus directed towards the cornea. A synchronised control unit triggers the stimulus and video capture, while a neural network processes the recorded sequences to detect blink responses in real time. The algorithm operates under the premise that a blink is detected by a change in eye morphology, monitoring the eye throughout the entire sequence and classifying it as open or closed. The sensor provides on-site alerts to enable immediate corrective action if required. The system was developed over multiple operational days in a commercial slaughterhouse processing 550 pigs per hour, generating more than 16,000 automated corneal reflex assessments. Some positive detections were recorded, although the great majority were associated with optical artefacts arising from operational conditions, such as movement, water, or dirt. However, one positive case was confirmed by expert observers, demonstrating the practical capability of the system to identify potential blinks. The expanding dataset is currently being used to refine detection robustness, particularly in face and eye localisation under challenging lighting and movement conditions. Beyond technical development, this work contributes to the discussion and validation of air stimulation as an alternative to traditional manual corneal testing in high-throughput environments. The results show the potential of AI-based systems to support continuous, objective and automated monitoring of stunning effectiveness, representing a step towards more transparent and data-driven animal welfare auditing in commercial slaughterhouses.

Time of last breath inside the stunner as an accurate proxy to necessary durations of exposure in controlled atmosphere stunning of pigs

J. Knöll[1], J. Gelhausen[2], D. Mörlein[2], J. Tetens[2], I. Wilk[1]
[1] Friedrich-Loeffler-Institut, Institute of Animal Welfare and Animal Husbandry, Dörnbergstr. 25/27, 29223 Celle, Germany, [2] Georg-August-Universität Göttingen, Department of Animal Sciences, Burckhardtweg 2, 37077 Göttingen, Germany

Controlled atmosphere stunning (CAS) using high concentration of carbon dioxide (CO2) is the most common method of stunning pigs at the time of slaughter in Europe. A key parameter of these systems according to the Regulation (EC) No. 1099/2009 is the duration of exposure of the animals to the atmosphere, which must be chosen to ensure that the vast majority of animals do not require re-stunning. As part of the project for Testing Inert Gases in order to Establish Replacements for high concentration CO2 stunning for pigs at the time of slaughter (TIGER), experiments were conducted in a commercial Dip-Lift system using a new gassing system, which allowed for residual oxygen concentrations <1%. In total, 1300 pigs were stunned and slaughtered using argon or nitrogen-argon based mixtures with 0% to 30% CO2 or high concentrations of CO2. The necessary duration of exposure was systematically estimated for each of the 9 gas mixtures. This was achieved by dynamically adjusting the duration of exposure for the next stunning sequence based on the evaluation of stunning effectiveness of the preceding sequences. The data was analyzed using a probit model with the gas mixture, residual oxygen and experimental phase as variables. The necessary durations of exposure, along with their confidence intervals were then estimated to ensure that only a predefined proportion of animals require re-stunning. Here we explore the possibility of estimating the necessary duration of exposure statistically using the times of last breathing activity inside the gondola, as an alternative to dynamically adjusting exposure times. For the different gas mixtures, means and standard deviations of the last (breathing) activity were estimated, based on manual video analysis of the stunning progress of all individual animals. To avoid confounding effects of the varying exposure duration in the dataset, methods from the survival analysis (R package survival) were employed to censor data for all animals for which breathing activity was detected after ejection. The data was analyzed using a linear model with the same variables as above. Necessary durations of exposure were estimated from the model as the duration where a set proportion of animals would statistically not take a breath after removal from the controlled stunning atmosphere. Confidence intervals of the necessary durations of exposure derived from this new method lay inside those calculated from the dynamic exposure duration approach for all 9 gas mixtures, with a mean absolute difference of the estimates of 15 s (6.3%). The mean size of confidence intervals deceased from 82 s for those from the dynamic exposure duration to 16 s for the new method. We conclude that necessary duration of exposure can be estimated with high statistical precision based on the time of last breath or overall activity inside the stunner. We propose that the last (breathing) activity may thus be a useful tool to estimate necessary durations of exposure for scientific evaluations of new gas atmospheres.By automating the process of determining the last (breathing) activity in each stunning sequence using computer vision methods, this approach could also be applied under commercial conditions to optimize exposure times for specific animal groups and to monitor deviations from normal operation, enabling fast or automatic parameter adjustments when necessary. Finally, extending this method may also allow identifying individual animals at risk of needing re-stunning after ejection before the need arises.

Detection before occurrence: Predicting stunning effectiveness and re-stunning necessity in pigs via computer vision-based tools

K. Zavyalova[1], J. Knöll[1], I. Wilk[1], H. Schomburg[1]
[1] Friedrich-Loeffler-Institut, Institute of Animal Welfare and Animal Husbandry, Dörnbergstr. 25/27, 29223 Celle, Germany

Effective stunning prior to slaughter is mandatory under Council Regulation (EC) No. 1099/2009 to prevent pain, fear and suffering. Failed pre-slaughter stunning in pigs is a pronounced threat to animal welfare during slaughter. Carbon dioxide (CO_2) stunning is currently the most widespread stunning method for pigs. Animals are stunned in groups within pen-shaped stunners (gondolas) by exposure to high concentrations of CO_2 for a defined duration. Due to stunner design and occupational safety limitations, direct observation of the animals during stunning is limited to video surveillance. Automated detection of parameters related to animal behavior and stunning progress could be used to continuously monitor the animals and detect potential markers for animal welfare issues or risk factors for requiring backup stunning. This study implements a computer vision–based detection of movement of pigs during CO_2 stunning. The initial focus is on determining the time of cessation of movement, which could serve as an early proxy for stunning effectiveness and potentially predict the necessity of re-stunning. Dataset used for training and testing was initially collected within the TIGER (Testing Inert Gases in order to Establish Replacements for high concentration CO2 stunning for pigs at the time of slaughter) project. The data includes footage from the front and back perspectives in the gondola for 1300 pigs (two pigs per gondola), along with manual annotations of movement events and the post-ejection re-stunning necessity for each animal. A pig instance segmentation model using YOLOv8n-seg model by ultralytics [v. 8.4.14] was retrained and validated using 100 manually annotated [80 train, 20 validation] frames extracted from video footage [Label Studio (HumanSignal) + Segment Anything Model, instance brush annotation], achieving preliminary box mAP50-95 of 0.87 and mask mAP50-95 of 0.84, enabling reliable separation and identification of animals despite dynamic background conditions. Subsequently, the trained model was used to segment pigs in video sequences. The movement was quantified using Farnebäck's approach to optical flow for every second frame at 50 fps and the Euclidean length of the flow velocity vector as the flow magnitude. The animals' movement intensity was determined as the mean flow magnitude within the regions of interest determined by the pig instance segmentation model. The raw movement intensity was smoothed with a rolling median (window = 25 frames). Analysis was limited to the stationary period of the gondola, excluding videos with the last movement at other times. The last movement within this period was detected by using the Q3+k*IQR threshold (upper quartile Q3, interquartile range IQR, Tukey's factor k=5). Currently the proposed method detects last movement accurately (absolute error<2.5 s) in 76% of cases compared to manual annotations. Next development steps include detecting the start of stunning sequences and ejection from the gondola and extending analysis up to time of ejection. Future development could focus on the detection of the time of loss of posture and distinguishing between the individual movement types. The finished system comprising the computer-vision based tool, cameras in the gondola and a warning system for the operators could be used to assist scientific investigations of controlled atmosphere stunning systems. In the future, the system could potentially be implemented at commercial slaughterhouses to monitor stunning progress and detect deviations from typical operation and adjust stunning parameters. This work was co-funded by the EU's Horizon Europe project 101136346 EUPAHW.

Validation of Best Practices to reduce tail, skin and lung lesions in pigs based on a survey with animal welfare experts

M. Fels[1], M. Jachens[1], N. Kemper[1]
[1] University of Veterinary Medicine Hannover, Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, Bischofsholer Damm 15, 30173 Hannover, Germany

As part of the EU Horizon project "aWISH" (Animal Welfare Indicators at the Slaughterhouse), "Best Practice Guides" are developed to improve animal welfare in pig farming, on transport and at the slaughterhouse. To ensure good effectiveness of the recommended Best Practices (BP), scientific experts for pig welfare were consulted in an online survey and asked to evaluate the proposed BP. A literature research was conducted to identify BP to reduce the occurrence of tail/ear lesions (TL), skin lesions (SL) and lung lesions (LL) in fattening pigs. Scientific experts were then surveyed about the identified BP using an online questionnaire. The experts were external scientists from different countries, the aWISH partners and the project's expert panel. Participants were asked to rate the proposed BP on a scale from 0% (unsuitable) to 100% (very suitable). Data were analysed using a mixed linear model with the BP as fixed effect and the expert-ID as random effect. A list of BP, ranked according to their rating result was compiled to include them in the Best Practice Guides. Overall, 47 completed questionnaires were collected. The top BP identified for TL were "Good health status" (78.9% agreement), "Good barn climate" (78.0%), and "Provision of straw as bedding" (70.6%) (all $p = 1.000$). To prevent TL, "organic manipulable material" was favoured compared to "non-organic material" (68.2% vs. 43.7%, $p<0.001$). Concerning SL, "Keeping littermates together from birth to finishing period" received high agreement (81.9%), as well as "Little regrouping/mixing of animals on farm and at the slaughterhouse" (82.7% and 75.3%) ($p = 1.000$). "Manipulable material on farm" was considered less effective for SL (53.9%, $p<0.001$). For LL, "Good barn climate" (88.9%) and "Good hygiene" (83.1%) were the top BP. Keeping pigs on fully slatted floor was not considered an adequate way to reduce LL (34.6%, $p<0.001$). Some BP were identified as effective for several welfare indicators, e.g. "No storage of manure in the stable, under the slatted floor" (TL 53.9% vs. LL 63.6%, $p=0.090$) or "Good barn climate" (TL 78% vs. LL 88.9%, $p=1.000$). "Low stocking density (i. e. more space than EU regulation)" showed similar agreement for all indicators (TL 67.2% vs. SL 68.3% vs. LL 63.8%, $p>0.05$). In this study, a total of 21 BP were identified and validated by experts to reduce tail/ear lesions and skin lesions, as well as 10 BP for reducing lung lesions. The BP will be classified based on the project's results and will be made available online to pig farmers, advisors, and veterinarians in easy-to-read infographics and comprehensive documents.

Integrating Welfare and Economic Assessment of the Weight-Detect AI System in Commercial Pig Production

M. Boimah[1], P. Thobe[1], T. Banhazi[2,3]
[1] Johann Heinrich von Thuenen Institute, Institute of Farm Economics, Bundesallee 63, 38116 Braunschweig, Germany, [2] 2InnoTech Vision ApS., Niels Pedersens Alle 2, 8830 Tiele, Denmark, [3] Wroclaw University of Environmental and Life Sciences, ul. Chełmońskiego 38C, PL51-630 Wroclaw, Poland

Weight sensors have become indispensable in contemporary livestock production, facilitating systematic, data-driven monitoring of animal growth. By eliminating the necessity for manual weighing, these systems not only enhance operational efficiency but also improve animal welfare by reducing handling stress and promoting more sustainable resource utilization (Hasan et al., 2024; Caja et al., 2016). Within the realm of precision livestock farming, automated weight monitoring serves as a pivotal connection between productivity, profitability, and farm resilience, especially when integrated with real-time analytics and AI-based decision-support systems (Losacco et al., 2025). In the framework of the EU-funded aWISH project, an AI-driven weight sensor system – Weight-Detect (WD; PLF AgriTech, Brisbane, QLD) was implemented on a commercial pig farm in Spain (Banhazi et al., 2025). The study aimed to achieve two primary objectives: (i) to assess the system's practical applicability under commercial farm conditions and (ii) to utilize its data outputs to evaluate overall pig welfare. Despite the promising potential of weight-sensing technologies, significant gaps persist in understanding their combined effects on animal welfare and financial performance in real-world farming systems. Addressing this gap is crucial to inform adoption decisions and guide the development of next-generation smart livestock technologies. Consequently, this study concurrently evaluates the welfare and economic impacts of implementing an AI-driven weight monitoring system in pig production. A hybrid data collection methodology was employed for the baseline and sensor-specific data, integrating on-site observations with remote data acquisition. Economic impacts were assessed using the TIPI-CAL model (Chibanda et al., 2020), whereby percentage changes observed on the pilot farm were applied to average Spanish farm models. Five implementation scenarios were simulated to estimate potential economic outcomes. Results demonstrate that early detection of growth stagnation enabled timely intervention during a respiratory disease outbreak, leading to measurable improvements in key "physical" and "mental" welfare indicators. Economic analysis showed that even minor delays in reaching market weight substantially reduced farm income, highlighting the sensitivity of profitability to health-related growth disruptions. However, early interventions facilitated by the WD system reduced treatment costs and performance declines, lowered mortality rates, and protected profit margins. Overall, the findings confirm that AI-driven weight monitoring delivers dual benefits: measurable welfare improvements and tangible economic gains. By enabling earlier, data-informed decision-making, the WD system represents a powerful tool for enhancing both animal well-being and financial sustainability in modern pig production.

Challenges in Establishing Ground Truth for Skin Alterations on Pig Carcasses for Training Computer Vision Algorithms

C. Pfeiffer[1], A. Voss[2], T. Heindl[1], A. Holzhacker[1], S. Kalburgi[2], C. Bonk[2], K. Maschat[1], J. Baumgartner[1]
[1] Animal Welfare Science Unit, University of Veterinary Medicine, Veterinärplatz 1, 1210 Vienna, Austria, [2] CLK GmbH Bildverarbeitung & Robotik, Zur Steinkuhle 3, 48341 Altenberge, Germany

Skin and tail lesions are widely used animal-based indicators of welfare in fattening pigs. Extracting welfare-relevant signals that point to problems on farm, during transport, or in the slaughterhouse requires large samples, standardized protocols, and well-trained assessors. Continuous manual scoring is time-consuming, costly, and limited by inter-observer reliability and repeatability. Computer-vision–based algorithms may offer a scalable tool to standardize the assessment of skin alterations (SA). Our preliminary objective was to develop an algorithm capable of detecting any SA; During development, we found that defining ground truth (GT) was considerably more complex than anticipated. Accordingly, the aim of this study was to describe the challenges and complexities involved in defining the GT for SA based on several approaches. A multi-camera system with auxiliary illumination captured five images per carcass was installed on the slaughter line upstream of decontamination in an Austrian slaughterhouse. Initially, 22 SA classes were defined. In total, 886 images were annotated. Inter-rater agreement between two trained veterinary students was evaluated on two datasets (83 and 236 images), each annotated three times. Intersection over Union (IoU) agreement was consistently low across all iterations. Between iterations, assessors were retrained, and several classes were discarded. An object-detection model (YOLOv8m) was trained on a subset of classes with sufficient samples (train 620, validation 133, test 133). The final model achieved a mean Average Precision of 0.252 at IoU 0.5 and 0.107 at IoU 0.5–0.95, indicating moderate detection performance with reduced localization accuracy at stricter overlap thresholds. Mean precision was 0.351 and mean recall (RC) was 0.285. Class-wise performance was heterogeneous: bruises had the highest RC (0.44) but lower precision (P) (0.36) due to many background false positives; old scratches (P 0.39; RC 0.26) and tail lesions (P 0.53; RC 0.31) were moderate; fresh scratches performed poorly (P 0.11; RC 0.03). Error analysis revealed two dominant failure modes: (1) true lesions missed and classified as background and (2) background misclassified as bruises. Detection performance varied substantially across lesion categories and was lowest for underrepresented classes. We therefore adopted an alternative scheme, based on the Welfare Quality® protocol for pigs, collapsing labels to two classes: animal-welfare-relevant vs. non–animal-welfare–relevant. One expert annotated 2877 images across five camera perspectives; 1000 images were used for inter-rater evaluation, yielding Cohen's kappa of 0.52. Image-classification models (YOLOv8) trained on these labels achieved higher accuracies (79%–96%), depending on perspective. However, this discrete scheme ignores the continuous spectrum from non– to clearly welfare-relevant findings. The study identified several challenges in GT: SA exhibited high variability in size, age, severity, and etiology; moreover, the image datasets contained a high proportion of process-induced post- mortem SA, implying that algorithms must be adapted for different slaughterhouses. Consequently, the overall strategy for establishing GT for SA requires revision. Objectively measurable a priori indicators should be prioritized (e.g. electro prods, multiple tattooing, SA attributable to aggressive interactions). In addition, validation should be expanded to encompass ante-mortem assessments in lairage areas, during transport and on farm.

Thermal Stress Detection in Poultry Using Audio Signal Analysis and Supervised Latent Space Structuring

P. Créach[1], C. Merchi[2]
[1] ITAVI, welfare, 7, rue du Faubourg Poissonnière, 75009 Paris, France, [2] SAPIENSYS, 6, rue des ardriers, 72000 Le Mans, France

Thermal stress represents a major challenge for animal welfare and productivity in poultry production systems, particularly in confined slaughter environments. In this communication, we propose a non-invasive acoustic monitoring approach for detecting and characterizing thermal stress under real industrial conditions, jointly analyzed with environmental hygrometric measurements. Microphones were deployed in pre-slaughter holding areas to capture audio recordings of poultry batches, while ambient temperature and humidity were continuously monitored to characterize the thermal load conditions. An initial dataset of few hundreds of audio segments was annotated by domain experts using a dual labeling scheme: (i) emotional valence (positive / negative) and (ii) vocalization type (distress call, contact call, comfort vocalization, etc.). Due to the limited size of the expert-labeled dataset, we developed a semi-supervised expansion strategy based on time-frequency representations and frequency patterns learned from annotated samples to retrieve and label acoustically similar patches in unlabeled recordings from the same production lot. The enriched dataset was subsequently used to train a convolutional autoencoder with a contrastively regularized latent space structured according to both vocalization class and emotional valence. This latent organization promotes explicit clustering of stress-related acoustic states while improving inter-class separability and robustness to environmental noise. To validate the physiological relevance of the learned representations, the latent stress indicators were further analyzed with respect to hygrometric variations, enabling the identification of correlations between acoustic signatures and environmental thermal conditions. The resulting system enables continuous temporal monitoring of acoustic stress indicators and paves the way for deployable, real-time animal welfare monitoring solutions in industrial poultry environments.

Validation of a computer vision model for automated tear staining assessment in pigs

S. Verlinde[1,2], K. Van Langeveld[1,3], R. P. Angela[4], N. Van Noten[1], P. Llonch[4], F. Tuyttens[1,3], J. Verwaeren[2], J. Maselyne[1]
[1] ILVO (Flanders Research Institute for Agriculture, Fisheries and Food), Burg. Van Gansberghelaan, 9820 Merelbeke-Melle, Belgium, [2] Ghent University, Department of Data Analysis and Mathematical modelling, Coupure Links 653, 9000 Ghent, Belgium, [3] Ghent University, Department of Veterinary and Biosciences, Heidestraat 19, 9820 Merelbeke-Melle, Belgium, [4] Autonomous University of Barcelona, Department of Animal and Food Science, Cerdanyola del Vallès, 08193 Barcelona, Spain

The extent of tear staining is considered a promising indicator of pig welfare. Yet current scoring protocols primarily rely on human visual interpretation of the stain-to-eye ratio, which may lead to limited inter- and intra-observer reliability due to the inherent visual ambiguity of the task. As a result, this limitation raises concerns regarding the broader reliability of tear staining as a useful welfare measure and highlights the need for a more reproducible assessment method. This study aims to validate a computer vision approach for tear staining detection by comparing its performance with two groups of human annotators with different levels of experience (expert and task-trained assessors). A dataset of 1,000 video-recorded pigs was manually collected at the bleeding lines of two commercial slaughterhouses, one in Spain and one in the Netherlands, with each clip capturing both sides of the pig's face under standardized lighting and at a fixed distance. The computer vision model processes these videos using two deep-learning modules: a detection model (YOLOv11) that identifies suitable frames and a segmentation model (DynUNet) that delineates the tear stain and eye regions, enabling the estimation of staining severity. To compare human and algorithmic assessment, two complementary tear staining assessment protocols are used: an adapted tagged visual scoring scale (TVAS) applied at clip level and manual annotations applied at frame level. Inter- and intra-assessor agreement is quantified using intraclass correlation coefficients for the visual scale and overlap-based metrics (e.g., Dice score) for frame-level annotations. Preliminary results indicate that the computer vision algorithm currently achieves a Dice score of 68% relative to expert annotations, with the full validation study still underway. By systematically comparing algorithmic and human assessments, this study aims to provide an initial validation of automated tear staining detection as a reproducible monitoring tool under commercial slaughterhouse conditions.

An investigation into the effectiveness of an alternative one-step head to body electrocution technique using mains voltage and off-the-shelf electrodes for euthanasia of large pigs (>130kg)

C. Cole[1], J. Norton[2], M. Denicourt[3], C. Klopfenstein[4], Y. Seddon[1]
[1] University of Saskatchewan, Western College of Veterinary Medicine, 52 Campus Drive, S7N 5B4 Saskatoon, SK, Canada, [2] University of Saskatchewan, College of Medicine, 107 Wiggins Road, S7N 5E5 Saskatoon, SK, Canada, [3] Université de Montréal, Faculté de médecine vétérinaire, 3200 Rue Sicotte, J2S 8H5 Saint-Hyacinthe, QC, Canada, [4] Centre de développement du porc du Québec inc, 815 Rte Marie-Victorin, G7A 3S6 Lévis, QC, Canada

Pig farmers want user-friendly and cost-effective methods for euthanizing compromised pigs and performing emergency herd culling. Commercially available electrical approaches such as the one-step stun-kill method applies current to the head and chest through specialized tongs. However, the high voltage equipment is costly and must be ordered from select companies. Canada's swine industry is interested in an off-the-shelf one-step electrocution technique utilizing accessible self-adhering electrodes (copper clamps) attached to the head and body at blood-rich locations. Current is then delivered from a 120 Volt alternating current (VAC) power socket travelling through the blood to target the brain and the heart. This technique could make euthanasia cheaper and enable personnel to be hands-off during implementation. The technique has been tested in pigs of five to 125kg, however it has not been validated as effective or humane for heavier pigs. This study evaluated whether one-step electrocution using off-the-shelf electrodes supplied with 120VAC induces unconsciousness and kills large pigs (130-340kg). Cull pigs (n = 21) from three weight categories (i:130-180kg, ii:190-240kg, iii: 250-340kg, n=7 pigs/category) were used. For each pig, weight, backfat (mm), and body condition score (1: emaciated to 5: obese) were obtained. The pig was sedated in a plastic-sided pen with a rubber mat floor, then anaesthetized to a light surgical plane while lying laterally. An electrocardiogram (ECG) and electroencephalogram (EEG) were recorded. Blood pressure was measured in two to five pigs/category. For euthanasia, two electrode combinations were tested: i) copper clamps on the skin of the groin (flank) and the upper lip (CFL); ii) a clamp on the flank and on a chain bridle running through the mouth (BCF). Clamps were connected to an electrical transformer plugged into a North American power socket, which applied 120VAC at 60Hz to the pig for 15 seconds (s) and the voltage and amperage (A) output were recorded. Before and after electrocution, palpebral, corneal, and nociceptive reflexes were tested, in addition to assessing heart and brain activity, and respiration. Preliminary results from 20 pigs (CFL: n=11 pigs, BCF: n=9) showed that 85% of pigs were killed with one 15s application of electricity, immediately displaying no reflexes suggestive of consciousness or respiration, and presence of cardiac fibrillation. Amperage through the pig was 0.50 ± 0.11A (mean ± SD) with CFL and 0.64 ± 0.15A with BCF. Three pigs >300kg were given a second 15s application due to body spasming post-electrocution (n=2 boars), and blinking (sow near full gestation). Following the first application of electricity, all pigs lacked a cardiac sinus rhythm and blood pressure flatlined and dropped below life sustaining levels. Full results will be available for the meeting. One-step electrocution with 120VAC applied through copper clamps consistently disrupted heart function and eliminated all signs of consciousness in. In boars and late gestation sows >300kg, sufficient current may not reach the brain and surrounding neural structures which is a concern for ensuring their unconsciousness and needs evaluation.

A protocol for the assessment of (un)consciousness after stunning during slaughter of cattle

C. Berg[1], J. Jerlström[1], M. Gerritzen[2], E. N. Sossidou[3], M. L. Ianetti[4]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, PO Box 234, 53223 Skara, Sweden, [2] Wageningen University and Research (WUR), P.O. Box 9101, 6700 HB Wageningen, Netherlands, [3] Veterinary Research Institute, Ellinikos Georgikos Organismos-Dimitra, Thermi, 57001 Thessaloniki, Greece, [4] Istituto Zooprofilattico Sperimentale dell'Abruzzo e del Molise, Campo Boario, 64100 Teramo, Italy

According to the European Regulation (EC) No 1099/2009, stunning of animals prior to exsanguination is mandatory (with limited exception for religious slaughter applied in some member states). The purpose of stunning is to render the animals insensible to stress, pain and suffering during bleeding. In practice, the animals are to be rendered unconscious before neck cutting. After stunning and during bleeding, the food business operator (FBO) must ensure and control that the animals remain unconscious until death supervenes. From an animal welfare point of view, rapid detection and immediate re-stunning of any insufficiently stunned animal is critical to prevent avoidable suffering. A structured, reliable and operational assessment of unconsciousness at slaughterhouses is therefore essential to minimise avoidable suffering and ensure timely corrective action. This study was carried out within the framework of the European Partnership for Animal Health and Welfare (EUPHAW) Set of Activities (SoA) 14, group 3 "Ruminants" and presents the evidence-based monitoring protocol developed to support official controls during the slaughter of cattle with stunning. The protocol is based on a semi-systematic review of recent peer-reviewed literature, integrates EFSA scientific opinions, and defines critical control points from restraint at stunning to confirmation of death. Moreover, the protocol outlines harmonised procedures based on both animal-based measures (ABMs) and resource- and management-based indicators, suitable for on-site inspection and auditing. The protocol covering the assessment of stun quality in cattle after using a mechanical stunning method suggests that the most reliable and feasible indicators of unconsciousness are loss of posture, absence of righting reflex, absence of rhythmic breathing and absence of spontaneous blinking and corneal reflex, although the latter, i.e. eye reflexes, are by some considered less feasible. The presence of spasms or seizures directly after the stun, the absence of muscle tone or the presence of excessive kicking can be used as indicators of unconsciousness but may require a more skilled observer. The post-stun convulsions may make it difficult to evaluate some of the spinal reflexes. The presence of vocalisations is considered a reliable indicator of consciousness, whereas the absence of vocalisations is not. For some indicators, such as gasping, nystagmus or eyeball rotation, presence indicates concern regarding the stun quality, and more indicators must then be evaluated. The protocol emphasises that no single indicator is sufficient alone. A combination of multiple indicators must be applied to confirm successful stunning and that the animal remains unconscious during the entire process until death by loss of blood has occurred. throughout all key stages: immediately after stunning, at sticking, and during bleeding until the animal is dead. The assessment should be carried out by properly trained operators. Further activities will be carried out in the framework of SOA 14 in order to fully validate this protocol and make it ready to be used in the context of slaughterhouses. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW.

Pilot insights into repeatable monthly animal welfare assessments on dairy farms

R. Wulf[1], J. Kleist[1], S. Demba[2], L. Bachmann[1]
[1] University of Applied Sciences Neubrandenburg, Faculty of Agriculture and Food Sciences, Brodaer Straße 2, 17033 Neubrandenburg, Germany, [2] University of Rostock, Faculty of Agriculture, Civil and Environmental Engineering, Justus-von-Liebig Weg 6b, 18059 Rostock, Germany

Reliable animal welfare assessments are essential for benchmarking and improving dairy production regarding societal demand and are mandatory due to §11 (8) of German Animal Welfare Act. Due to high personnel costs to measure animal welfare manually, efforts are currently ongoing to automatise the assessment. One challenge is aligning different data frequencies, such as annual or half year animal welfare assessments and daily or hourly sensor data. In order to automatise animal welfare assessments using daily available sensor data, the repeatability and reliability of manual animal welfare assessments must first be investigated. Hypothesis: We hypothesised that monthly assessments of animal welfare provide repeatable and reliable results in a limited time period. Experimental methods: This study is carried out on four commercial dairy farms in the north-east of Germany with varying herd sizes between 650 and 1,600 lactating cows. In all four farms the cows were held in loose housing systems with cubicles. Welfare assessments are carried out monthly over twelve consecutive months using the standardized Welfare Quality® Assessment protocol. According to the protocol, the welfare principle scores for good feeding, good housing, good health and appropriate behaviour were calculated based on 30 measures. Principle scores are rated on a 0 – 100 scale (0 = worst, 100 = best). The overall welfare score is the sum of the four welfare principles. All evaluations were performed by the same trained observer. Data were analysed at farm level. The data presented here derived from the winter period from December 2025 to February 2026. Statistical analyses: To assess differences in animal welfare assessments across this three-month period, a non-parametric Friedman test for repeated measures was performed including the four individual farms as blocks. All analyses were conducted in R (version 4.4.1). Results: According to the Welfare Quality® Assessment protocol, animal welfare was classified as “acceptable” in three farms during the three-month period. In one farm, the animal welfare classification changed from “acceptable” to “enhanced” and then back to “acceptable” due to a change in the assessment of the principle for appropriate behaviour; the principle for good health remained unchanged with low scores. The welfare principle scores for good feeding, good housing, good health and appropriate behaviour varied between 47.9 – 93.0, 37.0 – 47.4, 12.7 – 33.7 and 33.3 – 51.1, respectively. The overall welfare score lay between 144.9 – 206.8. The overall welfare score and the welfare principles showed no differences within the three-month period ($P > 0.05$). Discussion and conclusion: Even if the overall welfare score and the welfare principles at the farm level were repeatable in winter, only minor changes in welfare principles that were around the threshold for animal welfare classification led to an improved animal welfare classification. With regard to the future automatisation of animal welfare, the weighting used to classify animal welfare should be reconsidered. However, analyses will be repeated including the 12 consecutive months until the end of 2026 to align manually and automatically raised data.

A new protocol for the assessment of (un)consciousness during slaughter without stunning

M. Milazzo[1], S. Rota Nodari[2], A. Iannetta[1], M. Di Monte[2], M. P. Podaliri Vulpiani[1], E. Di Benedetto[2], G. Matteucci[1], L. Torricella[1], M. Gerritzen[3], J. Maters[3], L. Iannetti[1]

[1] Istituto Zooprofilattico Sperimentale dell'Abruzzo e del Molise (IZSAM), Viale Campo Boario 1, 64100 Teramo, Italy, [2] National Reference Centre for Animal Welfare, Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia-Romagna (IZSLER), Via A. Bianchi, 7/9, 25124 Brescia, Italy, [3] Wageningen University and Research (WUR), Droevendaalsesteeg 4, 6708 Wageningen,, Netherlands

In different EU countries, religious slaughter without prior stunning is still permitted under Article 4 of Regulation (EC) No 1099/2009, even if often strictly regulated. However, it remains a critical animal welfare issue due to the variable persistence of consciousness after neck cutting. A structured, reliable and operational assessment of unconsciousness at slaughterhouse is therefore essential to minimise avoidable suffering and ensure timely corrective action. This work was carried out within the framework of the European Partnership for Animal Health and Welfare (EUPHAW) Set of Activities (SoA) 14, group 3 "Ruminants" and presents a practical, evidence-based protocol designed to support official controls during the slaughter without stunning of cattle and small ruminants. The protocol integrates EFSA scientific opinions, DIALREL recommendations and recent peer-reviewed literature, defining critical control points from restraint to confirmation of death. It establishes harmonised monitoring procedures based on animal-based measures (ABMs), suitable for on-site inspection and auditing. Three sequential post-cut checkpoints are proposed, relying on the simultaneous evaluation of primary indicators of unconsciousness, particularly respiratory and ocular responses, together with supportive indicators such as posture and vocalisation. Species-specific time thresholds for expected loss of consciousness are incorporated (30–40 s in cattle; 15–25 s in small ruminants), reflecting anatomical and physiological differences relevant for inspection activities. Clear, decision-oriented criteria are defined, including back-up stunning whenever signs of consciousness persist, abnormal bleeding patterns occur, or any doubt exists regarding sensibility or loss of consciousness. The protocol further addresses key elements under official control responsibility, including adequacy of restraint systems, knife specifications, operator competence, documentation requirements and corrective actions. Particular attention is given to the interpretation of transitional "grey-zone" states and to distinguishing voluntary movements from anoxia-related convulsions, reducing the risk of misclassification during inspections. By providing structured checkpoints, validated indicators (including sensitivity, specificity and feasibility where available) and explicit decision rules, this protocol supports consistent enforcement of animal welfare requirements, enhances transparency of official controls and strengthens the role of competent authorities in safeguarding animal welfare during slaughter without stunning. Further activities will be carried out in the framework of SoA 14 in order to fully validate this protocol and make it ready to be used in the context of slaughterhouses. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW.

Gasping and gagging in pigs after CO2 stunning: indicator of insufficient stunning or part of the dying process?

J. Jerlström[1], V. Axberg Algotsson[1], C. Lindahl[3], C. Berg[2]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Box 7024, SE-75007 Uppsala, Sweden, [2] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Box 234, SE-532 23 Skara, Sweden, [3] RISE Research Institutes of Sweden, Department of Agriculture and Environmental Engineering, Box 857, SE-501 15 Borås, Sweden

One of the most common methods for stunning pigs at slaughter is exposure to high concentrations of carbon dioxide (CO2). The physiological mechanism involves acute hypercapnia and acidification of brain cells, which depresses brain activity and ultimately induces unconsciousness. However, the stunning process presents two key animal welfare challenges: preventing pain and fear during stunning and maintaining unconsciousness throughout bleeding. Failures in stunning can lead to unnecessary animal suffering and compromise worker safety. Animals must therefore be closely monitored after stunning to ensure they remain unconscious until death by exsanguination. This monitoring relies mainly on behavioural indicators such as the absence of corneal reflex, rhythmic breathing, and vocalisations. However, some indicators can be difficult to interpret after loss of posture. In particular, respiratory-related behaviours such as gasping and gagging may be difficult to distinguish from rhythmic breathing in slaughterhouse environments where high line speeds complicate observation. Therefore, the aim of this literature review was to synthesise current scientific knowledge on gasping and gagging after loss of posture in pigs stunned with CO2 to evaluate their relevance as indicators of stunning effectiveness. Although no unified definition of gasping exists, it is most commonly described as rapid intakes of air through a wide-open mouth, sometimes with head movements and airflow sounds. The literature suggests gasping is associated with severe oxygen deprivation and may reflect brainstem-mediated respiratory reflexes during hypoxia. These movements may occur even when cortical brain activity is markedly depressed, indicating that gasping does not necessarily reflect consciousness but a physiological response to hypoxia. However, its interpretation remains debated: some studies describe gasping as residual brainstem activity or possible recovery of brain function, whereas others interpret it as agonal respiration during the dying process. Gasping has also been reported together with other indicators of insufficient stunning, such as a positive corneal reflex, suggesting the animal may not be fully unconscious. This highlights the difficulty of using gasping as a reliable indicator when assessing stun quality in pigs. Scientific studies on gagging are limited. The behaviour is sometimes described as retching- or choking-like movements but is rarely reported in studies of CO2 stunning under commercial conditions. When mentioned, it often describes behaviours associated with loss of consciousness during CO2 exposure in experimental settings. Consequently, gagging lacks a clear operational definition after loss of posture. In addition, inconsistent terminology raises the possibility that behaviours described as gagging may correspond to gasping, which further complicates interpretation of the literature. In conclusion, this review highlights inconsistencies in how gasping and gagging are defined in the literature. These inconsistencies may create uncertainty for slaughterhouse personnel who rely on behavioural indicators to detect signs of consciousness after stunning. Further research combining behavioural observations with neurophysiological measurements of brain activity is needed to clarify the physiological basis and welfare relevance of these behaviours.

Effect of dietary inclusion of a Gracilaria chilensis by-product on post-weaning growth and health of pigs

C. Negrini[1], J. Glynn[1,2], G. Gardiner[2], L. Giblin[3], P. Lawlor[1]
[1] Teagasc, Pig & Poultry Research and Knowledge Transfer Department, Teagasc, Moorepark, P61 C997 Fermoy, Ireland, [2] South East Technological University, Department of Science, Cork Rd, Lisduggan Big, X91 K0EK Waterford, Ireland, [3] Teagasc, Food Research Centre, Moorepark West House, P61 C996 Fermoy, Ireland

Gracilaria chilensis, a red macroalga, contains phenolic compounds, proteins, lipids and minerals. Following agar extraction from Gracilaria chilensis, the residue underwent micro-filtration (to obtain insoluble fibre and protein) and cross flow-filtration (to obtain soluble fibre and peptides) to produce a Gracilaria by-product. This by-product may have potential as an alternative feed ingredient in pig diets. Our study evaluated the effect of dietary inclusion of this Gracilaria chilensis by-product in post-weaning (PW) diets on piglet growth, whole blood haematology and small intestinal health. At weaning (29±0.96 days; 8.4±1.01 kg), 72 pigs were formed into 10 pen groups containing 3 pigs, and 3 pen groups containing 2 pigs. Pen groups were blocked on pen group size at weaning, sex (entire male and female) and weaning weight. Within block pen groups were randomly assigned to one of two dietary treatments (n=13 pens/treatment): 1. Control diet; 2. Control plus 1% Gracilaria by-product (Gracilaria). Pigs were fed their experimental diets from weaning until day (d)21 PW, after which a common weaner diet was provided until d44 PW. Individual pig weights were recorded at weaning (d0) and d8, 14, 21, 27 and 44 PW. Feed disappearance was recorded for the intervals between pig weighings. At d8 PW, one pig from each pen containing 3 pigs (n=10 pigs/treatment) was euthanised to collect whole blood for haematology and intestinal tissue (duodenum, jejunum, and ileum) for mRNA analysis. Data were tested for normality using the Univariate procedure. Pig growth was analysed using PROC MIXED with day as the repeated measure; haematology and mRNA data were analysed using PROC GLIMMIX in SAS. Dietary treatment was included as a fixed effect, block as a random effect and weaning weight as a covariate when significant in the model. Pen was the experimental unit for growth performance, while individual pig was the experimental unit for haematological and mRNA data. Dietary treatment did not affect body weight, average daily feed intake, average daily gain or feed conversion efficiency at any period up to d44 PW. There was a tendency for mean corpuscular haemoglobin concentration (P=0.06) and basophil percentage (P=0.09) to be higher in Gracilaria pigs compared to Control, while the monocyte percentage tended to be lower in Gracilaria compared to Control (P=0.07). Although the basophil and monocyte ranges were within normal ranges for weaned pigs, this may indicate an altered white blood response, warranting further investigation with, perhaps, a longer intervention period. In the duodenal mucosa, CLAUD4 mRNA levels were lower in pigs receiving the Gracilaria diet compared to Control (P<0.001), suggesting reduced tight junction sealing and increased paracellular permeability in the duodenum in response to Gracilaria. In the jejunum, MUC2 levels were lower in Gracilaria pigs compared to Control (P=0.03), which may suggest a shift in barrier defence with relatively less mucus-based protection and greater reliance on tight junction regulation. In the ileal mucosa, CLAUD4 levels were higher in the Gracilaria group compared to Control (P=0.04), indicating tightening of the distal small intestinal barrier consistent with compensatory reinforcement following upstream permeability changes. Collectively, these results indicate localised intestinal responses to Gracilaria supplementation without negative effects on pig growth performance.

Protein and fiber source and inclusion level modulate feed preference in weaned piglets.

O. Tej[1,2], J. Leskovec[1], M. Colom-Pellicer[1], C. Güell Saperas[2], M. Ferrando Cogollos[2], D. Torrallardona[1]
[1] IRTA, Animal Nutrition, TP-7225, Km 3,8, 43120 Constantí, Spain, [2] URV, Chemical Engineering, Campus Sescelades, 43007 Tarragona, Spain

Weaning is a critical phase in piglet development during which feed acceptance plays a key role in intake and post-weaning adaptation. Two studies were conducted to evaluate the effect of inclusion level on feed preferences of weaned piglets ([Large White x Landrace] x Pietrain; 13 d post-weaning) for diets with different proteins and fiber sources (Trial 1), and of types of processing of fiber sources (Trial 2) using a two-choice preference test adapted from Solà-Oriol et al. (2009). In Trial 1, 144 piglets were allocated to 36 pens (4 piglets per pen), and they were offered double-choice combinations of 3 diets differing in the inclusion level (low, medium, high) of spray dried plasma (SDP) and soy protein concentrate (SPC), as animal or plant protein sources; and sugar beet pulp (SBP) and soybean hulls (SBH), as soluble or insoluble fiber sources. Choices were offered in four different periods of 3 days, one for each ingredient. Piglets showed significant increases in preference ($P < 0.01$) in response to the increasing inclusion levels of SDP from 0 to 3% (28 vs 72%), 3 to 6% (26 vs 74%) and 0 to 6% (27 vs 73%). Preferences for SPC did not follow a clear inclusion dose pattern as piglets showed no significant differences between 0 and 4% of inclusion (61 vs 39%), a decrease in preference from 4 to 8% (65 vs 35%; $P < 0.01$), and an increase in preference from 0 to 8% (37 vs 63%; $P < 0.01$). Increasing SBP levels from 0 to 4% (74 vs 26%) or 0 to 8% (90 vs 10%) significantly decreased feed preference ($P < 0.01$), while no significant differences were observed between 4 and 8% of inclusion (47 vs 43% preference). Similarly, increasing SBH levels from 0 to 2.5% (71 vs 29%) or 0 to 5% (83 vs 17%) significantly decreased feed preference ($P < 0.01$), with no difference between 2.5 and 5% of inclusion (58 vs 42% preference). In Trial 2, 108 piglets were allocated to 36 pens (3 piglets per pen) to assess whether processing methods could improve acceptance of fiber in diets. SBP and SBH were ground at either 3.0 (control) or 0.5 mm, or ground at 0.5 mm and extruded, before being added into the test diets at 8 or 5%, respectively, and compared against a control diet without added fiber. For SBH, it is not clear whether processing mitigated the negative effect of fiber inclusion, as no significant preference differences were found for any of the comparisons: 0 to 5% (59 vs 41%); 0 to 5% at 0.5mm (53 vs 47%); and 0 to 5% at 0.5mm and extruded (46 vs 54%). In contrast, processing of SBP did not improve preference compared to unprocessed SBP as adding SBP significantly reduced feed preference in all cases from 67 to 33% preference ($P < 0.01$). In conclusion, piglet feed preference is strongly influenced by protein source and fiber inclusion level. While it is not clear whether processing strategies can partially overcome the reduced acceptance of SBH, they are ineffective for SBP. These findings emphasize the need to consider both ingredient composition and processing when formulating diets for newly weaned piglets.

Effect of dietary inclusion of a Laminaria hyperborea by-product on post-weaning growth and intestinal health of pigs

J. Glynn[1,2], C. Negrini[1], G. Gardiner[2], L. Giblin[3], P. Lawlor[1]
[1] Teagasc, Pig Development Department, Moorepark, Fermoy, P61 C996 Cork, Ireland, [2] South-East Technological University, Eco-Innovation Research Centre, Department of Science, Cork road campus, X91 K0EK Waterford, Ireland, [3] Teagasc, Food Research Centre, Moorepark, Fermoy, P61 C996 Cork, Ireland

Laminaria hyperborea, a brown macroalga, contains minerals, fibre and fucose-rich polysaccharides such as fucoidan, which is considered a high-value bioactive compound. Fucoidan extraction from Laminaria, through mild acid, alkaline and screw pressing steps produces a Laminaria by-product. This by-product may have potential as an alternative feed ingredient in pig diets. Our study evaluated the effect of dietary inclusion of this by-product in post-weaning (PW) diets on piglet growth, whole blood haematology and small intestinal health. At weaning (29±0.96 days; 8.4±1.01 kg), 72 pigs were formed into 10 pen groups containing 3 pigs, and 3 pen groups containing 2 pigs. Pen groups were blocked on pen group size at weaning, sex (entire male and female) and weaning weight and within block were randomly assigned to one of two dietary treatments (n=13 pens/treatment): 1. Control diet; 2. Control plus 5% Laminaria by-product (LAM). Pigs were fed their experimental diets from weaning until day (d)21 PW, after which a common weaner diet was provided until d44 PW. Individual pig weights were recorded at weaning (d0) and d8, 14, 21, 27 and 44 PW. Feed disappearance was recorded for the intervals between pig weighings. At d8 PW, one pig from each pen containing 3 pigs (n=10 pigs/treatment) was euthanised to collect whole blood for haematology and intestinal mucosal tissue (duodenum, jejunum, and ileum) for mRNA analysis. Data were tested for normality using the Univariate procedure. Pig growth was analysed using PROC MIXED with day as the repeated measure; haematology and mRNA data were analysed using PROC GLIMMIX in SAS. Dietary treatment was the fixed effect, block was the random effect and weaning weight, when significant, was included as a covariate in the model. Pen was the experimental unit for growth performance, while individual pig was the experimental unit for haematological and mRNA data. Dietary treatment did not affect body weight, average daily feed intake, average daily gain or feed conversion efficiency during any period up to d44 PW ($P>0.05$). Regarding haematology, only monocyte percentage was affected by treatment and this was reduced in LAM-fed pigs compared to Control ($P<0.01$). Although monocyte values were within normal ranges for weaned pigs, this finding may indicate an altered white blood cell response to LAM which may warrant further investigation. In the jejunal mucosa, MUC2 mRNA levels were lower in LAM compared to Control ($P<0.001$), suggesting less mucus-based protection in the proximal region of the small intestine. However, in the ileal mucosa, CLAUD4 and MUC2 mRNA levels were higher in LAM compared to Control ($P<0.01$), indicating compensatory activation of both tight-junction and mucus-layer defence in the distal small intestine as a consequence of weakened proximal mucus protection. Collectively, these results indicate some localised intestinal responses to Laminaria by-product inclusion without negative effects on growth performance. Therefore, this macroalgal by-product can be safely incorporated into post-weaning pig diets at dietary inclusion rates of up to 5%.

Effects of pre- and post-weaning zinc and copper supplementation strategies on their homeostasis in plasma, intestinal mucosa and liver in pigs

J. S. Bee Tubin[1], J. V. Da Silva Duarte[2,3], I. Audet[3], D. Bueno Dalto[3]
[1] Universidade Estadual de Santa Catarina, Department of Animal Science, Rua Beloni Trombeta Zanin 680E, 89815630 Chapeco, Brazil, [2] University of Saskatchewan, Department of Large Animal Clinical Sciences, 105 Administration Pl, S7N5A2 Saskatoon, Canada, [3] Agriculture and Agri-Food Canada, Sherbrooke R&D Centre, 2000, College street, J1M0C8 Sherbrooke, Canada

The EU restriction on total zinc (Zn) levels in post-weaning diets of pigs cause transient hypozincemia that increases susceptibility to diarrhea. Due to the low post-weaning feed intake, alternatives to in-feed supplementation may help mitigate this issue. This study evaluated the effects of different pre- and post-weaning Zn and copper (Cu) supplementation strategies on their homeostasis in pigs. At d13 of age, 100 suckling pigs were randomly assigned to two oral treatments: S – 2 mL of saline or M – 2 mL of saline with 6.43 and 2.79 mg/L of Zn and Cu as sulfates. At weaning (d21), pigs from both pre-weaning treatments were randomly assigned to two supplementation strategies until d28: W – basal diet devoid of supplemental Zn and Cu and drinking water supplemented with 150 and 65 mg/L of Zn and Cu as sulfates or F – basal diet supplemented with 300 and 130 mg/kg of Zn and Cu as sulfates and drinking water devoid of supplemental Zn and Cu. Between d28-35, all pigs (SW, SF, MW and MF) received a regular diet with 300 and 130 mg/kg as sulfates. Samples were collected at d21, 28 and 35. Statistical analyses used one-way analysis of variance to compare pre-weaning treatments (S vs M) and also each nursery treatment (SW, SF, MW and MF) at d28 and d35 vs pre-weaning values (d21). At d21, M pigs had higher ($P \leq 0.05$) jejunum mucosa, liver and plasma (not for Cu; $P = 0.48$) Zn and Cu concentrations compared to S. At d28, both M groups showed a reduction ($P \leq 0.02$) in plasma Zn compared to d21. In jejunum mucosa and liver, however, Zn concentrations at d28 were not different from d21 in MW ($P \geq 0.66$) but were lower in MF pigs ($P \leq 0.05$). Compared to d21, SF pigs decreased ($P \leq 0.08$) Zn concentrations in plasma and liver but increased in jejunum mucosa whereas SW pigs enhanced ($P < 0.05$) Zn concentration in jejunum mucosa and liver at d28. Plasma (MW and MF) and liver (only MW) Cu concentrations dropped ($P \leq 0.03$) at d28 compared to d21. Plasma and liver Cu concentrations decrease ($P \leq 0.04$) in SW pigs at d28 but increased in jejunum mucosa for SF and SW ($P \leq 0.10$) compared to d21. At d35 when all pigs had been fed a similar diet for 1 week, plasma, jejunum mucosa and liver Zn concentrations decreased in both M groups ($P \leq 0.09$) compared d21. Liver Zn was higher in MW than MF ($P < 0.01$). For S groups at d35, the only detected effect was a reduction ($P \leq 0.01$) in hepatic Zn concentrations in SF pigs compared with d21 and compared to SW. For Cu at d35, all treatments had lower ($P \leq 0.01$) plasma and liver concentrations compared to d21 whereas both S groups had higher concentrations in jejunum mucosa ($P < 0.03$). In conclusion, pre-weaning Zn and Cu supplementation enhanced Zn and Cu status of pigs at weaning. The reduction in plasma and liver Zn concentrations at d28 and 35 suggests that 300 ppm Zn may not be adequate to maintain Zn status under post-weaning conditions. Independently of the pre-weaning strategy, post-weaning supplementation via drinking water was more efficient than in-feed supply to minimize (not prevent) the transient hypozincemia but it was detrimental to Cu homeostasis. The persistent decrease in liver Cu concentrations, even supplementing 21-fold the NRC recommendations, may be an indication of physiological adjustment, but it needs to be further investigated.

Characterization of a non-invasive indicator for LPS-induced inflammation in the saliva of pigs fed high or low fiber diets

M. Sciascia[1], M. Cavalleri[1], S. Görs[1], A. Vernunft[1], H. Reyer[1], M. Oster[1], L. Moscovice[1], K. Wimmers[1], J. Zentek[2], S. Dänicke[3], S. Kersten[3], C. Metges[1]

[1] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [2] Free University of Berlin, Institute of Animal Nutrition, Königin-Luise-Str. 49, 14195 Berlin, Germany, [3] Federal Research Institute for Animal Health, Institute of Animal Nutrition (ITE), Bundesallee 37, 38116 Braunschweig, Germany

Saliva has been the focus of a number of pig studies looking for a non-invasive alternative to blood, where indicators of altered metabolic and pathophysiological status could be identified. In the current study, we used an immune stimulation model with lipopolysaccharide (LPS) to alter the metabolic and physiological state of pigs, being fed high (HF) or low (LF) fiber diets. The aim was to identify indicators of immune stimulation in the saliva of LPS challenged pigs with the following selection criteria: (1) diet-independent, (2) significantly different concentration at all post-LPS challenge timepoints compared to the baseline timepoint, and (3) no concentration pattern comparable to control pigs not stimulated with LPS. Therefore, male German landrace littermate pairs (n=22) were fed diets containing 2.8% (LF) or 6.5% (HF) dietary fiber from 50 days of age (d). At 70 d, pigs were fitted with a jugular catheter and transferred to metabolic crates at 74 d. Before the start of the LPS experiment, six of the 44 piglets were excluded from the study due to diarrhea, lethargy or fever, therefore 38 pigs remained in the study. At 75 d, pigs were injected i.m. with either 30 µg/kg bodyweight LPS dissolved in 0.9% NaCl or an equal volume of NaCl as a control, creating 4 groups (HF-LPS, LF-NaCl; n=9/group) and (HF-NaCl, LF-LPS; n=10/group). The study was conducted across 9 experimental blocks with 2-3 littermate pairs per block, and all 4 groups represented. Saliva and blood samples were then taken at -15, 120, 240, 360 and 720 min relative to the LPS injection. In plasma and saliva, free amino acids (n=20), and amino-metabolites (n=13) were measured using HPLC and clinical chemistry parameters (n=10) were measured using an automatic enzymatic analyzer. In blood, hematological parameters (n=19) were measured using an automated Hematology Analyzer, whilst salivary cortisol was measured via ELISA. No blinding was used at any stage of the study. Data were analyzed in R (Version 4.5) using DIABLO (mixOmics) and two Linear mixed-effects models (LMM, lmer). Model 1 included the fixed effect of Time and evaluated time-dependent changes within each experimental group. Model 2 included the fixed effects of Diet, Time and Treatment and their interactions. Sow/Piglet were nested random effects in both Models. The DIABLO analysis showed that at all timepoints after LPS, HF-LPS and LF-LPS pigs differed from the controls in only one parameter, namely salivary 5-aminovaleric acid (5-AVA), a microbial metabolite of lysine. Subsequent LMM analysis confirmed that 5-AVA was significantly higher at all timepoints post-LPS injection and did not change in the NaCl pigs irrespective of diet. In addition, the concentration of 5-AVA was higher in LPS treated compared to NaCl treated pigs, whilst no difference in 5-AVA was observed between HF-LPS vs. LF-LPS and HF-NaCl and LF-NaCl pigs. Due to its stable and diet-independent association with an inflammatory response, 5-AVA could thus be a potential non-invasive indicator of systemic inflammation in pigs. This work is an outcome of the PIGWEB project funded by the European Union's Horizon 2020 research and innovation program under Grant Agreement No 101004770. Ethical consent (LALLF M-V/TSD/7221.3-1-039/21) for all procedures complied to German Animal Welfare Act guidelines and with Directive 2010/63/EU.

Serum magnesium and protein profiles in domestic pigs versus wild boars – possible links to tail biting behaviour

K. Büttner[1], K. Westhoff[2], M. Lierz[2], C. Irena[3]
[1] Unit for Biomathematics and Data Processing, Faculty of Veterinary Medicine, Frankfurter Straße 95, 35392 Giessen, Germany, [2] Clinic for Birds, Reptiles, Amphibians and Fish, Faculty of Veterinary Medicine, Frankfurter Str. 114, 35392 Giessen, Germany, [3] Section for Animal Welfare and Disease Control, Department for Veterinary and Animal Sciences, Grønnegårdsvej 8, 1870 Frederiksberg, Denmark

Establishing reliable reference values for blood parameters are essential for accurate interpretation, especially in wild species where baseline data are scarce. This becomes specifically relevant for comparison purposes to domestic pigs when one wants to reevaluate what is “normal”. For example, in the wild boar population, the behavioural disorder tail biting does not occur and the hypothesis exists that there might be a connection, amongst others, to metabolic differences that might play a role as causative factor. In the present study serum magnesium, total protein and albumin in 135 German wild boars were measured and compared to 60 conventionally reared cross-bred domestic pigs. In the wild boar cohort, age significantly affected magnesium ($p = 0.0012$) and albumin ($p = 0.0170$) but not total protein. Domestic pigs exhibited a markedly significant lower magnesium content with 0.73 mmol/l compared to juvenile wild boars (1.53 mmol/l, $p < 0.0001$) and subadult wild boars (1.37 mmol/l, $p < 0.0001$). For total protein and albumin, a similar pattern could be observed. Domestic pigs showed with 52.71 g/l for total protein and 26.47 g/l for albumin significant lower total protein values compared to juvenile wild boars (total protein: 73.35 g/l, $p < 0.0001$, albumin: 39.28 g/l, $p < 0.0001$) and subadult wild boars (total protein: 74.94 g/l, $p < 0.0001$, albumin: 42.36 g/l, $p < 0.0001$). The magnesium and total protein levels of domestic pigs fell below clinical thresholds for hypomagnesemia and hypoproteinemia, conditions not observed in the wild boar population under study. These findings support the hypothesis that the current management practices around weaning including standard diets according to common nutrient recommendations used in German conventional pig production may leave weaned piglets with critical mineral and protein deficits while no such problems exist in the wild boar population. Such deficiencies could increase post-weaning stress, gut dysfunction and may have a role in the pathogenesis of damaging behaviours such as tail biting.

Haematopoietic traits in indigenous and modern pig breeds are modulated by housing system and developmental stage

K. Kapoor[1], M. Oster[1], H. Reyer[1], C. Metges[1,2], N. Trakooljul[1], S. Ponsuksili[1], E. Muráni[1], K. Wimmers[1,2]
[1] Research Institute for Farm Animal Biology (FBN), Dummerstorf, Physiological Genomics, Wilhelm-Stahl-Allee 2, Dummerstorf, 18196 Rostock, Germany, [2] University of Rostock, Faculty of Agricultural, Civil and Environmental Engineering, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany

Pig farming is undergoing a process of diversification in order to meet the requirements of animal welfare, sustainability and consumer attitude. In terms of farming systems, these diversified approaches include an enriched housing environment and management practices such as extended suckling periods. In addition, diversification takes into account different breeds with specific characteristics. The interaction of breed, husbandry system and management could bring specific metabolic and immunological benefits that have not yet been sufficiently researched, particularly in the critical early stages of life. Haematological characteristics serve as key indicators of physiological status and immune resilience, providing fundamental insights for the evaluation of diversification. A 2×2 factorial study to assess haematological parameters was conducted using 512 piglets from two breeds (German Landrace, GL; German Saddleback, GS) which were raised under conventional (CON) or organic (ORG) housing conditions. Blood samples were collected at four stages of development, including suckling, pre-weaning, post-weaning and juvenile (70d). Complete blood counts were measured using an automated veterinary haematology analyser. This work was co-funded by the European Union's Horizon Europe project 101136346 (EUPAHW). Marked breed differences were observed with GS pigs consistently exhibiting higher total red blood cell (RBC) counts compared to GL ($P < 0.001$), across all developmental stages. Conversely, GL pigs showed higher counts of mean corpuscular volume (MCV) and mean corpuscular haemoglobin (MCH) at all observed stages ($P < 0.001$). With respect to the leukocyte profile, GS pigs maintained higher total white blood cell (WBC), lymphocyte, and monocyte counts than GL pigs ($P < 0.05$). Post-weaning, GS-CON pigs showed a significant decline in RBC, haemoglobin, and haematocrit (HCT) (4.12%, 6.77%, and 5.24%) compared to GL-CON (1.26%, 3.32%, and 1.92%) respectively, while levels of ORG-housed animals remained more stable. Housing effects at day 70 showed that ORG-housed pigs had reduced HCT and MCV, but significantly higher concentration of MCH compared to CON pigs ($P < 0.05$). Additionally, GL piglets under ORG conditions displayed significantly higher platelet counts (PLT) than GS counterparts ($P < 0.001$). Findings of the haematological profiles point to breed-specific strategies for physiological adaptation in which GS pigs have higher RBC counts but smaller cell size (MCV) putatively to maximise erythrocyte surface area for efficient oxygen uptake, whereas GL pigs possess larger, haemoglobin-rich cells (MCV, MCH). Elevated counts of WBC, LYMPH, and MONO in GS piglets across the developmental period potentially indicate a genetic predisposition for heightened immune surveillance to pathogens. Housing-related differences on day 70, specifically higher MCH and lower MCV under ORG compared to CON conditions, likely reflect compensatory mechanisms for dietary variations, such as methionine availability, thereby affecting erythrocyte maturation. Overall, breed and stage-dependent haematological responses observed underscore functional diversity in physiological and immune adaptation, supporting the concept of matching animal capabilities and needs with housing conditions to enhance resilience and welfare. Ongoing work will utilise transcriptomics to clarify the molecular mechanisms underlying these adaptations and their implications for resilience.

Improving meat quality in local Krškopolje pig breed using advanced optimum contribution selection approach

K. Poklukar[1], M. Čandek-Potokar[1], M. J. Mercat[2], S. Taussat[2], M. Škrlep[1]
[1] Agricultural Institute of Slovenia, Animal Science Department, Hacquetova ulica 17, 1000 Ljubljana, Slovenia, [2] IFIP – Institut du Porc, 9 boulevard du Trieux, 35740 Pacé, France

Krškopolje pig, Slovenian local breed, is characterised by a relatively high and variable intramuscular fat (IMF) content, a key property determining pork sensory quality. Unfavourable RYR1 C1843T mutation, known to negatively affect water holding capacity, is also present at relatively high incidence. Current breeding programme primarily focuses on the preservation of typical traits related to morphology, coat colour and prevention of inbreeding, while breeding for meat quality, particularly IMF, or reduction of unfavourable RYR1 C1843T frequency, is not yet considered. Therefore, the main aim of this study was to assess the potential for genetic selection for IMF, considering the constraints related to inbreeding and reduction of RYR1 mutation frequency using an advanced optimum contribution selection (aOCS) approach. Genotypic (60K Choice Genetic's Custom SNP-array) and phenotypic data (IMF content) were collected from 455 pigs including the information on farm, age at slaughter and pedigree data. Heritability and breeding values were estimated with 'blupf90+' software using a single-step genomic BLUP approach. Animal model included a random additive genetic effect of the animal, farm (fixed effect) and age at slaughter (covariate). NeEstimator v2.1 was used to estimate the effective population size, and optiSel R package was used to estimate segment-based inbreeding and to apply aOCS. Three scenarios were defined to evaluate different breeding strategies based on selection candidates (animals born from 2021 to 2024): 1) maximising genetic gain for IMF while constraining inbreeding, 2) prioritising the reduction of inbreeding, 3) reducing the RYR1 allele frequency while maintaining inbreeding at the same level. The heritability estimation for IMF content was 0.44 ± 0.10. The segment-based inbreeding coefficient was 0.154 and the effective population size was 46.5, suggesting that Krškopolje pig breed is at risk. The frequency of the unfavourable RYR1 allele was 0.18. As expected, the three scenarios tested revealed different results. The first one highlighted a genetic improvement of IMF (mean of breeding values increased from 0.071 to 0.229) while inbreeding remained stable. However, the RYR1 C1843T allele frequency slightly increased (0.18 to 0.19). The second one showed a decrease in offspring inbreeding (0.200 to 0.181), but also a reduction in expected breeding value (0.071 to 0.033), while the RYR1 allele C1843T frequency remained unchanged. In the last scenario, allele frequency decreased (from 0.18 to 0.15) as did the breeding values for IMF (0.071 to 0.063), while inbreeding remained stable. This study demonstrates that genetic improvement of meat quality is feasible in the Krškopolje pig; however, improvement can be achieved only for one objective at a time. At present, reducing the frequency of the unfavourable RYR1 mutation should be the primary objective of the breeding programme due to its strong effect on meat quality traits, particularly those related to water-holding capacity, while simultaneously ensuring the maintenance of the breed's genetic diversity. Although IMF content is highly variable in Krškopolje pig, its overall level in the population is still relatively high; therefore, we propose that it should be considered as a secondary objective to be addressed after reduction of the RYR1 mutation frequency. Acknowledgements: Funding by Slovenian Research and Innovation Agency (P4-0133, Z4-60178, J4-3094) and project GEroNIMO (EU H2020 GA no. 101000236) are acknowledged.

Computed tomography demonstrates high repeatability when compared to chemical analysis when measuring pork carcass composition

C. A. Vaz Do Amaral[1], F. Anderson[1], M. T. Corlett[1], M. Trezona[2], A. Williams[1], L. Pannier[1], G. E. Gardner[1]
[1] Murdoch University, School of Agricultural Sciences, 90 South Street, 6150 Perth, Australia, [2] Linley Valley Pork, Research and Development, 50 Linley Valley Road, 6560 Perth, Australia

Objective online technologies are used in commercial abattoirs to estimate carcass composition in pork carcasses. However, the accuracy of these technologies depends on the reference method used in their calibration, which can vary according to its precision and repeatability. To date, no study has been conducted to directly compare the repeatability of Computed Tomography (CT) versus chemical analysis as calibration reference methods for pork carcass composition. Therefore, this study aimed to assess the repeatability of carcass composition measurements taken by CT versus chemical analysis. We hypothesised that CT measurements would demonstrate less variability between repeat scans compared to chemical analysis run on repeat sub-samples. Twenty pig carcasses were selected based on maximising the range of carcass weight (60–80kg) and back fat measurement (P2; 7–16 mm). Carcasses were split into belly, shoulder, loin, and leg sections, CT scanned three times consecutively, and the proportions of lean, fat, and bone % were quantified. Following scanning, the carcass sections were ground, and three subsamples were taken from each section to estimate protein, fat, and ash content. Repeatability was assessed within each carcass section for both the repeated CT measures and the repeated chemical samples using mean absolute deviation (MAD). Supporting our initial hypothesis, CT measurements demonstrated less variability between repeat scans compared to chemical analysis run on repeat sub-samples. For most carcass sections, the MAD for CT measurements of lean, fat, and bone % varied between 0.01 and 0.06 units. The high repeatability of CT measurements observed may be attributed to the robustness of the CT scanning as a non-destructive technique and the use of an additional phantom calibration, beyond the standard calibration. It ensures that tissue measurements remain consistent, independent of external factors such as operator variability and environmental conditions. In contrast, the MAD values for chemical determination of protein, fat, and ash% varied between 0.24 and 0.65 units. This high variability observed in the chemical analysis method likely reflects the influence of destructive sampling procedures, where operator effects during knife dissection of tissues and non-carcass tissues can introduce variations. Additionally, incomplete homogenisation, cross-contamination between fractions, or inconsistencies in solvent extraction and drying procedures may also contribute to the variation. These results indicate that CT is a more repeatable reference method than the traditional chemical estimation of carcass composition.

A standardized workflow for reproducible pig microbiome profiling across laboratories

The lack of a standardized protocol for DNA extraction in pigs, an animal of biomedical and agricultural relevance, limits reproducibility and cross-study comparability in microbiome research. Technical variance introduced during DNA extraction can obscure biological signals and hinder data integration across studies. Building on a pilot study that identified commercial kits yielding consistent microbial profiles, this study aimed to validate their reproducibility at a larger scale in a multi-center replication study involving six independent research facilities in Germany. We evaluated the effects of three DNA extraction kits on microbial communities using 16S rRNA gene amplicon sequencing and shotgun metagenomics on identical samples processed independently at each institution. Fecal samples from 200 male German Landrace × Pietrain pigs were subjected to DNA extraction using the three kits, following manufacturer protocols at all six facilities. Amplicons targeting the V1-V2 and V3-V4 regions of the 16S rRNA gene and PCR-free metagenomic libraries were sequenced on an Illumina NovaSeq (250 bp and 150 bp paired-end, respectively). Quality control and bioinformatic analyses were performed using DADA2 and QIIME2 for amplicons and Trim Galore with moshpit distributions v2026.1 for metagenomes. Shannon entropy and Bray-Curtis distances were calculated as α- and β-diversity metrics. Two of the three kits maintained stable Shannon entropy across all six facilities in the metagenomic dataset. For 16S amplicons, entropy values were highly consistent across locations (V1-V2: 4.61–5.27; V3-V4: 4.63–5.49), with narrow interquartile ranges and similar medians. Several Kruskal-Wallis tests for location were statistically significant ($p<0.01$), but numerical differences were small and not accompanied by clear shifts in diversity, indicating sensitivity to minor variation rather than relevant biological effects. ADONIS analyses based on Bray-Curtis distances confirmed significant effects of location, extraction kit and their interaction across all sequencing methods ($p=0.001$). However, effect sizes were minimal, location explained 1.5–2.8% of the variance, extraction kit 6.7–8.5% and their interaction 1.3–1.8%, while residual variation accounted for 87–90%. Overall, despite minor statistically detectable compositional differences, microbial community structure was highly consistent across facilities and kits. These results show that the selected DNA extraction kits, combined with the standardized protocol used here, effectively reduce technical variance in multi-center pig microbiome studies. We propose this workflow as a standardized operating procedure (SOP) for future porcine microbiome research, providing a reproducible framework that supports robust cross-study comparability and large-scale meta-analyses.

Improving weaning piglets performance and blood immune parameters by supplementing iron through a milk cup system during lactation

L. Sobrevia[1], F. González-Solé[1], L. Blavi[1], A. Koppenol[1], S. Tibble[1]
[1] AB Neo, PL Fraga, C/ Comunidad de Murcia, parc. LIE-1-03, 22520 Fraga, Spain

Iron is an essential mineral for the health and development of piglets, especially during weaning. At birth, piglets have limited iron reserves that deplete quickly as they shift from sow's milk to solid feed at weaning. Iron deficiency can lead to serious health issues, such as iron-deficiency anemia, which negatively affects the growth and overall well-being of the animals (Perri et al., 2016). In the farrowing house, piglets usually recieve iron injected 2d post birth to provide additional iron. Whereas an alternative approach is by providing an iron supplement via the milk replacer. The aim of the trial was to evaluate performance and blood immune cell composition during lactation and its continuity in post-weaning phase in piglets receiving iron injection and additional supplement via the milk replacer. From a farm with 2500 sows equipped with an automated milk cup system (Pump'n'Grow, AB Neo) in farrowing pens, 4 multiparous sows with similar parity were selected. During lactation all piglets (Danbred x Duroc) had access to a creep diet (1.80 ppm Fe) and a fresh milk replacer (Danmilk Supreme®, 150 mg/kg Fe) to supplement sow milk via Pump'n'Grow cup system for 18 days with or without supplementation of 0.2% Piglet Boozt (liquid source of inorganic Fe, 26g/kg). Two days after birth all piglets were injected with Forceris® (1.5 ml containing 133.4 mg/ml of iron III and 355.2 mg/ml gleptoferron). Piglets were weaned at 24 days of age with an average body weight of 6.80 (+/- 1.43) kg. Upon arrival at the nursery facilities (AB Neo Centre of Excellence, Huesca, Spain) all piglets had access to a standard prestarter diet (2.16 ppm Fe) and were weighed at weaning and 15 days post weaning to investigate post weaning performance. Blood samples were taken 9 days pre- and 12 days post weaning for blood immune cell profile during lactation and crucial post weaning period. Pre-weaning treatments were considered as fixed factors in the model. Although weaning weight of the selected litters was significantly lower for the supplemented piglets (6.62 vs 7.73kg) ($p<0.001$), their post-weaning ADG was numerically higher compared to unsupplemented control animals (129.76 vs 110.79 g/d, respectively) ($p=0.134$). Hematocrit increased similarly in both groups between 9d pre and 15d post weaning (4.36 vs 3.15%) ($p=0.213$). Hemoglobin, the protein carrying oxygen in red blood cells tended to be further increased in supplemented pigs (1.07 vs 0.5%) ($p=0.092$), whereas the increase in number of red blood cells (1.25 vs 1.40%) ($p=0.257$) and eosinophils (involved in defense against parasites and allergic reactions) (0.46 vs 0.43%) ($p=0.796$) was similar for both treatments. The increase in monocytes (responsible for phagocytosis of microorganisms and damaged cells) was significantly higher (1.35 vs 0.11%) ($p=0.017$), indicating a better defense in chronic infections and weaning induced inflammation of supplemented piglets. Concentration of basophils and lymphocytes decreased around weaning. Supplemented piglets had a significantly lower decrease for basophils (-2.58 vs –3.14%) ($p=0.011$) indicating better release of histamine in inflammatory response around weaning, whereas no differences were found in the total reduction of lymphocytes (-7.54 vs –7.51%) ($p=0.851$) to fight viral infections and to create immune memory. None of the supplemented piglets required medication in the post-weaning period, whereas 5 of the control animals were treated. In conclusion, supplementing piglets during lactations with a liquid iron supplement (Piglet Boozt – AB Neo) via the milk replacer, resulted in better growth and blood immune status post weaning and lower medication use.

It's not just about feeding. Fatty acid composition of the local Angler Saddleback pig

A. Olschewsky[1], M. Krieger[1], D. Hinrichs[1], A. Sünder[2], D. Mörlein[2]
[1] University of Kassel, Animal Breeding Section, Nordbahnhofstraße 1a, 37213 Witzenhausen, Germany, [2] University of Göttingen, Department of Animal Sciences, Kellnerweg 6, 37077 Göttingen, Germany

Feeding is known to be the main factor influencing the fatty acid composition in adipose tissues of pigs, and in particular the proportion of polyunsaturated fatty acids (PUFA). In a first study using Angler Saddleback (AS) pigs, an endangered breed from Northern Germany, evidence was found that other factors than feeding could be involved. Therefore, a follow-up study was conducted to further evaluate the factors influencing the fatty acid composition in intramuscular fat (IMF) and backfat (BF) and to assess feeding strategies that best meet the lower nutritional requirements and the reduced growth potential of the breed. The study included 58 purebred AS pigs and consisted of two consecutive trials. The first trial involved two feeding variants with different types of roughage (hay vs. grass clover silage). In addition, pigs were fed concentrate reduced in energy (M=12.4MJ) and protein (M=14.2%) as compared to commercial feeding practices. In the second trial, pigs of two further feeding variants both received grass clover silage and two different concentrates, varying in their protein levels (12.3-14.2%), while having the same reduced amount of energy. In addition, the concentrate was fed restrictively from 90kg (first trial) and from 50kg (second trial). Backfat and meat samples were taken from the loin muscle (M. Longissimus thoracis et lumborum) between the 13th and 14th ribs for the analysis of IMF and fatty acid methyl esters (FAME). Using gas chromatography coupled with flame ionization detection, FAME in feed, IMF and BF was analyzed. The BF thickness was determined based on a three-point measurement. With the restriction of concentrate (first trial: M=2.6kg fresh matter/day/pig, SD=0.3; second trial: M=2.5kg, SD=0.1) and protein content, the roughage intake increased across the feeding variants (first trial: M=0.8kg fresh matter/day/pig, SD=0.6; second trial: M=1.6kg, SD=0.9). The BF thickness reached 3.8cm on average in the first trial (SD=0.4), and declined to a mean of 3.5cm in the second trial (SD=0.5) despite the higher age of the pigs (first trial: M=235 days, second trial: M=287 days). The IMF changed only marginally (first trial: M=2.2%, SD=1.3; second trial: M=2.5%, SD=1,0). This was the desired consequence of performance-based feeding with the aim of avoiding excessive fat build-up even during prolonged fattening periods. As expected, the increased roughage intake was accompanied by elevated amounts of PUFA in the diet (first trial: M=45.3%, SD=2.3; second trial: M=58.1%, SD=0.4). However, this was negatively correlated with the PUFA content in IMF (first trial: M=13.8%, SD=3.5; second trial: M=12.4%, SD=2.9) and BF (first trial: M=11.9%, SD=1.3; second trial: M=9.4%, SD=2.1) which was consistently at a low level. This underlines the influence of other factors than feeding. As pigs age, the proportion of adipose tissue generally increases, which is known to be associated with a decline in PUFA levels. However, since the fattening strategies only had a negligible effect on IMF content and actually reduced BF thickness, the influence of age appears to be less relevant here. As in our previous study with AS pigs, a genetic effect with regard to the PUFA level in adipose tissues seems to be reasonable. This may include a special ability to utilize roughage, which has been fed for decades to AS pigs. With this, our study highlights the potential of local pig breeds to make good use of local feed resources and thus provide special meat qualities.

The influence of the sex of fattening pigs on the content of vitamins A and E and cholesterol in the longest dorsal muscle

K. Dobiesz[1], W. Kozera[1], G. Żak[2], M. Szyndler-Nędza[2], A. Mucha[2], K. Karpiesiuk[1]
[1] University of Warmia and Mazury, Oczapowskiego 5, 10-719 Olsztyn, Poland, [2] National Research Institute of Animal Production, Sarego 2, 31-047 Kraków, Poland

Pork remains the most commonly consumed meat in Poland, highlighting the importance of research into its chemical composition and health-promoting properties. Meat is an important source of vitamins, minerals, protein and fat. Vitamins A and E, which are among the most important substances with antioxidant properties accumulated in animal tissues, are of particular significance. The vitamin content of meat depends on many factors, including genetic and environmental influences. Sex can also affect the muscle composition of fattening pigs. The aim of the study was to determine the effect of sex on the content of vitamins E and A and cholesterol in the longest dorsal muscle (musculus longissimus dorsi, LD) of DanBrad hybrid pigs. A total of 30 samples were collected, 10 each from the carcasses of gilts, barrows and non-castrated boars. The content of fat-soluble vitamins A and E and cholesterol was determined in the samples tested. The data collected were subjected to statistical analysis. A one-factor analysis of variance was performed, and the significance of differences between means was determined using Duncan's test and verified at two significance levels: $p \leq 0.05$ and $p \leq 0.01$. The results were statistically compiled using the Statistica PL 13.5 program. The α-tocopherol content (mg/kg) in the longissimus dorsi muscle was 2.026 in gilts, 1.510 in castrated boars, and 1.646 in boars; the β-tocopherol content (mg/kg) was 0.027, 0.022, and 0.016, respectively; the γ-tocopherol content (mg/kg) was 0.136, 0.096, and 0.093, respectively; the Δ-tocopherol content (mg/kg) 0.084, 0.053, and 0.064, respectively; total tocopherols (mg/kg) respectively 2.273, 1.681, and 1.816; retinol content (mg/kg) respectively 0.226, 0.195, and 0.248; and cholesterol content (mg/kg) respectively 28.46, 31.19, and 42.97. When analyzing the vitamin content in the longest dorsal muscle across the individual experimental groups, statistically significant differences were observed in α-tocopherol levels between gilts and surgically castrated boars, as well as in β-tocopherol levels between gilts and boars. Muscle tissue from castrated animals and boars contained significantly less γ-tocopherol than tissue from gilts. No statistically significant differences in Δ-tocopherol content were found in the analyzed muscle between the animal groups. The highest tocopherol (vitamin E) content was found in muscle from gilts' carcasses. Statistically significant differences in vitamin E levels were noted between gilts and castrated boars. Meat from boar carcasses had the highest retinol content, with a significant difference in this component observed between boars and castrated males. Samples of the longest dorsal muscle from boars contained significantly more cholesterol than samples from gilts and castrated males. The differences between groups regarding cholesterol were statistically significant. The results indicate that the sex of the fattening pigs had a significant effect on the vitamins A and E, and cholesterol content in the longest dorsal muscle. Financed by the Minister of Science under the "Regional Excellence Initiative" program

Sensory properties and mechanical parameters of the longest dorsal muscle in fattening pigs depending on sex

K. Dobiesz[1], W. Kozera[1], G. Żak[2], M. Szyndler-Nędza[2], A. Mucha[2], K. Karpiesiuk[1]
[1] University of Warmia and Mazury, Oczapowskiego 5, 10-719 Olsztyn, Poland, [2] National Research Institute of Animal Production, Sarego 2, 31-047 Kraków, Poland

The aim of this study was analyse the influence of the sex of fattening pigs on the sensory properties and mechanical parameters of the longissimus dorsi muscle. A total of 30 samples were collected, 10 each from the carcasses of gilts, barrows, and non-castrated boars. Sensory evaluation of the meat after heat treatment was carried out by a trained panel of five people. In the collected samples, the force and energy required for cutting were determined. The double compression test (TPA) was used to assess hardness, springiness, cohesiveness, chewiness, and resilience of the muscle tissues. The collected data were subjected to statistical analysis, and the results were compiled using the Statistica PL 13.5 program. A total of 30 samples were collected, 10 each from the carcasses of gilts, barrows, and non-castrated boars. Sensory evaluation of the meat after heat treatment was carried out by a trained panel of five people. In the collected samples, the force and energy required for cutting were determined. The double compression test (TPA) was used to assess hardness, springiness, cohesiveness, chewiness, and resilience of the muscle tissues. The collected data were subjected to statistical analysis, and the results were compiled using the Statistica PL 13.5 programme. Analysis of the sensory properties of the longitudinal dorsal muscle showed a significant influence of gender on most of the characteristics studied, with particular emphasis on the desirability of smell and taste, as well as juiciness. The lowest desirability of smell (3.60 points) and taste (3.35 points) was recorded in the group of boars, as confirmed by statistically significant differences ($p \leq 0.05$) compared to gilts and pigs. For taste desirability, these differences were highly significant ($p \leq 0.01$) compared to pigs (4.70 points). At the same time, boars were characterised by the highest taste intensity (4.60 points), which, given the low desirability, suggests the presence of unusual aromas. The juiciness parameter was most favourable in boars (3.85 points) and gilts (3.70 points). Pork meat was significantly less juicy (3.15 points; $p \leq 0.05$) than the other groups. Although no statistically significant differences were found, there was a noticeable tendency towards a higher assessment of the tenderness of gilt meat (3.30 points) compared to boars (2.65 points). Analysis of the physical parameters of the LD-muscle showed a clear distinction between boar meat and the other groups. Boar meat was characterised by the highest cutting force (82.48 N) and cutting energy (217.45 J). These values were statistically significantly higher ($p \leq 0.01$) compared to pigs and gilts. The muscle tissue of gilts was distinguished by the highest elasticity (0.772), cohesiveness (0.712), and springiness (0.326) compared to the other groups ($p \leq 0.05$). The greatest weight losses during heat treatment were recorded in boars (38.34%), which differed significantly from the results obtained for pigs and gilts. When analysing hardness and chewiness, no statistically differences were observed. The highest values for these features were recorded in the longissimus dorsi of boars, and the lowest in pigs. In terms of technology, gilt and pig meat have much better mechanical parameters (lower cutting force) and sensory qualities (higher desirability) than boar meat. The high instrumental hardness of meat from boar carcasses (cutting force and energy) is a significant barrier to their acceptance as a raw material of high culinary quality.

Evaluation of handheld near infrared spectrometers (NIRS) for prediction of fat quality traits at slaughter

Z. Bodor[1], Y. Chen[1], D. Mörlein[1]
[1] University of Göttingen, Department of Animal Sciences, Kellnerweg 6, 37077 Göttingen, Germany

The fatty acid composition of pig meat and fat is considered a relevant quality trait affecting its nutritional value, sensory and also the further processing properties. Hence, on-site predictions at slaughter would facilitate quality control, decision making and product sorting. Therefore, this project aims to evaluate the feasibility of two handheld NIRS devices that appear to be promising solutions for this goal. Further goal is to find the most appropriate measurement condition (carcass status, body part) for the prediction of fatty acid composition. In a pilot study (PS) 22 carcasses (11 fatty and 11 normal-weight pigs) were chosen for the data acquisition in a slaughter house. Five repeated scans were taken along an approximately 10 cm of the backfat and neckfat (left carcass) using two handheld devices (Trinamix PAL-One – for PS – and PAL-Two later on, and Viavi Micronir OnSite-W). Spectra were obtained both, on hot (about 45 min. p.m.) and cold carcasses (about 24 hrs. p.m.). In the later course of the project, spectra were collected on the neckfat of 430 carcasses (cold, 24 hrs. p.m.), with the pigs originating from two different husbandry systems (conventional, and ecological farming) from Germany. Fatty acid composition of subcutaneous fat was determined in duplicate using GC-FID after fat extraction and preparation of the fatty acid methyl esters (FAME). FAME data (average of the two repeats) were matched with average of NIRS spectra per sample in the case of PS. Multivariate statistical methods were applied after pre-treatment of the spectra (e.g., Savitzky-Golay smoothing and detrending or baseline shift correction). Principal component analysis (PCA) was used for pattern recognition, and partial least square regression analysis (PLSR) was applied for quantitative prediction models of individual fatty acids as well as main groups of fatty acids (saturated -SFA, mono-unsaturated-MUFA, poly-unsaturated-PUFA) using leave-one-out cross-validation. PLSR models were built separately for the back- and neck fat on the two datasets from warm and cold carcasses. Spectral data of the 430 pigs was analysed also with PCA-LDA for the classification of the origin of pigs (husbandry systems). The pilot study revealed effects of location of data acquisition and environmental conditions: backfat width (over M. longissimus) being usually lower than neckfat thickness can result in insufficient spectral acquisition. The window size of the instrument – in some cases – can be bigger than the cut surface (backfat) where spectra are taken. PCA model of PS showed the separation tendency of the spectra of warm and cold carcasses. PLSR models provided better prediction accuracies (R^2CV) in the case of MUFA and PUFA compared to SFA content with both devices. R^2CV of the prediction models ranged from 0.50-0.85, and error value (RMSECV) lower than 2.5% in all cases. PCA models based on cold carcass spectra of 430 pigs did not show a clear separation tendency according to the husbandry system or the slaughter date. However, PCA-LDA classification yielded a clear distinction of the husbandry conditions. Separation trend and better prediction parameters (R^2CV, RMSECV) on the cold carcass could be explained by the cooling process during the warm carcass measurements, which shows the demand for more stable environmental conditions. Regression models provided promising results for the prediction of groups of fatty acids (e.g., PUFA, MUFA), especially with the VIAVI device (950-1650 nm). Further analyses will focus on the extension of the reference dataset and improvement of the robustness. The GlasSchwein project is funded by the German Federal Office for Agriculture and Food (Project ID 28DI107B23).

GlasSchwein: Development of predictive models for parameters of meat quality and quantity along the pork value chain

F. Heinrich[1], Y. Chen[1], Z. Bodor[1], D. Mörlein[1], R. Hölscher[2], V. Beck[3], S. Retz[4], A. O. Schmitt[1]
[1] University of Göttingen, Department of Animal Sciences, Margarethe-von-Wrangell-Weg 7, 37075 Göttingen, Germany, [2] Hölscher + Leuschner GmbH & Co. KG, Siemensstraße 15, 48488 Emsbüren, Germany, [3] Brand Qualitätsfleisch GmbH & Co. KG, Brandstraße 21, 49393 Lohne, Germany, [4] Center for Sustainability Transformation Research in AgriFood Systems, Driverstraße 22, 49377 Vechta, Germany

The German pork production industry faces increasing economic pressure to improve sustainability and differentiate its products from international competitors. However, existing approaches to digitalize and transfer information between stakeholders that could help to alleviate these problems are often silo solutions, fragmented and lack consistent single-animal traceability. To address these challenges, “GlasSchwein” (“Glass Pig”) is a joint project between partners from industry and academia in Lower Saxony, Germany, that aims to digitalize the pork value chain via a shared data platform connecting relevant actors. By enhancing transparency and active exchange of information throughout the value chain, interoperability is increased, allowing processes to be more easily controlled and optimized. Furthermore, this transparency enables a differentiation of pork products and a targeted improvement of meat quality, facilitating better monetization of individual animals. Piglets are equipped with UHF RFID ear tags, enabling the automatic detection and tracking of each individual pig throughout its entire lifecycle. By utilizing 3D cameras, we obtain automatic daily weight measurements for every pig during the fattening period. In the slaughterhouse, carcass and meat quality traits are assessed using multiple different non-invasive methods, such as ultrasound, near-infrared spectroscopy and hyperspectral imaging. These approaches aim at providing novel quality parameters, allowing farmers to be remunerated for more than just the slaughter weight and lean meat content of their pigs. Additionally, they present new targets for breeding programs to enhance meat quality and increase consumer appeal. A central objective of this project is to utilize comprehensive data obtained along the value chain with its wide variety of data sources to develop predictive models for meat quality and quantity, as well as other relevant metrics, such as the optimal slaughter date. In addition to predicting future parameters, the statistical relationships between them are analyzed. This may provide the opportunity to replace expensive and time-consuming measurements with more cost-effective approaches. Of particular interest is also the impact of pre-slaughter handling and transport between the farm and the slaughterhouse on meat quality, which could create further incentives for improving animal welfare. Preliminary results suggest an association between growth rate of the pigs during the fattening period and different quality measures. However, this association is dependent on the sex of the animals. For example, only sows exhibit a significant correlation between growth rate and lean meat percentage. Notably, this tendency – albeit to a lesser extent – can already be observed after less than a month of fattening. This early indicator provides farmers with the opportunity to potentially influence the meat characteristics by adjusting the type or quantity of feed for individual pigs. However, further analyses are needed to confirm this, along with additional use cases relating to meat quality. The GlasSchwein project is funded by the German Federal Office for Agriculture and Food (Project ID 28DI107B23).

Effect of turmeric supplementation on growth performance, nutrient digestibility, and blood parameters in growing pigs subjected to heat stress

L. Pu[1,2], S. Shanmugam[1,2], J. H. Kim[1,2], K. Lee[1,2], K. Han[2], I. H. Kim[1,2]
[1] Dankook University, Department of Animal Biotechnology, 119, Dandae-ro, 31116 Cheonan, South Korea, [2] Smart Animal Bio Institute, Dankook University, 119, Dandae-ro, 31116 Cheonan, South Korea

Heat stress is a major environmental challenge in pig production, negatively affecting feed intake, growth performance, nutrient utilization, and physiological homeostasis. Prolonged exposure to high ambient temperatures induces oxidative stress, inflammation, and immune suppression, ultimately impairing productivity and animal welfare. Natural feed additives with antioxidant and anti-inflammatory properties have gained increasing attention as sustainable strategies to mitigate heat stress–related losses. Turmeric (Curcuma longa), rich in bioactive compounds such as curcumin, has been reported to possess antioxidant, anti-inflammatory, and immunomodulatory effects. Therefore, the objective of this study was to evaluate the effects of dietary turmeric supplementation on growth performance, nutrient digestibility, and blood parameters in growing pigs subjected to heat stress, with the aim of assessing its potential as a nutritional strategy to alleviate heat stress and improve production efficiency. A total of 210 ([Yorkshire × Landrace] × Duroc; 24.3 ± 3.51 kg) growing pigs were assigned to one of three dietary treatments: a basal diet (CON), TRT1, CON + 0.05% turmeric; and TRT2, CON+0.10% turmeric. Data was analyzed in a complete randomized block design using the GLM procedures of SAS (SAS Institute, Cary, NC, USA). Linear and Quadratic polynomial contrasts were used to examine the graded levels (0.05- 0.10%) of turmeric supplementation. . Pigs fed graded level of turmeric supplementation showed linearly improved $P < 0.05$ body weight and average daily gain (ADG) at the end of week 6. Furthermore, pigs fed 0.10 % of turmeric showed tended to improve feed intake with no notable changes on feed conversion ratio (FCR). In addition, nitrogen digestibility was improved in pigs fed graded level of turmeric supplementation. However, there were no notable changes observed on fecal gas emissions or fecal scores. Whereas, blood biochemical analysis revealed significant reductions in serum aspartate aminotransferase (AST) and blood urea nitrogen (BUN) levels, suggesting a potential alleviation of oxidative stress. Overall, dietary turmeric supplementation improved growth performance and nitrogen utilization in finishing pigs and may serve as a nutritional strategy to mitigate heat stress. Keywords: turmeric supplementation; growing pigs, blood profile; oxidative stress

Effect of increasing level of L-carnitine for lactating sows on sow body mobilization, milk composition, litter growth and sow plasma cytokines

C. Larsen[1], D. Nguyen[1], K. L. Mønsted[1], T. Bruun[2], A. Strathe[1]
[1] University of Copenhagen, Grønnegårdsvej 3, 1870 Frederiksberg, Denmark, [2] SEGES Innovation P/S, Agro Food Park 15, 8200 Aarhus, Denmark

It was hypothesized that increasing levels of dietary L-carnitine for lactating sows would improve the energy utilization of the sow and increase milk production and quality, litter growth and improve body condition and inflammatory status of the sow. In a dose response trial with 6 groups including 245 sows, the sows were fed increasing levels of L-carnitine (0, 179, 294, 532, 734 and 941 mg/kg feed) from 5 days prior to expected farrowing and until weaning at day 28. On day 1 after farrowing the litter was standardized to 15 piglets. The BW and backfat thickness of the sow and the litter weight were measured at standardization and at weaning. In a subsample of 67 sows blood samples from the jugular vein were collected at standardization and weaning and analyzed for IL-6, IL-10 and TNF-α. Milk samples were taken at d 17 of lactation analyzed for DM, fat, protein and lactose and a Brix value was measured. Spline models and linear models were fitted to data and compared for each of the response variables. For all response variables the individual concentration of dietary L-carnitine for each sow was included as fixed effect. All models accounted for a random week batch effect. The final statistical models for analyzing data on changes in sow BW and backfat thickness, litter size and litter ADG included the parameters: sow parity, total litter weight at standardization, sow body weight at standardization, and the sow's average daily feed intake. Models for analyzing milk and blood data included sow parity. P-values below 0.05 were considered statistically significant. The number of weaned piglets (13.6±1.2, P=0.295) and the ADG of the litter (3.1 kg/day, P=0.534) was unaffected by dietary treatment. The loss of back fat was not affected by dietary L-carnitine (P=0.937). For the BW loss the spline fitted better to data than the linear model (P=0.037) and the BW loss was reduced by 3.7 kg with addition of 436 mg L-carnitine pr. kg feed compared to the control group. Milk composition was unaffected by dietary treatment (P>0.05). Plasma IL-6 concentration at litter standardization was best fitted using a spline compared to the linear model (P=0.0303). There was effect of dietary treatment (P=0.0175), but not parity (P>0.05). The plasma IL-6 concentration was highest (2742 pg/mL) at 1002 mg L-carnitine pr kg. Plasma IL-6 concentration at weaning was best fitted using af spline compared to the linear model (P=0.0219). There was effect of dietary treatment (P=0.0132), but not parity (P>0.05). The plasma IL-6 concentration was highest (2735 pg/mL) when fed 1002 mg L-carnitine pr kg. IL-10 concentration at standardization was best fitted using a spline model compared to the linear model. There was effect of dietary treatment (P=0.0341) but not parity (P>0.05). The IL-10 concentration was highest (76.4 pg/mL) at 748 mg L-carnitine pr kg. The plasma TNF-α concentration at standardization and weaning and IL-10 at weaning was not affected by dietary treatment (P>0.05). A reduction in the BW loss could have a positive impact on the following reproduction, but it is not likely that a difference of 3.7 kg would affect reproduction negatively. I Higher dietary L-carnitine increases metabolic rate, fat mobilization, and milk production, all of which naturally elevate metabolic IL-6 signaling after farrowing and during lactation. The rise in IL-10 reflects a normal anti-inflammatory compensatory response balancing increased IL-6. In conclusion, only minor effects were seen on sow plasma cytokines concentrations and sow BW loss when feeding increasing levels of L-carnitine during lactation.

Effect of increasing level of extruded linseeds for lactating sows on changes sow body mobilization, litter gain, milk composition and plasma cytokines.

E. Christensen[1], C. Larsen[1], K. Mønsted[1], D. Nguyen[1], S. Jensen[3], T. Bruun[2], A. Strathe[1]
[1] University of Copenhagen, Grønnegårdsvej 3, 1870 Frederiksberg, Denmark, [2] SEGES Innovation P/S, Agro Food Park 15, 8200 Aarhus, Denmark, [3] Aarhus University, Blichers Allé 20, 8850 Tjeke, Denmark

It was hypothesized that increasing levels of dietary omega-3 fatty acids for lactating sows can improve milk production and quality, litter growth and improve body condition and inflammatory status of the sow. In a dose response trial with 6 groups in total including 208 sows, the sows were fed increasing levels of extruded linseed (0, 1.2, 2.4, 3.6, 4.8 and 6.0 % of Easylin) from 5 days prior to expected farrowing and until weaning at d28. On d1 after farrowing the litter was standardized to 15 piglets. The BW and backfat thickness of the sow and the litter weight were measured at standardization and at weaning. In a subsample of 56 sows blood samples from the jugular vein were collected at d6 and 17 and analyzed for IL-6, IL-10 and TNF-α. Milk samples were taken at d 6 and 17 of lactation and analyzed for DM, fat, protein and lactose using MilcoScan, as well as fatty acid composition and a Brix value was measured. Spline models and linear models were fitted to data and compared for each of the response variables. For all response variables the individual daily intake of α-linolenic acid (ALA) for each sow was included as fixed effect. All models accounted for a random week batch effect. The final statistical models for analyzing data on changes in sow BW and backfat thickness, litter size and litter ADG included the parameters: sow parity, total litter weight at standardization, sow body weight at standardization, and the sow's average daily feed intake. Models for analyzing milk and blood data included sow parity. P-values below 0.05 were considered statistically significant. The BW loss (P=0.573) and mobilization of back fat (P=0.473) was unaffected by inclusion of extruded linseed. Number of weaned piglets was not affected by dietary treatment (P=0.620), but there was a tendency for increased litter ADG with 22 g/d per 1% unit extruded linseed (P=0.090). Milk fat % at d6 was best fitted using a linear model and linear model was different from the null model (P=0.0409). There was effect of dietary treatment (P=0.0333). An increased intake of 1 g ALA increased the fat % by 0.029. The ALA content (4.71 mg/100 g milk) was optimized at 33.47 g of dietary ALA per day. Milk protein % at d17 was best fitted using a spline model. There was effect of dietary treatment (P=0.0088). The milk protein % was optimized (4.57%) at a daily intake of ALA at 21.5 g/d. The n-6:n:3 ratio of the milk at d17 was best fitted using a spline model. There was effect of dietary treatment (P<0.001). The n-6:n-3 ratio of the milk was decreased with increasing dietary ALA and was lowest at 41.5 g of dietary ALA per day with a n-6:n-3 ratio at 2.50 and highest at 8.0 g of dietary α-linolenic acid per day with a n-6:n-3 ratio at 10.9.. The small increase in litter ADG could be a result of increased content of fat and n-3 fatty acids in the milk. Plasma IL-6 at d17 was best fitted using a spline model compared to the linear model and there was effect of dietary treatment (P=0.0087) . The lowest daily intake of ALA (8.23 g/day) resulted in the highest plasma concentration of IL-6 (16358 pg/mL). Plasma IL-6 at d6, IL-10 and TNF-α was not affected by dietary treatment (P>0.05). High dietary ALA lowers plasma IL-6 because it reduces arachidonic-acid–derived inflammatory eicosanoids and activates anti-inflammatory transcription factors. In conclusion, increasing dietary levels of ALA altered the milk composition and the inflammatory status of the sow, but only a tendency for increased litter ADG.

Lactation feed intake and feed intake relative to body weight are associated with litter weaning weight across sow parities

C. Mulvenna[1], M. Sungirai[1], R. Muns[1]
[1] Agri-Food and Biosciences Institute (AFBI), Monogastric Research Group, Large Park, BT26 6DR Hillsborough, United Kingdom

Lactation is an energetically expensive process for sows, requiring sufficient feed intake (FI) to support milk production, litter growth and maintenance of sow body condition (or growth for gilts) for subsequent parities. Lactation FI and water intake (WI) are known to be associated with litter performance. However, both vary between sows due to body size and across parities. Thus, making absolute intake difficult to interpret across sows. Expressing intake, relative to sow body weight may provide a size-adjusted indicator to determine if lactation intake is adequate. This study aimed to quantify lactation FI and WI influence on litter weaning weight from consecutive parities. We hypothesized that the novel metric, lactation FI relative to sow body weight (FI:BW ratio) would be positively correlated with litter weaning weight across parities 1-5, and WI would increase with increasing lactation feed intake. This study was conducted at AFBI pig research farm. 43 sows (landrace x large white) were monitored over 5 consecutive parities (1-5). Sows and their piglets were housed in conventional individual farrowing crates. From the day of farrowing, food and water were provided to sows Daily FI (kg), WI (L), were recorded for each individual sow. On the day of weaning (28 days post-farrowing) sows and their respective litters were weighed. Statistical analyses were conducted using R (Version 4.3.1). Linear mixed-effects models included sow as a random effect to account for repeated measurements across parities. Fixed effects included either total lactation FI or FI:BW ratio, parity, and total piglets weaned. Additional models evaluated associations between WI, FI, and litter weaning weight. Significance was set at $P<0.05$. Interactions between intake variables and parity were tested and were not significant. Total lactation FI ranged from 112 to 240 kg and total lactation WI ranged from 348 to 1052 L. Litter weaning weight decreased with increasing parity relative to parity 1 ($P < 0.01$). Approximately 14% of the variation in litter weaning weight was attributable to between-sow differences. Total lactation FI was positively associated with total litter weaning weight ($\beta = 0.196 \pm 0.039$ kg per kg feed; marginal $R^2 = 0.577$; conditional $R^2 = 0.635$; $P < 0.001$). Each additional kilogram of feed consumed during lactation increased litter weaning weight by approximately 0.20 kg. Similarly, there was a significant positive relationship between FI:BW and litter weaning weight (marginal $R^2 = 0.568$; conditional $R^2 = 0.627$; $P < 0.001$), demonstrating that higher FI relative to sow size supported increased litter weaning weight. Water intake was associated with FI ($\beta = 2.16 \pm 0.40$; marginal $R^2 = 0.262$; conditional $R^2 = 0.640$; $P < 0.001$), indicating that sows consuming more feed also consumed more water (mean 3L:1kg feed ±0.59). However, WI alone was not significantly associated with litter weaning weight ($P > 0.05$), suggesting that its influence on litter performance may be driven by FI. These findings confirm the importance of maximising sow FI during lactation to support litter growth. While WI increased with FI, it did not independently predict litter weaning weight in the current dataset. These results support the hypothesis that FI:BW ratio was positively associated with litter weaning weight across parities and may be a useful metric to assess adequacy of size-adjusted intake in lactating sows.

E. coli and early mortality: Association of MUC4, MUC13 and FUT1 parental genotypes with pre-weaning mortality in a commercial pig population

J. De Kort[1], J. Depuydt[2], K. Hooyberghs[1,3], S. Janssens[1], N. Buys[1], W. Gorssen[4]
[1] KU Leuven, Center for Animal Breeding and Genetics, Department of Biosystems, Kasteelpark Arenberg 30, 3001 Leuven, Belgium, [2] Vlaamse Piétrain Fokkerij vzw, Aardenburgkalseide 254, 9990 Maldegem, Belgium, [3] Liège Université, Unit of Animal Genomics, GIGA and Faculty of Veterinary Medicine, Avenue de l'Hôpital 11, 4000 Liège, Belgium, [4] ETH Zürich, Animal Genomics, Universitätsstrasse 2, 8092 Zürich, Switzerland

Diarrhoea caused by enterotoxigenic Escherichia coli (ETEC), particularly F4 and F18 strains, remains an important cause of mortality in pigs and results in substantial economic losses. Genetic resistance to ETEC infections has been associated with SNP markers located near candidate genes such as MUC4, MUC13 and FUT1, which are involved in intestinal mucin biology and host receptor glycosylation. While these markers have been proposed as indicators of host resistance through the absence of functional receptors for specific fimbriae (F4 and F18), their relevance for pre-weaning mortality (PWM) under commercial production conditions is not yet fully established. The objective of this study was therefore to evaluate associations between parental genotypes at three E. coli–related loci (MUC4, MUC13 and FUT1) and PWM. The dataset consisted of 739 genotyped hybrid sows and 1370 genotyped Piétrain boars used on a commercial farm in Flanders, Belgium. In total, 1381 litters with complete parental genotypes and phenotypic records for piglets born alive and pre-weaning mortality were available. Genotype distributions were assessed for Hardy–Weinberg equilibrium. Exploratory analyses included genotype frequencies and calculation of mean PWM across genotypes and parental genotype combinations. To account for the binomial nature of the data, generalized linear mixed models with a logit link were fitted, modelling the number of pre-weaning deaths relative to the number born alive. Models included parental genotype (or genotype combination) as fixed effect, parity and gestation length as covariates and sow and boar as random effects to account for repeated observations. For MUC4 and FUT1, no significant associations were detected at sow level, boar level, or parental genotype combination level ($p > 0.05$). In contrast, for MUC13, no significant effects were observed when analysing sows or boars separately, but parental genotype combinations were significantly associated with PWM ($p = 0.0309$). For the MUC13-related marker ASGA0091537, the C-allele has previously been associated with resistance to F4 fimbriae adhesion. In the present study, litters from CT×CT (odds-ratio = 0.75, $p = 0.0012$) and CT×TT (odds-ratio = 0.82, $p = 0.0125$) parental genotype combinations (boar x sow) showed significantly lower mortality compared with the reference combination TT×TT. Random effects indicated substantial variability between sows (σ^2sow = 0.136) and boars (σ^2boar = 0.072), suggesting that individual animal effects remain important determinants of PWM. Overall, these results indicate that under commercial conditions, MUC4 and FUT1 genotypes are not strongly associated with pre-weaning mortality. However, parental genotype combinations at the MUC13 locus may influence early piglet survival, potentially reflecting non-additive or heterozygote-related effects. It should be noted that the present study only included records on pre-weaning mortality, while some of these markers have primarily been associated with resistance to post-weaning diarrhoea. Although the observed effects are moderate, these findings highlight the importance of evaluating marker effects under practical production environments and considering parental genotype interactions when assessing candidate genes for ETEC resistance.

Rethinking AI for Animal Welfare: Framing, Misinformation and Ethics

M. A. Von Keyserlingk[1], K. Sheng[1], B. Foris[2], D. M. Weary[1]
[1] The University of British Columbia, Animal Welfare Program, 2357 Main Mall, V6T 1Z6 Vancouver, Canada,
[2] University of Veterinary Medicine, Animal Welfare Science Unit, Veterinaerplatz 1, 1210 Vienna, Austria

Animal welfare is a complex, multi-faceted concept, and how ”good welfare” is defined often depends on the values and priorities of various decision-makers. Artificial Intelligence (AI) is increasingly framed as a tool for monitoring and improving farm animal welfare, but is this framing justified? Recently, we systematically examined how the welfare impacts of precision livestock farming (PLF) are framed in the literature and found that most studies used positive language, implying that technology use improves animal welfare. However, despite this positive framing, few studies were able to draw a clear connection between a specific PLF measure and a concrete welfare outcome. Instead, much of the language remained vague, falling short of establishing a link between a given technology and a welfare improvement, indicating “welfare-washing”. Equally limited was the discourse surrounding the ethical deployment of technology in livestock farming and the potential welfare risks that PLF use may introduce. This “welfare-washing” bias extends beyond the scientific literature. Using ChatGPT’s text-to-image model, we show how general purpose AI can reinforce misinformation about livestock farming to the broader public through hidden internal mechanisms. The model consistently romanticized farming, depicting dairy cows grazing on pasture and pigs rooting in mud, even when explicitly prompted for realistic depictions of industrialized farming. The root cause of this bias lies in the model’s internal prompt revision process, hidden from users, which rewrites inputs to produce more aesthetically appealing images. When we bypassed this process, the base model demonstrated clear awareness that most farm animals in industrialized countries are housed intensively, producing images that accurately reflected modern farming practices (i.e., pigs housed on concrete). Our work shows that hidden internal mechanisms within AI have the potential to erase the reality of controversial topics like intensive livestock farming. These types of algorithms can further exacerbate the disconnects between public perception and actual farming practices, hindering meaningful dialogue addressing disconnects between farming with societal values, and undermining the social sustainability of both AI and livestock farming. These concerns are further compounded by the hidden costs of AI itself. Many PLF solutions are now being scaled up using AI, but AI is not a value-neutral tool. Criticisms include its massive energy consumption during training and inference time, mining of rare minerals and natural resources to build the physical infrastructure hosting these digital systems. Concerns also exist regarding the exploitation of labour from marginalized communities for data labeling and review of toxic content, and large-scale scraping of internet data without consent or regard for copyright. From a One Welfare perspective, the environmental and societal harms associated with on-farm AI use may not be offset by animal welfare improvements, even under conditions where such improvements are well-established. Moving forward, we propose adapting the 3Rs framework, the internationally accepted ethical principles guiding the humane use of animals in science, for use when integrating AI into livestock farming. We suggest researchers consider: 1) replacement: should AI be used at all? 2) reduction: minimize the number and size of models, computations, and iterations while maintaining scientific integrity and, 3) refinement: include validation steps and improve energy efficiency in both training and deployment.

The Digital Ethogram: A Multimodal, High Time-Resolution Representation of Animal Behaviour

T. D. Parsons[1,2], D. Foy[1,3]
[1] DAT-AI-LAB, 505 Byrd Road, 19348 Kennett Square, United States, [2] University of Pennsylvania School of Veterinary Medicine, Swine Teaching and Research CenterSchool of, 382 West Street Road, 19348 Kennett Square, United States, [3] AgriGates, 1827 Dickinson Street, 19146 Philadelphia, United States

Ethograms have long served as the foundational framework for describing animal behaviour, primarily based on human visual observation and historically focused on species-specific motor patterns. Human observational capacity often limits ethograms to behaviours with an onset lasting 1 to 10 seconds. Advances in video recording have improved the quality of behavioural observations by better controlling intra- and inter-observer reliability and reducing the possible impact of the observer on the animal's behaviour. The use of wearable sensors and acoustic monitoring has expanded the ways we can capture animal behavioural data. However, these technologies are often applied as extensions of existing observational paradigms rather than as catalysts for redefining behavioural representation itself. The advent of these high-frequency, multimodal data streams raises the question of whether traditional ethogram structures are appropriate for fully appreciating the subtlety and complexity of behavioural data, especially when destined for analysis by Artificial Intelligence (AI). A simple behavioural transition from lying to standing is traditionally coded as a single event with a lone timestamp. However, high-frequency digital monitoring devices enable the description of this transition by hundreds of data points or more. Such a transition from lying to standing can be decomposed into distinct phases, revealing behavioural structure that often is not visible within traditional ethogram frameworks. Furthermore, the synthesis of digital data streams from multiple types of time-resolved detectors further extends the observational landscape and offers even richer datasets. Here, we introduce the concept of a digital ethogram and describe the metrics required for synchronized video, inertial measurement units, and acoustic data to enable the representation of behaviour across multiple temporal and biological scales. Digital ethograms retain the interpretability of classical ethology while enabling higher resolution measures of latency, duration, intensity, asymmetry, and behavioural sequencing. By pairing annotated behavioural labels with multimodal sensor signatures, these representations yield reproducible datasets well-suited to machine-learning applications while remaining grounded in biological meaning. Importantly, this approach shifts the focus from isolated behavioural snapshots to continuous behavioural streams, enabling the detection of health- or welfare-relevant patterns, such as early indicators of discomfort or subtle changes in movement quality, with greater robustness. By reframing ethograms as compilations of structured temporal representations rather than solitary human-coded observations, digital ethograms derived from multimodal, high-temporal-resolution data promise to support more nuanced, scalable, and biologically meaningful insights into animal behaviour, welfare, and health. Digital ethograms do not replace human observation, but extend it, providing a scalable framework for behavioural science in the era of big data, precision livestock farming, and AI-enabled health and welfare assessment and insights.

Health and Welfare Commission perspectives on AI and farm animal welfare

L. Boyle[1]
[1] *Teagasc, Pig and Poultry Reseacrh and Knowledge Transfer, Moorepark, P61 C996 Fermoy, Ireland*

The rapid integration of artificial intelligence (AI) into livestock systems presents both transformative opportunities and significant challenges for animal welfare. As precision livestock farming evolves, AI-driven tools—such as real-time monitoring, predictive analytics, and automated decision support—offer potential to enhance early disease detection, optimize management practices, and improve individual animal outcomes in increasingly intensive production environments. These uses remain largely focused on increasing production efficiency and performance rather than on improving animal welfare. The Health and Welfare (HW) Commissions view is that technologies must not serve merely as efficiency enhancers that perpetuate confinement-based systems or mask underlying welfare deficits. We believe that welfare science must play a critical role as AI becomes more deeply embedded, ensuring that technological advancements prioritise ethical considerations, holistic well-being, and the "One Welfare" framework over reductionist fixes. Key concerns include the risk of further alienating animals from stockpeople, reducing sentient beings to data points, and reinforcing large-scale intensive models through economic dependencies on high-tech interventions. By centring welfare expertise at the intersection of ethics, science, and emerging technologies, the HW Commission advocates for responsible AI deployment that aligns with consumer expectations, scientific evidence on the benefits to welfare of facilitating natural behaviours and pasture access, and broader societal demands for humane livestock production. This perspective provides an essential anchor for balanced discourse, guiding the livestock sector toward innovations that genuinely advance animal welfare rather than merely sustaining current paradigms.

From data streams to breeding values: developing and harmonizing novel phenotypes for sustainable livestock genetic improvement

L. F. Brito[1]
[1] *Purdue University, Department of Animal Sciences, 270 South Russell Street, 47907 West Lafayette, United States*

The rapid expansion of data collected in livestock production systems, including genomic information, on-farm records, sensor-derived measurements, and other high-throughput phenotypes, offers unprecedented opportunities to refine animal breeding programs. However, the effective use of these data requires careful consideration of how traits are defined, measured, standardized, and integrated across diverse data sources. This presentation will discuss key steps involved in the development and implementation of novel phenotypes for genetic improvement. First, emphasis will be placed on the identification and definition of biologically meaningful traits derived from emerging data streams. Such traits must be evaluated for data quality, repeatability, and genetic parameters to determine their suitability for inclusion in breeding programs. Second, the importance of harmonizing data structures and standardizing phenotypes across farms, recording systems, and technologies will be highlighted, as inconsistencies in measurement protocols and data formats remain major barriers to large-scale analyses. Examples from dairy cattle and other livestock systems will illustrate how integrating phenotypes from traditional recording systems with information derived from sensors and other technologies can support the study of complex traits related to health, welfare, efficiency, and resilience. Particular attention will be given to approaches and tools for integrating heterogeneous datasets, ensuring data quality, and investigating the genetic architecture of newly developed traits. Finally, the presentation will discuss how well-defined and standardized phenotypes can be incorporated into genetic evaluations and breeding objectives, ultimately enabling the development of more informative selection tools. These topics are highly relevant to researchers, breeding organizations, and industry stakeholders seeking to translate rapidly expanding data resources into practical genetic improvement strategies.

Data standardisation for welfare and genetics evaluations

A. Granados Chapatte[1], S. Orlandini[1]
[1] International Committee for Animal Recording, Arthur van Schendelstraat 550, 3511 MJ Utrecht, Netherlands

Today, a wide range of sensors and monitoring systems are rapidly expanding to measure additional animal characteristics, expanding the opportunities to collect data related to the welfare of animals, their individual and group behaviour, robustness and sustainability performance. These technologies generate a new volume of data which can be used to effectively prevent harmful events, to support early detection tools, breeding strategies and targeted interventions in individual animals, farms or at the population level. To be able to widely implement such strategies and tools, those systems and the data collected need to seamlessly communicate to deliver reliable, robust, high-quality, and comparable data. ICAR plays a central role in building scientific and practical consensus for establishing joint international guidelines for harmonization, validation and certification of devices, methods and exchange of data. Achieving consensus on trait definitions, reference standards, and data usage is essential to ensure consistency and value. This multidisciplinary collaboration brings together expertise from across the dairy value chain, helping translate cutting-edge academic research into practical tools and real-world applications. As sensor technologies continue to evolve, ICAR is creating the framework needed to evaluate new devices, to facilitate interoperability and data flows, and harmonize how their results are interpreted. Several initiatives and projects have emerged in this context.

European Network on Livestock Phenomics: an international initiative aimed at promoting and resourcing advanced phenotyping in livestock

G. Schiavo[1], S. Bovo[1], J. Maselyne[2], T. Norton[3], L. Fontanesi[1], & Eu-Li-Phe Consortium[1]
[1] University of Bologna, Animal and Food Genomics Group, Dept. of Agricultural and Food Sciences, Viale Fanin 46, 40127 Bologna, Italy, [2] ILVO (Flanders Research Institute for Agriculture, Fisheries and Food), Technology and Food Science Unit, Burg. Van Gansberghelaan 115 bus 1, 9820 Merelbeke, Belgium, [3] KU Leuven, Department of Biosystems, Kasteelpark Arenberg 30, 3000 Leuven, Belgium

Phenomics aims to systematically characterize the phenome, namely the set of observable physical and molecular traits of an animal. In livestock systems, high-resolution phenotypic data generated through precision livestock farming (PLF) technologies, imaging, sensors, and omics approaches are increasingly central to breeding, management, health, and welfare decisions. However, the rapid expansion of data-intensive phenotyping raises major challenges related to data management, interoperability, standardization, ethical use, and the integration of artificial intelligence (AI) tools. The European Network on Livestock Phenomics (EU-LI-PHE; COST Action CA22112) was established to foster multidisciplinary collaboration addressing these challenges. This contribution presents the structure, objectives, and ongoing activities of EU-LI-PHE, with particular emphasis on ethical, regulatory, and data-governance aspects of advanced livestock phenotyping within the evolving AI landscape. EU-LI-PHE brings together approximately 500 members from more than 50 countries, spanning animal breeding, PLF, genomics, bioinformatics, engineering, economics, and social sciences. The Action is structured into five Working Groups (WG): WG1 (Phenotyping technologies) addresses existing technologies and infrastructures and defines roadmaps for high-dimensional, whole-animal data acquisition. WG2 (Genome-to-phenome integration) consolidates knowledge on genomic and epigenomic contributions to phenotypic variation and identifies priorities for translational applications. WG3 (Computational resources and data analysis methodologies) advances computational models, analytical tools, computational infrastructure, and AI frameworks for large-scale data management and interpretation. WG4 (Economic impact, regulation, policy, and societal aspects) evaluates economic implications, regulatory and data-governance frameworks, and societal acceptance. WG5 (Stakeholder engagement, communication, and dissemination) ensures coordinated stakeholder interaction and dissemination across all WGs. Within this framework, particular attention is devoted to enhance data interoperability across species and to achieve FAIR data principles. A great importance is also given to ethical and legal implications of large-scale data and to the societal acceptance of AI-driven models in decisions. Capacity building is supported through training schools, Short-Term Scientific Missions, Virtual Mobility Grants, and targeted conference grants, with strong emphasis on inclusiveness and early-career development. Since 2024, numerous mobility and dissemination grants have strengthened collaboration and skills in big data analytics and responsible innovation. By integrating technological, computational, ethical, and policy perspectives, EU-LI-PHE contributes to defining a coordinated European roadmap for livestock phenomics. The network aims to ensure that AI-enabled phenotyping in PLF systems develops within a robust framework of data standardization, responsible governance, and societal trust, ultimately supporting sustainable and resilient livestock production. Acknowledgment: EU-LI-PHE (CA22112) is funded by the European Union – COST European Cooperation in Science & Technology.

SENSTARA: Advancing sensor-based indicators of animal resilience, health, and welfare in precision livestock farming

D. Foy[1], J. M. Gautier[2], B. Foris[3], C. Morgan-Davies[4], L. Dale[5], P. P. Nielsen[6], G. A. Franchi[7], X. Díaz De Otálora[8]
[1] AgriGates Inc, , 19146 Philadelphia, United States, [2] Institut de l'Elevage, CS 52637, 31321 Castanet Tolosan, France, [3] University of Veterinary Medicine, Veterinaerplatz 1, 1210 Vienna, Austria, [4] Scotland's Rural College, Kirkton, FK20 8RU Crianlarich, United Kingdom, [5] LKV Baden-Württemberg, Heinrich-Baumann-Str. 1-3, 70190 Stuttgart, Germany, [6] RISE Research Institutes of Sweden, Scheelevägen 17, 223 70 Lund, Sweden, [7] Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark, [8] Universitat Politècnica de València (UPV), Camino de Vera s/n, 46022 Valencia, Spain

Livestock systems are increasingly challenged by climate change, production intensification, and growing societal expectations regarding animal welfare, environmental sustainability, and transparency. In this context, Precision Livestock Farming (PLF) technologies offer powerful tools for continuous animal monitoring. However, translating large and heterogeneous sensor datasets into robust, biologically meaningful indicators that can be consistently applied across species, production systems, and environmental conditions remains a major challenge. SENSTARA is an international Working Group within the EAAP Precision Livestock Farming Commission that aims to advance sensor-based assessment of animal resilience, health, and welfare in livestock systems. Through advanced sensing technologies, modelling, and artificial intelligence, SENSTARA promotes the development, validation, and harmonization of sensor-derived indicators, metrics, and models, thereby improving methodological standardization across species and production systems. Its scientific and technological scope encompasses wearable, environmental, and physiological sensors; imaging technologies such as infrared thermography and video-based monitoring; acoustic and environmental sensing systems; and advanced data analytics, modelling, and artificial intelligence approaches. By fostering collaboration among researchers, technology developers, industry stakeholders, and policy actors, SENSTARA provides an open and interdisciplinary platform to accelerate the translation of PLF innovations into practical, transparent, standardized, and scalable decision-support tools.

Data preprocessing transparency as a requirement for robust sensor based livestock indicators

G. Franchi[1], B. Foris[2], J. M. Gautier[3], C. Morgan-Davies[4], L. M. Dale[5], P. P. Nielsen[6], X. Diaz De Otálora[7], D. Foy[8]
[1] Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark, [2] University of Veterinary Medicine, Veterinaerplatz 1, 1210 Vienna, Austria, [3] Institut de l'Elevage, CS 52637, 31321 Castanet Tolosan, France, [4] Scotland's Rural College, Kirkton, FK208RU Crianlarich, United Kingdom, [5] LKV Baden-Württemberg, Heinrich-Baumann-Str. 1-3, 70190 Stuttgart, Germany, [6] RISE Research Institutes of Sweden, Scheelevägen 17, 22370 Lund, Sweden, [7] Universitat Politècnica de València, Camino de Vera s/n, 46022 Valencia, Spain, [8] AgriGates LLC, , Philadelphia, United States

Precision Livestock Farming (PLF) technologies generate continuous behavioural and physiological data that hold substantial potential for advancing the assessment of animal performance, health, and welfare. In addition to animal-borne devices, many research and commercial settings also rely on production and environmental monitoring systems, gas-measurement technologies (e.g., methane measuring units), imaging platforms, acoustic sensors, and location-tracking systems. However, a major but often overlooked challenge is the lack of transparency in how commercial systems handle raw sensor data before delivering research-ready outputs. Typically, the protocols describing procedures for data cleaning, filtering, aggregation, interpolation, and anomaly handling are undisclosed. These undocumented preprocessing steps directly affect the reliability, comparability, and biological interpretability of sensor-derived indicators. In practice, customers, including farmers, advisors, and researchers, may receive only aggregated daily values, without access to underlying high-resolution data or knowledge of how missing values, outliers, or device failures were addressed. Such limitations create risks for biased assessments, restrict the integration of multi-sensor information, limit harmonisation across sensors, species, and production systems, and undermine reproducibility, especially when validation studies rely on special high-resolution datasets not accessible in routine use. A growing number of sensor technology manufacturers openly provide raw data at the highest resolution available, enabling transparent and standardised preprocessing within research workflows. Yet wide variation persists across sensor types, species applications, and commercial platforms. The EAAP PLF Working Group SENSTARA (Sensors and Standards Development for Research Activities) sheds light on these discrepancies, aiming to raise awareness of their scientific implications and promote minimum expectations for data transparency. We propose a collaborative effort, including fact sheets, standard operating procedures for data cleaning, and community dialogue, to develop pragmatic, species-agnostic guidance that supports more robust and interpretable use of sensor-derived indicators across the full spectrum of PLF technologies. This contribution invites researchers, developers, and industry partners to engage with SENSTARA in shaping a more transparent and reproducible future for PLF research.

Effect of milk replacer formulations on goat kids' growth performance and small intestinal development.

K. Capdevila Ospina[1], F. Zamuner[1], B. Leury[1], A. Cameron[2], K. Digiacomo[1]
[1] The University of Melbourne, Parkville, 3010 Melbourne, Australia, [2] Meredith Dairy Ply Ltd.,, Meredith, 3333 Meredith, Australia

The pre-weaning milk feeding is an essential nutritional phase and one of the main investments for the rearing of goat kids. Different substitutes, rather than goat milk (i.e. whole cow milk, cow milk replacer, milk whey), have been used in dairy goat farms, with cow's milk (whole or replacer) being the most profitable option (Zamuner et al., 2023). However, the differences in composition of goat milk compared with cow milk (+30% fat, +19% protein, +16% total solids,-8% lactose) could affect the growth and health performance of the kids consuming cow's milk, with special concerns around the lactose levels that could potentially lead to gastrointestinal effects (diarrhea or bloating). This experiment aimed to investigate the effect on growth performance and small intestinal development of goat kids fed different goat and cow milk powder formulations. 416 male goat kids were randomly assigned at birth to 1 of 4 treatments: Goat milk powder (GP; n = 100), Cow Milk powder (CP; n = 105), Goat mix (GM; n = 103), or Cow Mix (CM; n = 108). The GM was formulated to mimic the CP components, while the CM reached the GP components. The GM included lactose (8.5%) and whey protein (3%); the CM included cream (22%), whey protein (27%) and lactose (4%). Goat kids had ad libitum access to their assigned milk formulation until weaning (5 weeks). Body weight (BW) was recorded at birth, and weeks 2, 5, 7, and 9 weeks old. At week 5, a subset of 40 kids (n = 10/group) were slaughtered. Hot and cold carcass weights were recorded, and duodenum samples were collected for histology analysis. The villi length (VL), villi weight (VW), crypt depth (CD), muscular thickness (MT), epithelium thickness (ET) and number of villi per cm (NV) of the duodenum samples were measured using Image J software (version 1.54 Wayne Rasband and National Institutes of Health, USA). All data were analysed using mixed model with repeated measure in SAS (Statistical Analysis System; version 9.4.01). From 2 weeks old onward, the GP and CM formulations had better growth performance (144 g/d vs 100g/d; P<005). At 7 weeks, kids fed GP (13.0±0.1kg) and CM (12.5±0.1kg) were 18% heavier than those fed CP (11.0±0.1kg) and GM (11.4±0.1kg; P<0.05). The GP kids had 11% greater hot and cold carcass weights compared to kids fed CP and GM (P<0.05); no differences were shown between GP and CM carcass weights (P>0.05).There was a tendency for the villi length in the GP group to be longer than in the other groups (P=0.07), while no differences were found between groups for VW, CD, MT, ET and NV. Overall, kids fed the CM formulation have a similar growth performance than those fed the GP formulation, with the addition of being a cost-effective alternative for dairy goat farms. The similar growth performance of the GM with the CP formulation suggests that the level of lactose included in these formulations could influence goat kid performance. The histological results suggested no differences in the duodenum development under the four powder formulations. Further analysis into circulating metabolites (including glucose, total protein, and non-esterified fatty acids) will provide a better understanding of the metabolic implications of the milk powder formulation of goat's overall performance. It was concluded that CM and GP formulations are effective feeding alternatives that commercial producers can implement.

Impact of Colostrum and Serum Derived IgG with Cream or Vegetable Oil on Growth and Immune Status of Dairy Goat Kids

S. J. Mabjeesh[1], Y. Wein[1], Y. Ashbel[1], C. Sabastian[1], R. Komakech[1], R. Tadmor-Levi[1], T. Theresa Casey[2], C. Ferreira[2], N. Argov-Argaman[1]

[1] The Hebrew University of Jerusalem, Animal Sciences, Hertzel St 229, 7610001 Rehovot, Israel, [2] Purdue University, Animal Sciences, 2550 Northwestern Ave, 47907 West Lafayette, United States

Colostrum plays a crucial role in providing passive immunity to newborn dairy goat kids by supplying maternal IgG and IgM antibodies shortly after birth. While most studies on colostrum focus on antibody concentration and timing of feeding, less attention has been given to the colostrum matrix, particularly the fat phase in which antibodies are embedded, and how this matrix affects IgG absorption, metabolism, growth, and immune function. The objective of this study was to determine how different combinations of IgG source (colostrum vs. serum) and fat source (colostrum cream vs. vegetable oil) influence the efficiency of IgG absorption, passive immunity, and growth performance. Forty-four newborn dairy goat kids were randomly assigned at birth to one of four colostrum or colostrum-replacement treatments: pooled whole colostrum (PC; n = 12; body weight; BW 2.98 ± 0.12 kg), pooled skimmed colostrum supplemented with vegetable oil (PO; n = 10; BW 3.13 ± 0.15 kg), adult goat serum formula with colostrum fat (SF; n = 11; BW 2.75 ± 0.20 kg), or adult goat serum formula with vegetable oil (SO; n = 11; BW 2.61 ± 0.15 kg). Each kid received its assigned treatment at 10% of BW during the first 24 h of life, divided into several meals. Blood samples were collected at 24 and 48 h of age to determine serum IgG and IgM concentrations, and BW was recorded at birth, 30 and 60 days of age to calculate average daily gain (ADG). Health status and general vigor were monitored throughout the experimental period to detect any clinical signs related to treatment. Data were analyzed using a mixed model (JMP Pro), with colostrum source and age as fixed effects, kid as a random effect, and a repeated-measures structure for variables measured over time. Body weight was affected ($P< 0.01$) by colostrum source, with the highest BW at 60 days observed in kids fed SF (8.43 kg) and the lowest in those fed SO (6.82 kg), whereas PC and PO kids showed intermediate BW (7.84 kg). As expected, BW increased from 30 to 60 d of age, and ADG was greater ($P< 0.03$) during the first 30 days (125 g/ d) than from 30 to 60 days (113 g/ d), indicating a decline in growth rate with age. A partial analysis (n = 5) of serum IgG concentration showed that levels at 48 h (8.14 mg/ mL) were lower than at 24 h (9.23 mg/ mL), reflecting the normal decline following gut closure, and IgG concentrations were numerically lowest in the SO group (5.72 mg/ mL) compared with the other sources (9.67 mg/ mL). These results suggest that, under the conditions of the present study, IgG absorption at 24 h was not primarily determined by the origin or nominal concentration of IgG (serum vs. colostrum), but was influenced by the type of fat present in the colostrum or formula matrix (colostrum cream vs. vegetable oil). The findings highlight the capacity of serum-based colostrum formulas, particularly when combined with colostrum cream, to support substantial passive immunity, growth rate, and BW in dairy goat kids, offering a potential strategy when maternal colostrum is limited or variable. At the same time, replacement of colostrum cream with vegetable oil in serum-based formulas appeared to compromise growth and IgG status, pointing to the importance of matching both the immunological and nutritional components of natural colostrum. Further research is warranted to elucidate the mechanisms by which colostrum fat composition modulates IgG transport across the gut and to optimize colostrum-replacement formulations for commercial dairy goat systems.

Effect of breed on rumen microbiota in lambs treated with aqueous extract of Tithonia diversifolia as an additive

O. T. Barreto Cruz[1], D. C. Mogollon Vergara[1], R. D. Castañeda Serrano[1], J. C. Henao Zambrano[2], M. A. Ospina Barrero[3]

[1] Universidad del Tolima, Animal Production, 42 street N° 2, 730001 Ibague, Colombia, [2] Universidad Cooperativa de, Animal Production, Block 5, Salado, 730003 Ibague, Colombia, [3] Universidad del Tolima, Biology, 42 street N° 2, 730001 Ibague, Colombia

The use of additives in animal nutrition, such as monensin, has been relevant due to the emergence of antibiotic-resistant microorganisms. The inclusion of plant extracts, such as that of Tithonia diversifolia (TDE), is presented as an alternative to improve ruminal microbiota and animal health. This study analyzed how the breed of lambs influences the response to these treatments in terms of bacterial diversity and abundance. Twenty-eight lambs from the Katahdin, Santa Inês, and Pelibuey breeds, with an average weight of 19.03 ± 4.57 kg, were randomly assigned to four treatment groups: Control (no additives), Monensin (20 mg/day), TDE (5 g/day), and TDE (10 g/day), for a duration of 42 days. Ruminal fluid was collected at the time of slaughter, and an analysis of bacterial composition. For bacterial community analysis, raw read quality was inspected with FastQC and processed in QIIME 2, including import, visualization, quality filtering and removal of chloroplast and mitochondrial sequences using the DADA2 algorithm. From the amplicon sequence variant (ASV) table, a relative abundance table was generated and used to estimate taxon abundances at phylum, family and genus levels based on the SILVA v138 database. Microbial community data were analyzed and visualized in R, importing the abundance table with taxonomic assignments into the phyloseq package and generating plots at genus and family levels with ggplot2. To minimize bias from low-abundance features, ASVs with fewer than 5 reads and samples with fewer than 5,000 reads were removed prior to downstream analyses. Permutational multivariate analysis of variance (PERMANOVA) was used to test for differences in multivariate community composition. The results demonstrated that breed had an impact on the differential composition of the ruminal bacterial community. The breeds exhibited variations in the abundance of certain phyla and bacterial genera. For instance, lambs of the Katahdin breed showed a higher abundance of Ruminococcus in the TDE10 treatment, suggesting an enhancement in fiber degradation, contributing to increased production of propionate and butyrate. In contrast, Pelibuey lambs exhibited a greater presence of Rikenellaceae in the TD5 treatment, which may favor acetate production. Lambs of the same breed exhibited consistent trends in ruminal bacterial community abundance, displaying similar abundance profiles across treatments. This breed-specific microbial patterning aligns with prior research demonstrating host genetic effects on microbiota. In conclusion, based on our results, the effect of breed on ruminal microbiota is evident, with specific differences in the abundance of bacterial groups in response to the treatments. These findings suggest that interactions between diet, type of additive, and breed may influence the efficacy of treatments in the development of microbiota, highlighting the necessity to consider breed genetics when implementing additives in ruminant feeding.

Replacing corn grain with dried sugar beet meal in fattening goats: effects on feed efficiency, gastrointestinal microbiota and plasma metabolomic profile

M. Penati[1], F. J. Giráldez[2], M. Dehnavi[2], P. Cremonesi[3], F. Biscarini[3], F. Ceciliani[1], C. Lecchi[1,4], A. Martín[2], M. J. Ranilla[2,5], M. Hosseini Ghaffari[6], L. Abdennebi-Najar[7,8], S. López[2,5], S. Andrés[2]

In Mediterranean and North African production systems, identifying drought-tolerant, cost-effective feed resources is essential to reduce reliance on irrigated cereal crops such as corn. Sugar beet represents a promising alternative energy source for small ruminants. This study evaluated the effects of replacing corn with dehydrated ground sugar beet roots in fattening Murciano-Granadina goat kids, a breed widely reared in Mediterranean regions. Twenty-four 5-month-old male kids were allocated to three dietary treatments (n = 8 per group) and fed complete pelleted diets ad libitum for 49 days. The experimental diets contained either 18% corn (CTRL), 9% corn and 9% dehydrated ground sugar beet roots (SB09), or 18% dehydrated ground sugar beet roots (SB18). The sugar beet ingredient consisted of dehydrated ground sugar beet roots (90% DM), with 7.6% crude protein and 12.4% NDF (DM basis). Feed intake, growth performance, nutrient digestibility, rumen fermentation parameters, the composition of ruminal, fecal, and salivary microbiota, and circulating metabolic, oxidative, and inflammatory markers were evaluated. Plasma metabolomic profiling was performed to explore systemic metabolic responses to dietary treatments. Sugar beet inclusion reduced feed intake and average daily gain ($p < 0.05$), whereas dry matter digestibility was not affected. Ruminal pH and total volatile fatty acids remained stable across diets, while butyrate and valerate increased in SB-fed animals ($p < 0.05$). Ruminal microbiota showed dose-dependent responses: SB09 increased bacterial richness and evenness, whereas SB18 reduced richness and promoted sugar-fermenting taxa (e.g., Olsenella, Candidatus Endomicrobium) at the expense of fibrolytic bacteria (e.g., Treponema, Roseburia). Fecal and salivary microbiota did not differ among treatments. SB diets were associated with lower circulating insulin levels, whereas oxidative stress indicators (AOPP, TBARS, FRAP) and inflammatory markers (leptin and lactoferrin) were not influenced by diet. Preliminary metabolomic analyses revealed metabolic shifts associated with dietary treatments, highlighting pathways potentially linked to energy and lipid metabolism. Dehydrated ground sugar beet roots can be included in fattening goat diets without impairing ruminal stability or systemic oxidative status. However, high inclusion levels negatively affect intake and growth performance. Moderate inclusion appears to be the most effective compromise, maintaining microbial diversity while limiting performance losses, and may represent a practical alternative to corn in Mediterranean and North African goat production systems. Keywords: Sugar beet; goat kids; feed efficiency; ruminal fermentation; gastrointestinal microbiota; plasma metabolomics

Feeding hydroponic barley sprouts to early lactation dairy goats: consequences for intake, nutrient utilization, milk performance, and immune markers

S. J. Mabjeesh[1], R. Komakech[1], Y. Wein[1], C. Sabastian[1], H. Haim Tagari[1]
[1] Hebrew University of Jerusalem, Animal Sciences, Hertzel St 229, 7610001 Rehovot, Israel

Dairy production in arid and semi-arid regions is increasingly constrained by climate change, chronic water scarcity, and limited availability of high-quality forages, thereby stimulating interest in alternative, water-efficient feed resources such as hydroponically produced barley sprouts (BS). The objective of this study was to evaluate the effects of including BS in total mixed rations (TMR) for early-lactation dairy goats on feed intake, nutrient digestibility, milk yield (MY) and composition, as well as selected blood and immune parameters. All the TMRs for the different dietary treatments were prepared at commercial feed center four weeks before the experiment began. After mixing and chopping in a stationary mixing wagon, the diets were tightly packed and sealed into plastic to ensure anaerobic conditions. The TMRs included wheat silage and a heterofermentative inoculum, and all rations including the SB diet were fermented and stabilized before and during the experimental period. Thirty-six multiparous dairy goats, which were consuming wet TMR under standard farm management practices (mean ± SE: 3.01 ± 0.17 kg/d MY and 35 ± 12 DIM at the beginning of the trial), were allocated to one of three TMR groups after a 2-week adaptation phase and observed for 6 weeks. The treatments included a control diet and two experimental diets where BS harvested at either 5 or 7 days replaced parts of the dietary CP, starch, and NDF, while ensuring the overall chemical composition of the diets remained similar. Furthermore, SB mainly replaced the wheat silage, leading to adjustments in roughage NDF by altering the quantities of alfalfa and oat hay in the diets. Milk yield was recorded daily, and milk composition was determined weekly. In the final week of the experiment, feces, rumen fluid, and blood were sampled to assess apparent total-tract digestibility and rumen and blood traits; additional blood samples were collected in week 3 and 6 to quantify peripheral leukocyte expression of immune-related genes. Data were analyzed using mixed models including diet, time, and their interaction as fixed effects, and goat nested within diet as a random effect, with repeated measures over time. Dry matter intake (DMI) was greater ($P< 0.01$) in goats fed the control diet compared with sprout-fed goats (2.60 vs. 1.53 kg/ d), and both MY and energy-corrected milk (ECM) were higher ($P< 0.004$) in the control (MY= 3.05 kg/d) than in the BS diets (MY= 2.31 kg/d). In contrast, milk fat, protein, and lactose concentrations did not differ among treatments, and feed efficiency (ECM/DMI) was not affected by BS inclusion. Apparent digestibility of organic matter and gross energy was lower ($P< 0.01$) in control goats than in goats fed BS, indicating improved energy utilization with sprout inclusion despite reduced intake. Expression of HSP70 in peripheral blood leukocytes was greater ($P< 0.05$) in week 3 in goats fed the 5-d BS diet, whereas IL1b expression did not differ among diets but decreased from week 3 to week 6 ($P< 0.05$), suggesting a time-related modulation of inflammatory signaling. In conclusion, high inclusion of hydroponic BS in TMR for early-lactation dairy goats reduced feed intake and milk production despite higher organic matter and energy digestibility, and was associated with altered HSP70 expression. These findings suggest that bioactive compounds present in hydroponic sprouts may influence intake regulation and immune-related responses, highlighting both the potential and the limitations of BS as an alternative feed resource for dairy goats in arid regions.

Milk and plasma multi-omics: insights into feed conversion and residual intake in dairy goats.

J. Kirkham[1], F. Zamuner[1], A. Cameron[2], N. E. Doomun[3], D. De Souza[3], B. Leury[1], K. Digiacomo[1]
[1] The University of Melbourne, School of Agriculture, Food and Ecosystems Science, Royal Parade, 3010 Parkville, Australia, [2] Meredith Dairy Pty. Ltd., 106 Camerons Rd, Meredith 3333, Australia, [3] Metabolomics Australia, Bio21 Institute, 30 Flemington Rd, Parkville 3052, Australia

Improving feed efficiency (FE) in dairy production systems is important for reducing input costs and improving sustainability. Feed conversion ratio (FCR; the ratio between feed intake and milk production) and residual feed intake (RFI; difference between actual and predicted feed intake for a given production level) are common estimates of FE. Additionally, measuring FE on a large scale is costly and time consuming, requiring individual feed intake and production data. Thus, high throughput tools to screen animals for FE are attractive. Metabolomics and lipidomics provide powerful tools for understanding the physiological mechanisms underpinning FE traits. This experiment aimed to investigate the differences in omics' profiles between early lactation dairy goats divergent for FE (FCR vs. RFI). From 54 early-lactation Saanen does (12 mo old), dry matter intake (DMI; daily), body weight (BW; three times weekly), milk yield (daily) and milk composition (twice weekly) was recorded for 49 d. The DMI and energy-corrected milk (ECM) were used to calculate FCR (DMI/ ECM). The RFI was calculated as regression residuals of DMI on metabolic bodyweight and ECM. Metabolomic and lipidomic profiling was carried out on 32 does (selected on divergence for RFI), with focused comparisons of the seven most extreme high- (H-RFI; high efficiency, low RFI values) and low- (L-RFI; low efficiency, high RFI values) RFI animals (n = 7/group) and a separate n = 7/group comparison based on FCR (H-FCR and L-FCR) to investigate pathway differences. Phenotypic data was subject to REML analysis using GenStat (22nd ed). The omics data was normalised by median, log10-transformed, and analysed based on peak intensities using MetaboAnalyst 6.0 (https://new.metaboanalyst.ca). Pathways with $P < 0.05$ and false discovery rate (FDR) < 0.20 were considered significant. Area under curve (AUC) > 0.8 and $P < 0.05$ were considered candidate biomarkers for individual lipids and metabolites. Six goats overlapped between efficiency classifications: 4 were H-RFI and H-FCR, 1 was L-RFI and L-FCR, and 1 H-RFI but L-FCR. The oPLS-DA models explained a greater proportion of the variation of RFI in both milk and plasma compared to FCR (RFI: 14–32%; FCR: 15–23%). The H-RFI and L-RFI goats had no differences in BW and ECM ($P > 0.05$). However, the H-RFI (high efficiency) goats consumed 0.4 kg DM/d less feed than the L-RFI (low efficiency) goats ($P < 0.05$), highlighting the independence of RFI from production traits. Alternatively, the H-FCR goats had a greater ECM than L-FCR (3.7 vs 2.6 kg/d; $P < 0.001$), lower BW (44 vs. 52; $P < 0.05$), but no differences in DMI ($P > 0.05$). This suggests that genetic selection based on FCR could unintentionally alter other physiological characteristics. Metabolomic pathway analysis revealed 6 differential pathways distinguishing divergence in FCR (including galactose metabolism) and 2 for RFI (including biosynthesis of unsaturated fatty acids) in milk and plasma. Glutathione metabolism was of significance in both RFI and FCR ($P < 0.02$; FDR < 0.20). Across milk and plasma, 59 candidate biomarkers were identified for FCR and 75 for RFI. In our experiment it was concluded that distinct metabolic profiles were evident between FCR and RFI in early lactation dairy goats, attributed to differences in amino acid and energy metabolism.

Associations of residual feed intake with growth performance, body size, carcass traits, meat quality and blood parameters in growing Naimi lambs

A. El Awad[1], O. Alsheblak[1], M. Eltemamy[1], A. Kullan[1], E. Neumann[1], S. Alalawi[1], T. Alketbi[1], S. Matarneh[1], H. Alshamsi[1], S. Alalawi[1], A. Alkaabi[1], A. Alkuwaiti[1], D. Alketbi[1], D. Albahar[1], T. Alkaabi[1], J. Loor[2], A. Elolimy[1]

Residual feed intake (RFI) is a key efficiency trait that can reduce feeding costs and improve the sustainability of sheep production. This study evaluated how divergence in RFI is associated with growth performance, body size, carcass traits, meat quality and blood parameters in Naimi sheep. We hypothesized that lambs with low RFI would consume less feed without impaired growth and would display shifts in carcass, meat and blood profiles compared with high RFI lambs. Forty male lambs (59.8 ± 4.3 d of age; 18.9 ± 1.3 kg BW) were subjected to a 15-d adaptation and a 63-d test period and were fed diet containing 30% forage (Alfalfa hay) and 70 % concentrate on DM basis with individual recording of feed intake and growth. Residual feed intake was calculated for all lambs during the test, and animals were ranked retrospectively and classified as most-efficient (M-EFF; n = 18, RFI = −0.06 ± 0.03) or least-efficient (L-EFF; n = 22, RFI = 0.05 ± 0.04). Data were analyzed using mixed models with RFI group as fixed effect in SAS 9.4. Initial and final BW, backfat thickness and average daily gain did not differ ($P > 0.05$) between groups, whereas M-EFF lambs had 10% lower ($P = 0.01$) average daily dry matter intake than L-EFF lambs. The M-EFF lambs had greater ($P = 0.02$) rump depth and tended ($P \leq 0.10$) to have greater shoulder width and body proportionality and area indices. However, the M-EFF lambs had lower ($P = 0.01$) loin girth and tended ($P \leq 0.10$) to have shorter ear length, smaller muzzle diameter, and lower pelvic and dactyl thorax indices. Carcass traits indicated that M-EFF lambs had thicker body walls ($P = 0.02$), larger neck base diameter ($P = 0.05$) and wider foreshank ($P < 0.01$), and tended ($P \leq 0.10$) to have greater testis and rack measurements, while reduced ($P = 0.01$) loin and leg bone measurements. Regarding meat quality, M-EFF lambs had greater ($P < 0.01$) muscle pH at 0 h post-mortem and tended ($P = 0.09$) to have greater pH at 24 h with a tendency ($P = 0.07$) for greater meat cohesiveness. Most-efficient lambs also exhibited greater ($P \leq 0.05$) blood pCO_2, glucose, hematocrit and hemoglobin and lower ($P = 0.03$) blood pH, together with altered red blood cell and leukocyte indices. In conclusion, M-EFF lambs maintained similar growth with lower feed intake compared with their L-EFF counterparts. Furthermore, M-EFF group showed greater body wall thickness and lower loin and bone proportions. They also showed alteration in post-mortem muscle pH and in blood variables related to oxygen-carrying capacity and metabolic status. These findings indicate that improved feed efficiency in desert-adapted lambs is associated with shifts in tissue distribution, muscle pH and hematological profile, supporting the use of RFI for sustainable genetic improvement.

How diet can improve lamb muscle lipid profiles and rumen microbiome

B. Fuchs[1], D. Dannenberger[1], L. Perkins[2], N. Scollan[2]
[1] Research Institute for Farm Animal Biology (FBN), Core Facility Metabolomics & Lipidomics, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [2] Queen's University Belfast, Institute for Global Food Security, 19 Chlorine Gardens, BT9 5DL Belfast, United Kingdom

Omega-3 fatty acids are a type of polyunsaturated fatty acid found in various foods, which have been shown to have numerous health benefits when consumed in optimal amounts. These benefits include promoting cardiovascular health, supporting cell structure, and modulating the inflammatory response. Rich sources of n-3 PUFA include oily fish, seeds, nuts, and brassica vegetables. The lipid profiles and fat content of meat products can be influenced by two main factors: genetics and diet. Grass is a rich source of alpha-linolenic acid (C18:3 n-3), a precursor to longer chain fatty acids, but its deposition in muscle is limited due to significant hydrogenation in the rumen. The use of feed supplements to increase n-3 PUFA levels is also limited by the toxicity of certain long-chain PUFA to rumen microbiomes. Microalgae, on the other hand, has been shown to have protective properties that allow LC n-3 PUFA to bypass rumen processes without being damaged. This study investigates how animal diet impact fatty acid composition, specifically omega-3 PUFA, and the concentration and distribution of lipid species across classes. The aim of this study was to investigate the effect of lamb diet on production performance, muscle lipid profiles and effect on rumen microbiome. Lipid extracts from Longissimus and Leg muscle samples (n=26) from grass, concentrate and high microalgae as well as grass and concentrate treatments, respectively, were reconstituted in 900 µL 20% of mobile phase B (mobile phase B was 90% isopropanol, 10 mM ammonium formate and 0.1% HCOOH in ultrapure water) and 100 µL chloroform and centrifuged. 3 µL was injected into the UHPLC/MS system. Lipids were then directly analyzed using a Vanquish UPLC-System (Thermo Scientific, Waltham, MA, USA) with a heated electrospray ionization (HESI) QExactive plus Orbitrap mass spectrometer (Thermo Scientific, Waltham, MA, USA) in positive ion mode. Chromatographic separation took place on a reversed-phase column (Accucore Polar Premium 100×2.1 mm (2.6 µ) with guard column: Accucore Polar Premium 10×2.1 mm (2.6 µ)) from Thermo Scientific (Waltham, MA, USA). Identification and quantification of individual lipid species were performed by LipidSearch Software 5.1 from Thermo Scientific (Waltham, MA, USA) on product level (MS/MS fragmentation). At the start of the study, all the ruminal volatile fatty acids (VFA) were similar between the control and the microalgae treatment. At time of the slaughter propionic acid was the only VFA with significant difference between both treatments and the microalgae treatment lowered the propionic acid concentrations from 24 to 15 mmol/L. A methane reduction of 23% was estimated by microalgae treatment compared to control. The number of bacteria and archaea genera present in gastrointestinal samples during the study decreased similarly across the different treatments. The results of the untargeted LC-MS lipidomics study of lamb muscle diet treatments shows that C18:3 n-3 lipid species are mainly incorporated into phospholipids of Longissimus and Leg muscle after grass diet treatment, but also into TGs of exclusively Leg muscle. The algae diet treatment leads to a considerable increase of C22:5 and C22:6 n-3 in specific phospholipids and TGs that is not seen in the grass diet treatment.

The supply with branched chain volatile fatty acids during the transition period and the lactation of dairy ewes.

A. Foskolos[1], A. Gomez[2], D. Kleinsdchmit[2], E. Skepetari[1], V. Galanis[1], N. Vasileiou[1], E. Malisiova[1], M. Alexandraki[1], D. Kantas[1]

[1] University of Thessaly, Animal sceince, Camus Gaiopolis, 41500 Larisa, Greece, [2] Zimpro Corp, Eden Prarie, 55344 Minnesota, United States

The aim of the present study was to investigate the effects of supplying branched-chain volatile fatty acids during the transition period and in lactation in dairy ewes. Forty pregnant Karagouniko breed ewes were allocated into ten pens of four animals each, based on expected lambing date and anticipated litter size. One month before the expected parturition, one of two treatments were randomly assigned to each pair of similar pens: (1) control, without supplementation (CTR), and (2) dietary supplementation with 4 g/day of a feed additive containing branched-chain volatile fatty acids (IsoFerm, Zinpro; ISF). The study lasted until 60 days postpartum and included three periods: (1) prepartum, (2) suckling period up to 40 days postpartum, and (3) lactation period. Dry matter intake before and after parturition did not differ between treatments, although it differed significantly between time periods (on average 1.45 and 2.25 kg at 21 days before and 21 days after parturition, respectively; $P < 0.001$). Litter size was not different between CTR and ISF ewes and averaged 1.75 lambs/ewe. Lamb birth weight was higher in ISF ewes, and lamb body weight continued to be higher for ISF lambs until weaning, where ISF lambs resulted 2.1 kg heavier (or 14.8 % heavier; $P = 0.04$) compared with CTR lambs. The overall average daily gain was higher in lambs nursed with dams fed ISF (282 vs 245 g/d for ISF vs CTR lambs, respectively; $P = 0.04$). Milk yield at 55 days postpartum tended to be 10.9% higher in ISF ewes, whereas milk protein concentration was lower compared to CTR ewes (5.42 vs. 6.48% for ISF and CTR, respectively; $P < 0.05$). A similar decreasing trend was observed only in the percentage, but not in the total yield, of whey protein β-lactoglobulin (β-LG). Furthermore, specific alterations were observed in milk fatty acid profile, which were mainly associated with changes in the animals' energy metabolism due to ISF supplementation. Previous studies have demonstrated that ISF supplementation improved NDF rumen degradation providing higher metabolizable energy, reducing body reserves mobilization during transition. In conclusion, IsoFerm supplementation improved the energy metabolism of dairy ewes during the periparturient period, leading to increased milk production and lamb body weight and growth until weaning.

Comparing weaning strategies: growth performance of dairy goat kids in intensive systems

K. Capdevila-Ospina[1], F. Zamuner[1], B. Leury[1], A. Cameron[2], K. Digiacomo[1]
[1] The University of Melbourne, School of Agriculture, Food and Ecosystem Sciences, Parkville, 3010 Melbourne, Australia, [2] Meredith Dairy Ply Ltd.,, 106 Cameron Rd, 3333 Meredith, Australia

Weaning carries important economic, management and nutritional consequences for dairy producers. Depending on production type, dairy goat farms set different target criteria (e.g. age, weight, solid feed intake) and employ either abrupt or gradual weaning strategies. Early weaning strategies can reduce milk-feeding costs, particularly when milk-based diets and labour are expensive. Despite the effect of age at weaning being explored in goat kids, only a few have investigated weaning methods from artificial milk-feeding systems, and only one focused on the pen level. This experiment aimed to investigate the effects of 5 different weaning methods on growth performance in female goat kids at the pen level. Four week old female goat kids (n=270) were randomly assigned to one of 5 treatments (n = 54/ group): abrupt weaning at 5 weeks (ABW5), or 6 weeks (ABW6), diluted weaning (DIL; concentration of milk replacer was reduced by 20%/ each day with ad libitum feeding), restricted access (RES; access to milk feeder for 4 hrs/ day from week 5 for 7 days), diluted and restricted access [DILRES; combination of reduced milk replacer (DIL) and limited access (RES)]. Daily intake (dry matter intake; DMI) of milk replacer, pellets and straw was recorded daily from weeks 4 to 7, with ad libitum access to solid feed in all the groups. Pellet and straw were introduced to the kids at 2 weeks old, but consumption was recorded only from week 4. The body weight (BW) was recorded at birth, then weekly from week 4 to 8 and again at 12 weeks old. All data were analysed using a mixed model with repeated measures in SAS (Statistical Analysis System; version 9.4.01), with treatment as a fixed effect, kid ID as a random effect, and initial BW as a covariate. Initial body weight at 4 weeks old did not differ between groups. At week 6, the ABW6 (11.8 kg) and DIL (11.4kg) groups were 10% heavier than the kids in ABW5 (10.2 kg), REST (10.5 kg) and DILREST (10.2 kg) groups ($P<0.001$). However, at week 7 (one week after all groups were weaned), no differences were found in BW (SED=±0.15; $P>0.05$). At 8 weeks old, kids in the RES group were lighter than those weaned at ABW6 (12.1 vs 12.7; $P<0.01$), with no difference between the other treatments. At 12 weeks, the DILRES (16.8 kg) group was 3% lighter than those weaned under DIL, ABW6 and RES (17.4 kg; SED=±0.15; $P<0.01$), but similar to those under the ABW5 method. The DMI varied between groups during weeks 5 to 6 according to access to the milk replacement. However, from week 6 to 7, when all the groups were weaned, the DMI was greater in kids weaned in the ABW5 group. The total DMI from week 4 to 7 weeks was numerically lower for DILRES (7.1 kg/kid) than ABW5 (7.9 kg/kid), RES (8 kg/kid), ABW6 (8kg/kid) and DIL (8.4 kg/kid). Two kids (0.7%) died of pneumonia during the experiment. Overall, kids weaned under an abrupt (ABW5 or ABW6) or gradual (DIL, REST and DILREST) weaning method had a similar BW 1-2 weeks post-weaning. However, kids weaned using the DILRES method were 3% lighter 6 weeks post-weaning at 12 weeks old. From a growth-performance perspective, all examined weaning methods are suitable for use at the pen level on intensive dairy goat farms. The choice of weaning method should consider the costs and intake of milk replacer and solid feed. Further investigation into the impact of weaning methods on the circulating metabolites (e.g. glucose, total protein and non-esterified fatty acids) during and after weaning, and on feed intake beyond the first week post-weaning is warranted.

Assessment of feeding rations in small ruminant farms using the Small Ruminant Nutrition System

G. Batikas[1], S. Dokou[1], A. Zemou[1], S. Vouraki[2], G. Arsenos[1]
[1] Aristotle University, University Campus, 54124 Thessaloniki, Greece, [2] University of Ioannina, Kostakioi, 47100 Arta, Greece

Nutrition plays a critical role in productivity, health, and welfare of small ruminants, hence also affecting farm profitability. The objective of this study was to assess nutritional management practices and feeding rations in commercial small ruminant farms in the region of Eastern Macedonia and Thrace, Greece. Data were collected from 37 farms using a standardized questionnaire documenting general farm characteristics, nutritional management strategies, and ration formulation. Feedstuff and bulk tank milk samples (n=3) were collected from each farm for chemical composition analysis. Feeding rations for milked animals were evaluated using the Small Ruminant Nutrition System (SRNS), a mechanistic model that predicts nutrient requirements. Inputs included the physical and chemical composition of rations, the chemical composition of bulk tank milk, and average milk production data per animal. The DMI input was based on the daily feed offered per lactating animal as reported by the farmer. Grazing was not included in the SRNS evaluation, as no farm practiced grazing during the first three months of lactation. Descriptive statistics were computed using R programming language. A formal nutritional plan was absent in 45.9% of farms, while 37.8% relied on feedstuff company protocols. Farms used period-specific feeding rations during the dry period (94.4%), steaming up (86.1%), and flushing (61.1%). Average starch content was 33.7% ± 3.15% and concentrate to forage ratio was 1.5 ± 0.42. On average, dietary energy supply exceeded modeled requirements by 62.3% in sheep and 53.5% in goats, whereas protein oversupply averaged 70.5% and 111.2%, respectively. Mean rumen degradable nitrogen supply corresponded to 123.5% and 121.9% of requirements in sheep and goats, respectively. Estimated urea production energy cost in sheep and goats was 0.177 Mcal/day and 0.190 Mcal/day, respectively. Overall, the findings indicate higher energy and protein supply relative to animal requirements in both sheep and goats, contributing to elevated costs and potential animal health risks. These results emphasize the need for improved farmer training and evidence-based ration formulation. This work is part of a research project funded by the Region of Eastern Macedonia & Thrace (ELKE-AUTH:76290).

Exploring the ruminal metabolome of sheep supplemented with essential oils

E. Rodrigues Cavalheiro Junior[1], O. Pricila Prado Calixto[2], E. Jorge Pilau[3], R. De Oliveira Venci[3], R. Martin Do Prado[1]

[1] Université Laval, Animal Science - FSAA, 2425, rue de l'Agriculture, G1V 0A6 Quebec, Canada, [2] Universidade Estadual de Londrina, Department of Animal Science, College of Agricultural Sciences, Celso Garcia Cid Highway (PR-445), Km 380, 86057-970 Londrina, Brazil, [3] Universidade Estadual de Maringá, Department of Chemistry, Avenue Colombo, 5,790, Jardim Universitário, 87020-900 Maringá, Brazil

Understanding rumen function is key to improving feed efficiency, reducing methane emissions, minimizing antimicrobial interventions, and ultimately promoting the sustainability of ruminant production. Dietary interventions are central to rumen manipulation, as they represent an accessible and rapid approach to modulate rumen function. However, despite decades of research, a large proportion of the rumen metabolome remains uncharacterized, limiting our understanding of the metabolic responses to dietary strategies. This study aimed to characterize the ruminal metabolome of sheep fed essential oils from garlic or rosemary. Thirty-five crossbred lambs were assigned to five treatments: control, garlic low-dose (30 mg/kg DM; GL), garlic high-dose (216 mg/kg DM; GH), rosemary low-dose (86 mg/kg DM; RL) for 105 days, and rosemary high-dose (216 mg/kg DM; RH). At slaughter, rumen fluid samples were collected from three animals per treatment. The rumen fluid was centrifuged, and the cell-free supernatant was subjected to two extraction methods with either ethyl acetate or methyl tert-butyl ether. Ultra-high-performance liquid chromatography coupled with tandem mass spectrometry, operated in both positive and negative ionization modes, was used to obtain fragmentation data. The resulting data were processed using the Global Natural Products Social (GNPS) platform to generate a molecular network. Compounds were putatively annotated by comparing fragmentation spectra with the GNPS database, public spectral libraries, or through manual annotation. A total of 7,064 chemical entities were detected in the rumen fluid overall, of which 47 compounds were putatively identified through molecular matches in public databases. When ethyl acetate extraction was used, 3,269 chemical entities (46.28% of the total) were detected, of which 12 were putatively identified. The chemical entities exclusive to each treatment were distributed as follows in negative mode: no additive, 64; GL, 29; GH, 92; RL, 81, and RH, 81; and in positive mode: no additive, 111; GL, 72; GH, 458; RL, 145; and RH, 151. When methyl tert-butyl ether extraction was used, 3,795 chemical entities (53.72% of the total) were detected, of which 35 were putatively identified. The chemical entities exclusive to each treatment were distributed as follows in negative mode: no additive, 64; GL, 83; GH, 57; RL, 9; and RH, 43; and in positive mode: no additive, 223; GL, 688; GH, 340; RL, 105; RH, 157. Despite the large number of putative metabolites, only 0.67% of the detected compounds matched existing spectral libraries. This study provides a snapshot of the rumen fluid metabolome of sheep fed different essential oils at different concentrations. Less than 1% of the detected chemical entities matched available spectral libraries, highlighting the vast untapped potential of the rumen for the discovery and characterization of novel compounds. Key words: garlic, essential oils, rosemary, rumen metabolome, sheep, untargeted metabolome

Sex-specific effects of local and imported alfalfa on performance, intake, digestibility, morphology, methane emissions, and nitrogen balance in Korean crossbred goats

K. Kwan-Woo[1], L. Eun-Do[1], K. Hyo-Jin[1], B. Sung June[1], T. Byamungu Mayange[1]
[1] Rural Development Administration, National Institute of Animal Science, Gyeongnam, 50000 Hamyang, South Korea

We hypothesized that imported alfalfa would improve nutrient utilization and reduce enteric methane emissions compared with local alfalfa due to potentially lower ash and fiber contents resulting from differences in harvest maturity and agronomic practices, and that these responses would differ between female and male Boer × Korean native crossbred goats (Capra hircus) raised in Korea. Both forages were alfalfa hay (not dehydrated pellets). Eight mature Korean crossbred goats were used, including four females (initial BW 40.9 ± 1.4 kg) and four males (48.6 ± 1.3 kg). Treatments were arranged in a repeated 2 × 2 factorial design with forage source (local vs. imported alfalfa) and sex (female vs. male) as main effects. Diets were formulated at a forage-to-concentrate ratio of approximately 55:45 and adjusted to body weight to meet growth requirements. After a 7-day cage adaptation period, followed by a 30-day dietary adaptation period in individual cages, the goats were transferred in stages to metabolic chambers for measurement of gas exchange and nitrogen balance. Growth performance, nutrient intake, apparent digestibility, morphometric traits, methane (CH_4) and carbon dioxide (CO_2) emissions, and nitrogen utilization were evaluated. Data were analyzed using the PROC MIXED procedure of SAS, with forage source, sex, and their interaction included in the model; significance was declared at $p<0.05$. Chemical composition analysis revealed that imported alfalfa had lower ash (5.7 vs. 11.4%) and neutral detergent fiber (45.5 vs. 51.8 %) than local alfalfa, despite similar crude protein levels. Sex markedly influenced intake, excretion, and gas emissions. Male goats had greater total dry matter intake than females (38.2-38.3 vs. 27.0-31.2 kg), accompanied by higher fecal output and greater CH_4 energy loss (290.6-327.2 vs. 108.1-169.0 kcal/d). Males also produced higher absolute CH_4 and CO_2 emissions, consistent with their greater intake and metabolic activity. Apparent digestibility, particularly of fiber fractions, was improved in goats fed imported alfalfa, with the response being more pronounced in females. Female goats fed imported alfalfa showed the lowest CH_4 (11.6 g/d) and CO_2 (508.1 g/d) emissions, suggesting improved fermentation efficiency and lower enteric energy loss. Male goats fed imported alfalfa also had lower CH_4 (21.9 g/d) and CO_2 (1038.3 g/d) emissions than males fed local alfalfa. In contrast, nitrogen retention and nitrogen use efficiency were higher in females than in males. Morphology also improved under imported alfalfa, particularly in males, with greater body length, withers height, chest width, and chest girth. These results indicate that the observed advantages of the imported alfalfa were attributable to its specific compositional profile rather than origin per se, and that imported alfalfa is not universally superior to local alfalfa. Overall, forage source and sex jointly influenced nutrient utilization and enteric emissions in Korean crossbred goats. Imported alfalfa improved digestibility and reduced gaseous losses, especially in females, indicating that sex-specific feeding strategies based on measured forage quality may enhance production efficiency while mitigating environmental impact in goat systems.

The lactation and seasonal effects on glucose utilization in dairy goats under high ambient temperature

S. Thammacharoen[1], C. Chitueakul[1], K. Yutthaworawit[1], P. Bunkhan[1], S. Veeraman[1], N. Saipin[2], N. Chaiyabutr[1,3]
[1] Faculty of Veterinary Science, Chulalongkorn University, Physiology, Henri Dunang Rd., Pathumwan, 10330 Bangkok, Thailand, [2] Faculty of Science, Ramkhamhaeng University, Agricultural Technology, Ramkhamhaeng Rd., 10240 Bangkok, Thailand, [3] The Royal Society of Thailand, The Academy of Science, Dusit, 10300 Bangkok, Thailand

Background: Lower milk yield has been demonstrated in both dairy cows and goats raised under tropical areas. High ambient temperature (HTa) is the major external factor influenced milk synthesis by mammary gland. Lactose is the main milk component supporting milk yield. Much evidence suggested that glucose utilization is influenced by HTa conditions. Objective: The present experiments have focused on the effect of HTa on glucose utilization using intravenous glucose tolerance test (IVGTT). The objective of this experiment is to investigate whole-body glucose utilization in dairy goats fed under tropical conditions. Methods: An IVGTT was performed in dairy goats at different physiological stages including lactation, mid- and late- pregnancy (n=5 each). Next, we investigated the effect of natural HTa on IVGTT in dairy goats from two different seasons: summer and winter (n=8 each). Results & discussion: Early lactation goats had higher basal blood glucose concentration (43.2 ±1.9 mg%) and lower the area under curve from IVGTT (6584 ±459 mg%.min) than those mid- and late- pregnancy (35.4 ±3.4 and 36.3 ±2.7 mg%; 8170 ±851 and 8659 ±530 mg%.min, respectively). The results suggested that during early lactation basal plasma glucose and glucose uptake capacity might be prioritized to support milk synthesis. This indicates an important role of the homeorhetic control on mammary gland functions. Next, the average noon ambient temperatures (Ta) were 35.7 ± 1.6 ˚C (winter) and 38.7 ± 1.0 ˚C (summer). With the Ta difference at 3 ˚C between winter and summer seasons (seasonal ΔTa), neither the rectal temperature (39.1 ± 0.1 and 39.3 ± 0.1 ˚C, respectively) nor the IVGTT curve (8283 ± 918 and 9197 ± 1012 mg%.min, respectively) differed significantly between seasons. Although the IVGTT protocol from the current experiment could demonstrate the effect of lactation on the whole-body glucose utilization, the test failed to differentiate the seasonal HTa effect with seasonal ΔTa at 3 ˚C. This possibly comes in part from the small difference in Ta between winter and summer. Conclusion: Whole-body glucose utilization, as measured by IVGTT, is significantly different during the transition from pregnancy to lactation. A wider range of seasonal ΔTa is needed to investigate the effects of natural HTa on glucose utilization in dairy ruminants.

Technologies for Individual Sensing of Poultry in Commercial Hen Houses

V. Bloch[1], M. Ross[2], A. Haron[2], Y. Heler[1], A. Godo[1], I. Halachmi[1], S. Druyan[2]
[1] ARO Volcani, Agricultural and Biosystems Engineering, 68 HaMaccabim Road, 7505101 Rishon LeZion, Israel, [2] ARO Volcani, Animal Sciences, 68 HaMaccabim Road, 7505101 Rishon LeZion, Israel

Precision livestock farming increasingly relies on sensing technologies capable of monitoring individual animals within commercial production systems. In poultry houses, however, most sensors measure environmental conditions at the house level rather than the physiological or behavioral state of individual birds. Because modern poultry houses may contain tens of thousands of animals, such average measurements may not accurately represent the conditions experienced by individual hens. Individual sensing is therefore essential for early detection of welfare problems, improved climate control, and adaptive flock management. This study presents several complementary technological approaches for non-invasive sensing of individual poultry in commercial housing systems. The first approach focuses on physiological monitoring using infrared thermography. A sensing unit equipped with a low-cost infrared camera was installed near feeders to estimate the body temperature of individual broilers during voluntary visits. Thermal images of the head region were automatically processed and body temperature was predicted using a regression model based on image-derived features. Validation against implanted temperature loggers showed that the system can estimate body temperature with an accuracy of about ±0.27 °C. Continuous measurements indicated that the thermal state of individual birds may differ from environmental temperatures measured by conventional house sensors, highlighting the potential of individual sensing to improve heat-stress detection and management. The second approach addresses behavioral monitoring in cage-free laying hen houses using artificial intelligence based computer vision techniques. High-resolution cameras installed in a commercial house were used to collect large-scale video data of flock activity. Deep-learning models detect and track individual hens and identify behavioral events characterized by rapid coordinated movements that are associated with aggressive chasing behavior. The detection system achieved about 90% accuracy in identifying individual birds and enables automated alerts indicating possible harmful interactions within the flock. A third example explores the use of artificial intelligence for optimizing cooling perches designed to mitigate heat stress in laying hens. Computer vision algorithms analyze the positions and postures of hens resting on perches to detect resting or lying behavior and quantify perch utilization patterns. Combined with environmental measurements, these observations allow estimation of hens' preferences for different perch cooling conditions and support adaptive management of perch-based cooling strategies. Developing individual sensing systems for poultry presents challenges that differ from those encountered in monitoring large farm animals. Poultry houses contain very large populations with high stocking densities, resulting in frequent occlusions and making continuous identification of individuals particularly challenging. The small body size of hens and the economic constraints of poultry production also limit the feasibility of wearable sensors. These constraints suggest that future poultry monitoring systems will rely on scalable sensing infrastructures combining computer vision, thermal imaging, and machine learning. Rather than attaching sensors to each bird, such systems aim to extract individual-level information from shared sensing platforms capable of monitoring thousands of animals simultaneously, thereby enabling improved welfare monitoring, early detection of stress, and more precise environmental management.

Seeing the Unseen: AI-Powered Detection of Feeding, Drinking, and Resting Behaviors in Broiler Production

M. Alexy[1,2], G. Toth[2]
[1] Óbuda University, John von Neumann Faculty of Informatics, Bécsi út 96b, 1034 Budapest, Hungary, [2] Eötvös Loránd University, Faculty of Informatics, Egyetem tér 1-3, 1053 Budapest, Hungary

Artificial intelligence powered by computer vision is opening new possibilities for behavior monitoring in poultry meat production. We present a computer vision-based framework for automated detection of feeding, drinking, and resting behaviors in commercial broiler systems. Our research was conducted at a large-scale broiler farm in eastern Hungary, where 21,000 Ross 308 broiler chickens were raised per fattening cycle in each poultry house, each with a floor area of 1,400 m². A total of 4 cameras were used for data collection, mounted on the ceiling and arranged in 2 rows, with 2 cameras in each row. Validation used Birdwatcher video data processed at one frame per second, generating nearly 10,000 images, from which representative samples were manually annotated in Roboflow. A YOLOv12 object detection pipeline, integrated into Google Colab and deployable locally, detects birds and assigns behaviors through dynamically defined feeder-drinker regions. Under commercial conditions, a representative model achieved 95.7% mAP@50, 93.6% precision, and 96.0% recall. A Python application extracts time-stamped events to support downstream analytics, rolling-window prediction, anomaly detection, and early welfare alerts across poultry systems.

Investigation on chickens' escape behaviour in the free-range area related to the presence of birds of prey

L. Hofmann[1], A. Langehennig-Peristenidou[1], N. Kemper[1], N. Volkmann[1]
[1] Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, University of Veterinary Medicine Hannover, Bischofsholer Damm 15, 30173 Hanover, Germany

Free-range systems enable laying hens to perform their full range of natural behaviour, thus improving animal welfare. Nevertheless, there are also negative aspects associated with this type of husbandry. For instance, the potential access for predators represents a major risk factor for the welfare and health of chickens using the free-range area. Chickens exhibit different escape reactions depending on the type of predator, which have so far been studied mainly under laboratory conditions. This study investigates chickens' behaviour and vocalisation in free-range when exposed to the presence of a bird of prey. The generated findings can be used for developing deterrent methods, for instance. Data were collected on a farm with a mobile housing system and one flock (990 hens, 20 roosters) with daily access to a free-range area. Video cameras and microphones recorded chickens' behaviour and vocalization in the area in the direct proximity of 11.3 m maximum to the mobile house continuously over three months (Daily from 9 am – 7 pm). Behavioural observations included the identification of the animal that first perceived the predator (first animal) and its reaction. The perception point was examined, which reflects the time point at which the predator was detected, and the following behaviour was differentiated in freezing (in the open or closed area), moving forward (at normal or increased speed) and flapping wings (while running). Additionally, chickens' vocalisation, specifically typical warning calls, and the corresponding behaviour of the flock were analysed. So far, data from five consecutive days were evaluated resulting in 63 situations in which a predatory bird was visible. The corresponding behaviour of the animals was analysed. Preliminary results showed that the first animal was a rooster in 57.1% of the situations observed, while in 31.7% it was a hen, and in 11.1% of cases it could not be clearly identified. Thus, male reactions dominated. In 74.6% of the situations, no vocalisations, respectively warning calls, were recorded. Furthermore, the results showed that after perceiving the predator, the first animal exhibited freezing in 100.0%, most often followed by movement at normal speed (63.5%) or wing flapping (17.5%). Regarding the behaviour of the flock, no consistent behaviour patterns similar to this of the first animal were observed. Nevertheless, it was apparent that most of the animals continued to move at normal speed (71.4%) when the first animal perceived the predator, while 30.2% showed freezing as well. The following behavioural patterns of the flock were variable or occurred in parallel. To date, the results indicate that the combination of behavioural and vocal analysis offers new insights and is valuable to develop potential effective deterrent methods for birds of prey. The evaluations are still being continued, and further investigation will be conducted to include flock without roosters and with other genetics. This research is funded by the Lower Saxony Ministry of Science and Culture and the Volkswagen Foundation as part of the zukunft.niedersachsen program within the ZERN project.

Automated Poultry Behavior Monitoring via Hybrid Multi-Object Tracking and Learned Visual Descriptors

B. Ramon[1], J. Tarres[2], M. Piles[2], C. Antens[1]
[1] Computer Vision Center, CVC, Universitat Autonoma de Barcelona, 08193 Bellaterra, Spain, [2] IRTA, Animal Breeding and Genetics, Torre Marimon, 08140 Caldes de Montbui, Spain

Animal welfare has become a fundamental pillar in modern poultry production, necessitating objective and scalable monitoring methods to ensure health and productivity. This study presents the design and implementation of an automated monitoring system using advanced computer vision techniques to track and analyze chicken behavior. The methodology, utilizes the YOLOv8 architecture for the robust detection and segmentation of animals in high-density environments. To address the complexities of individual tracking, the project evaluates state-of-the-art Multi-Object Tracking (MOT) algorithms, such as BoT-SORT and ByteTrack, which achieved a high precision rate of 99.7% in Multiple Object Tracking Accuracy (MOTA). A significant contribution of this research is the development of a hybrid tracking solution based on a library centered on motion prediction. To enhance identity preservation, the system integrates two distinct approaches for visual descriptor extraction. First, it employs HoG (Histogram of Oriented Gradients) to capture manual features related to texture and orientation. Second, the study implements a convolutional Auto-Encoder trained specifically on poultry image crops. This unsupervised deep learning model learns a latent space (embeddings) that captures the unique visual characteristics of the animals. Data association between consecutive frames is then solved using the Hungarian algorithm, optimizing the balance between tracking stability and computational overhead. Experimental results demonstrate the system's capability to generate detailed trajectory maps and spatial activity heatmaps, which identified non-homogeneous movement patterns within the enclosure. The Auto-Encoder approach proved to be a viable and flexible alternative to manual descriptors, yielding competitive performance in maintaining identity consistency. Finally, the study proposes future research lines involving generative AI models, such as Stable Diffusion and SAM v3, to automate data labeling and enhance the detection of complex positive behavioral events like pecking, preening and dustbathing.

From climate projections to building adaptation: a decision-support tool for heat stress in French poultry farming

Y. Guyot[1]
[1] *ITAVI, 7 faubourg poissonnière, 75009 Paris, France*

Heat stress is a growing threat to broiler production in France, as rising temperatures reduce feed intake, impair growth performance and increase mortality risk. Quantifying future thermal exposure at the farm level is therefore essential for guiding adaptation investments. We present an interactive decision-support tool that combines an ensemble of 10 regional climate models (following TRACC scenario) with a building-level thermal model to map projected heat stress indicators across metropolitan France at département resolution, from the historical period through 2099. Outdoor Temperature-Humidity Index (THI) is computed daily from maximum temperature and humidity drawn from the DRIAS climate portal, at 8 km resolution across three 30-year periods: historical (1976–2005), near future (2030–2060) and far future (2070–2099). Seven annual indicators are derived per département: exceedance days above THI thresholds of 66, 73 and 79, corresponding respectively to mild, severe, and very severe stress; annual maximum and summer-average THI (June–September); and two body weight gain loss metrics based on a −2.1 %/°C linear relationship above 21 °C, expressed as both daily-episode and annualised values. Ensemble uncertainty is communicated as median, interquartile range and full model spread, both at pixel level on spatial maps and along département-level time series spanning the full 1976–2099 period. A steady-state enthalpy and moisture balance extends the analysis indoors, solving a quadratic equation for indoor temperature as a function of outdoor conditions, ventilation rate, animal metabolic heat production, stocking density and optional evaporative misting. Indoor specific humidity is resolved from a concurrent water vapour balance accounting for animal latent heat, ventilation renewal and misting input. A physical feasibility check warns users when the configured misting rate would saturate indoor air beyond an adjustable relative humidity threshold, a situation where evaporative cooling becomes ineffective. All seven indicators are recomputed on-the-fly for any combination of building parameters, enabling direct comparison of outdoor and indoor thermal conditions. Ensemble projections show a consistent and substantial increase in heat stress indicators across all French regions and periods. Indoor modeling reveals that building configuration and misting can partially offset outdoor heat stress, though this benefit varies with local climate and animal density. Designed for direct use by farmers, technical advisors and policy makers, the framework links probabilistic climate projections to building-level adaptation scenarios in an accessible visual interface.

Direct monitoring of Salmonella typhimurium using smartphone CL imaging

G. Shtenberg[1], N. R. Nirala[1,2]
[1] Agricultural Research Organization - Volcani Institute, Institute of Agricultural and Biosystems Engineering, HaMaccabim Rd. 68, 7505101 Rishon LeZion, Israel, [2] The Robert H. Smith Faculty of Agriculture, Food and Environment, Institute of Biochemistry, Food Science and Nutrition, Rechvot, 1 Rehovot, Israel

Salmonella typhimurium, a primary causative agent of enteric diseases, poses a persistent global health threat, particularly in resource-limited settings that require rapid, sensitive, and cost-effective diagnostics. Traditional diagnostic methods, such as bacterial culture and serology, are hindered by lengthy processing times, low sensitivity, and the need for specialized laboratory infrastructure. Addressing these limitations, this study presents a novel, label-free chemiluminescence (CL) gel-imaging platform for the specific detection of S. typhimurium based on aptamer-mediated signal inhibition. The bioassay utilizes agarose gels functionalized with a high-affinity anti-S. typhimurium aptamer and an intermediate metal catalyst. A luminol-H□O_2-metal ion system generates uniform light emission across the gel matrix in seconds and is stable for 10 minutes of illumination. Hence, upon sample introduction, the specific binding of S. typhimurium to the immobilized aptamers induces steric hindrance, creating distinct signal inhibition zones that are easily captured and quantified using a smartphone camera. Under optimal conditions, this point-of-care platform achieved a limit of detection of 10 CFU/mL in 1 hour and a linear dynamic range of 10_1–10_5 CFU/mL. Furthermore, the assay demonstrated >90% specificity against a broad panel of cross-reactive species, including Escherichia coli, Staphylococcus aureus, Bacillus cereus, and five other Salmonella serovars. Overall, this aptamer-driven, smartphone-readable CL-gel approach offers a robust, on-site diagnostic tool for rapid pathogen screening, with significant potential for adaptation to other enteric threats.

Dual-Mode Portable Biosensing Platform for Rapid and Sensitive Detection of Salmonella typhimurium

G. Shtenberg[1], S. Arumugam[1]
[1] Volcani Institute, Institute of Agricultural and Biosystem Engineering, Hamaccabim 68, 7505101 Rishon Lezion, Israel

The rapid increase in food contamination and associated illnesses necessitates the development of effective pre-detection strategies for microbial pathogens. In this study, we present a dual-mode biosensing platform for the efficient and reliable detection of Salmonella typhimurium (S. typhimurium) in foods. As a major contributor to enteric fever and typhoid, the detection of S. typhimurium requires constant monitoring due to its significant public health impact. Our approach depicts dual-mode detection, a reflectance-based optical biosensor using an indirect antibody assay combined with biochemical signal amplification through horseradish peroxidase (HRP) enzyme activity and photothermal imaging of the enzyme activity. The insoluble reaction products generated by HRP activity and infiltration into the porous silicon matrix alter the reflectance spectra proportionally to the bacterial concentration. Additionally, the enzyme activity was photothermally detected via TMB (3,3′,5,5′-Tetramethylbenzidine) catalysis, with reaction temperature (DT, °C) varying by logarithmic concentration. The specificity and selectivity of the anti-Salmonella antibody were validated against individual and mixed other bacterial strains. Under optimized conditions, the sensor achieved a limit of detection (LOD) of 3 CFU/mL (R_2= 0.995) and demonstrated a linear response in the range of 10_0 to 10_4 CFU/mL using the reflectance method. Additionally, the sensing platform was tested with spiked food samples, including chicken, tahina, and chocolate, exhibiting good recovery, reproducibility, and specificity. This biosensing strategy demonstrates significant potential for field-based applications, offering high sensitivity, a wide dynamic range, and rapid detection capabilities without requiring sample enrichment. The label-free, portable interferometric system functions independently of external light sources, further enhancing its suitability for on-site deployment. Importantly, this proof-of-concept platform can be readily adapted for the detection of various pathogenic microorganisms within complex food matrices.

Effect of enhanced early life nutrition on gene expression profiles of key metabolic tissues in Holstein Friesian bull calves

K. Keogh[1], S. Coen[2,3], P. Lonergan[3], S. Fair[4], D. Kenny[2]
[1] University of Galway, School of Biological and Chemical Sciences, University Road, H91CF50 Galway, Ireland, [2] Teagasc, Animal and Grassland Research and Innovation Centre, Grange, C15 PW93 Meath, Ireland, [3] University College Dublin, School of Agriculture and Food Science, Belfield, D04 V1W8 Dublin, Ireland, [4] University of Limerick, Department of Biological Sciences, Bernal Institute, V94 T9PX Limerick, Ireland

Improved nutritional status in calves during the early life period has been shown to induce positive latent effects for many economically important traits, including improved lifetime growth and carcass composition. The liver has a central role in intermediary metabolism and therefore is likely to mediate the effect of improved nutrition. However, knowledge of the role of the liver towards this effect in young calves is currently lacking. The objective of this study was to evaluate the transcriptomic response of liver tissue of bull calves offered either a high or moderate plane of nutrition from 2 to 12 weeks of life. Thirty Holstein-Friesian bull calves (mean age: 17.5 days; mean weight 48.8kg) were assigned to either a high (HI; n=15) or moderate (MOD; n=15) energy dietary treatment group. Calves in the HI group were individually offered 10L of milk replacer, ad libitum concentrate and 500 g/day of hay, whilst those in the MOD group were offered 4L of milk replacer, 500 g of concentrate and 500 g hay per day. All calves were euthanised at 12 weeks of age and liver tissue samples harvested from each calf. Tissue samples were subsequently used for global transcriptomic analysis. RNA-sequencing data were analysed bioinformatically for the determination of genes differentially affected by early life plane of nutrition. Additionally, the relationship between differentially expressed genes and markers of differential growth were further established through a co-regulatory network analysis. Phenotypic markers of differential growth included average daily gain, liver weight, liveweight, milk replacer and concentrate intake as well as systemic concentrations of metabolic hormones (IGF-1, insulin) and glucose. Following differential feeding up to 12 weeks of age, HI calves achieved a growth rate of 0.88 kg/day, whilst MOD calves grew at 0.58 kg/day ($P < 0.001$). In total 174 genes were differentially expressed (adj. P-value <0.1; fold change > 1.5) in the liver between HI and MOD calves (100 genes down-regulated and 74 up-regulated in HI compared to MOD). Pathway analysis revealed enrichment (adj. P-value <0.05) of metabolic pathways, biosynthesis of amino acids and steroid hormone biosynthesis as a consequence of improved nutritional status. Co-regulatory network analysis of differentially expressed genes with phenotypic growth measurements highlighted a positive relationship between the RHOJ gene, which is involved in vascularisation, with both concentrate intake and liveweight, whilst the NTS gene, involved in fat metabolism, was positively related to glucose concentrations. Additionally, IGF1 gene expression was positively connected to growth rate, liver weight and systemic concentrations of IGF-1. Enhanced early life nutritional status contributed to altered metabolic and steroid hormone processes within the liver tissue, which may lead to subsequent improved animal performance. This study highlights an effect of enhanced nutritional status during early life on the transcriptional control of liver tissue in calves. Results from this study can be further utilised to augment early life nutritional management in cattle with potential latent benefits for overall lifetime performance. This study was funded by Science Foundation Ireland (16/IA/4474).

The first feeding matters: effects of passive immunity transfer on growth performance in dairy-beef calves under practical field conditions

S. Wiedemann[1], E. Thesing[2]
[1] Rhine-Waal University of Applied Sciences, Faculty of Life Sciences, Sustainable Food Systems, Marie-Curie-Str. 1, 47533 Kleve, Germany, [2] Intervet Germany GmbH, A company of MSD Animal Health, Feldstr. 1a, 85716 Unterschleißheim, Germany

Adequate colostrum intake is essential for passive immunity transfer in neonatal calves and may influence long-term productivity. While this relationship has been widely studied in dairy replacement calves, less information is available for dairy-beef production systems under practical farm conditions. The objective of this field study was therefore to investigate the association between passive immunity transfer and growth performance of dairy-beef calves raised under practical management conditions, including a relatively restrictive milk feeding regime. The study was conducted on a commercial dairy farm and included 43 male HF-calves raised for veal. Colostrum management parameters, including colostrum volume, timing of first feeding and colostrum quality were recorded. Colostrum quality was assessed using Brix refractometry and serum samples were collected between d 2 and 7 of life to determine immunoglobulin G (IgG) concentrations using ELISA. Passive immunity transfer was evaluated using established thresholds and calves were categorized into groups with adequate (≥18 g/L) or insufficient (<18 g/L) serum IgG concentrations. After the colostrum phase calves received milk replacer twice daily (2 × 2.5–3 L; 113 g powder/L) reflecting a relatively restrictive feeding regime compared with current recommendations for intensive calf rearing. Growth performance was monitored through weighing during the rearing period and by recording carcass weight at slaughter at approximately 7.5 months of age (mean age 236 days). Data were analysed using linear regression models and mixed models including birth weight as a covariate. Overall, 37% of calves showed insufficient passive immunity transfer (<18 g/L serum IgG). Serum Brix values were strongly correlated with serum IgG concentrations (r^2=0.61), confirming their suitability as a practical on-farm monitoring tool for passive immunity status. During the first weeks of life, average daily weight gains were relatively low (approximately 0.3–0.4 kg/day), reflecting the restrictive feeding intensity on the farm. Nevertheless, calves with adequate passive immunity transfer exhibited consistently higher growth than calves with insufficient IgG concentrations. At approximately 33 d of age, adequately supplied calves already showed higher body weights (52.9 vs. 49.5 kg) and higher average daily gains. These differences persisted throughout the fattening period. At slaughter, calves with adequate IgG concentrations reached significantly higher carcass weights (150 vs. 134 kg; $P<0.05$). Correspondingly, average daily gains until slaughter were higher in adequately supplied calves (1.04 vs. 0.91 kg/day). Health parameters recorded on farm did not differ significantly between groups, which may partly reflect limitations of routine health monitoring under field conditions. However, the clear differences in growth performance highlight the importance of early-life immune status for long-term productivity in dairy-beef systems. These results indicate that adequate passive immunity transfer can partially compensate for suboptimal feeding conditions during early calf rearing. Under practical production conditions, early colostrum management therefore represents a key factor influencing long-term growth performance in dairy-beef systems. Routine monitoring of colostrum quality and passive immunity transfer using simple on-farm tools such as Brix refractometry may help identify management deficits early and improve both animal health and production efficiency in dairy-beef production systems.

Effect of post-weaning or pre-finishing concentrate supplementation at pasture on growth and carcass characteristics of early-maturing dairy-beef steers

J. Mcmorrow[1,2], A. K. Kelly[2], M. Mcgee[1], D. A. Kenny[1]
[1] Teagasc, Animal & Grassland Research and Innovation Centre, Grange, A85 VP65 Dunsany, Ireland, [2] University College Dublin, School of Agriculture and Food Science, D04 V1W8 Dublin, Ireland

In Irish pasture-based dairy-beef systems, early-maturing, spring-born steers are typically finished over 25 months during a third grazing season, whereas current research blueprint systems achieve finishing at 22-24 months during the second indoor winter. Reducing finishing age to 19 months, prior to a second winter housing, can improve profitability and sustainability; however, achieving adequate subcutaneous carcass fat remains a primary challenge for low-input, early-finish grass-based production systems. A high plane of nutrition during early life (3–21 weeks of age) increases adipose hyperplasia and hypertrophy in calves harvested at 5 months of age. Improved early-life nutrition may promote adipogenesis and feed efficiency, potentially predisposing cattle to a greater carcass fat score when finished at an earlier developmental stage. The aim of this study was to determine the residual effect of post-weaning or pre-finishing plane of nutrition at pasture and finishing age on growth and carcass characteristics of early-maturing dairy-beef steers. Spring-born Aberdeen-Angus × Holstein-Friesian male (n=100) were assigned to one of five production systems following a common indoor calf rearing period (n=20/system). (Control): 22-month finishing age following indoor winter finishing on grass silage + 375 kg concentrate DM (Total lifetime concentrate, 750 kg DM). S2-S5: 19-month finishing age at the end of the second grazing season; S2 & S3: Received high (375 kg) and medium (185 kg) concentrate DM, respectively, during the first grazing season, to exploit early-life feed efficiency, and no concentrates pre-finishing (Total concentrate, 750 kg and 565 kg DM, respectively). S4: Pasture + 375 kg concentrate DM for 90 days pre-finishing (Total concentrate, 750 kg DM). S5: Pasture + zero concentrates pre-finishing (Total concentrate, 375 kg DM). Live weight was recorded regularly and post-slaughter, carcass data were collected. Data were statistically analysed using mixed models. During the first grazing season, average daily live weight gain was greater ($P < 0.05$) for S2 and S3 than S1, S4 and S5, resulting in S2 and S3 being heavier at housing ($P < 0.05$). At the start of the second grazing season, live weight remained heaviest for S2, lightest for S1, S4 and S5 ($P < 0.05$), however S3 was intermediate ($P > 0.05$). During the second grazing season live weight gain was greater ($P < 0.05$) for S4 (supplemented pre-finishing) compared to all other systems (un-supplemented). Carcass weight was heavier ($P < 0.05$) for S1 (22 months) compared to the 19-month systems, which did not differ. No differences were observed in carcass conformation or fat scores between production systems ($P > 0.05$). Although the additional three months of development for S1 yielded the heaviest carcasses, the 19-month systems achieved commercially acceptable fat scores (mean ≥6.0 on a 15-point scale). Feeding half of the allocated 'finishing' concentrate budget (185 vs. 375 kg DM) in the first grazing season (S3), compared to all of the allowance (375 kg DM) in the first grazing season (S2) or pre-finishing during the second grazing season (S4), effectively supported lifetime carcass gain without compromising carcass specifications, while reducing concentrate input and obviating a second winter housing period. The economic and environmental implications of reallocating lifetime concentrate budgets and reducing finishing age merit further assessment.

Effects of nutrition and methane-suppressing feed additives on plasma metabolites of pre-weaned replacement Holstein heifers

O. Cristobal Carballo[1], S. O'Callaghan[1,2], S. A. Goldansaz[1], T. Yan[1], G. Scoley[1]
[1] Agri-Food and Biosciences Institute, Sustainable Livestock Sciences, Large Park, BT26 6DR Hillsborough, United Kingdom, [2] Queens University of Belfast, School of Biological Sciences, 19 Chlorine Gardens, BT9 5DL Belfast, United Kingdom

Variations in nutrient intake in pre-weaned calves have shown to activate epigenetic mechanisms that affected the long-term animal performance. Feeding methane suppressing feed additives to pre-weaned calves can affect the rumen microbiota by producing less CH4; however, this may also result in ruminal fermentation changes that compromises nutrients intake and animal performance. Feeding calcium peroxide (CaO2) has shown to reduce up to 29% methane production in finishing beef cattle; however, it has also shown reduction in nutrient digestibility and volatile fatty acid production. The aim of this study was to evaluate the effects of pre-weaning milk intake and methane-suppressing feed additives (MSFA) in the starter concentrate on the early metabolic development of replacement heifers. Thirty-six replacement Holstein calves were randomly arranged in a 2 x 2 Latin square experimental design. Calves were fed milk replacer (MR) at either 4 or 8 L for 63 days (step-weaned from days 42-63) and supplemented with a starter concentrate containing either Calcium carbonate (control) or CaO2 (MSFA) from days 5 to 83. Heparin plasma samples were taken at day 63 of age and frozen at -80°C until metabolomic analysis. Ultrahigh Performance Liquid Chromatography-Tandem Mass Spectroscopy was used to analyse plasma metabolites. Following imputation of missing values, and log transformation, a two-way ANOVA was used to identify biochemicals that differed significantly between experimental groups. Biochemicals that achieved statistical significance of $p \leq 0.05$ were analysed. Results showed that the intake of CaO2 affected ($P < 0.05$) the microbial activity by decreasing some metabolites of secondary bile acid sub pathways and increasing those in the benzoate sub pathway. Metabolites related to energy metabolism showed that calves drinking 8L MR but consuming CaO2 fold decreased ($P < 0.05$) glucose, lyxonate, fructose and mannose in plasma by 0.87, 0.64, 0.84 and 0.75, respectively, when compared to control calves. Dicarboxylic fatty acids metabolites were elevated ($P<0.05$) in the plasma of all calves fed CaO2 when compared to control calves. Additionally, calves fed 4L MR and CaO2 had a 1.51-fold increase ($P<0.05$) in 3-hydroxybutyrate. For the protein catabolism, all calves consuming 8L MR, especially calves fed CaO2 , decreased ($P < 0.05$) plasma metabolites in sub pathways such as: amino acid metabolism, branch chain ammino acids, methionine metabolism and dipeptides. Calves fed 8L MR and CaO2 not only showed reduction ($P < 0.05$) in metabolites corresponding to metabolic cycles such as glutamate and methionine, but also in gamma-glutamyl ammino acids and vitamins C, B5 and A when compared to their counterpart consuming 4L MR and CaO2. It is concluded that the intake of CaO2 affected the metabolism of the rumen microbial ecosystem by increasing some metabolite derived from microbial activity in the host's plasma. In the calves, adding CaO2 to the starter concentrate reduced the metabolism of carbohydrates, whilst favouring the metabolism of fats. Additionally, the ingestion of 8L MR decreased the catabolism of proteins and ammino acids, and oxidative metabolites, however, those calves consuming CaO2 showed lower concentrations of vitamins C, B5 and A in plasma. Future work might involve the analysis of additional time points pre- and post-treatment to determine the impact of milk replacer intake and calcium peroxide supplementation in the long-term of replacement heifers.

Effect of dietary supplementation in Rubia Gallega calves assessed by ultrasound measurements

C. Montes[1], S. Crecente[1], C. García[2], R. Alonso[2], T. Moreno[1]
[1] Mabegondo Agricultural Research Centre, Betanzos–Santiago Road, km 7, 15318 A Coruña, Spain, [2] Meat Technology Centre, San Cibrao das Viñas, 32900 Ourense, Spain

Dietary supplementation with essential oils derived from hydrolysed R. communis oilseed (Bovino Plus ®) was evaluated as a nutritional strategy to modulate dorsal subcutaneous fat thickness (SCF12) and Longissimus muscle area (ULMA) at the 12th-13th rib interface. Twenty-four Rubia Gallega male calves from Mabegondo Agricultural Research Centre herd were randomly assigned to one of three treatment groups for 90 days: control (G0), 10 mL/animal/day of essential oils supplement (G1) or 20 mL/animal/day of essential oils supplement (G2). Animals were fed indoors with concentrate and hay ad libitum. The intake of concentrate was calculated daily for each group as the difference between the amount offered and the amount refused (mean daily intake 6.08 kg DM/calve/day). Male calves were weighed every 15 days from weaning to slaughter to determine average daily gain (ADG). In addition, thoracic perimeter (TP) was measured using a tape measure. The 24 male calves were subjected to two ultrasound exams: one at weaning and another immediately prior to slaughter. Ultrasound measurements were performed using an EXAPAD MINI device (Humeco) to assess SCF12 and ULMA in transverse section. Images were obtained using a 2.5 MHz linear transducer integrated into an Exapad Mini unit (Humeco). The imaging parameters used were as follows: depth 160 mm, frequency 2.5 MHz, focal zone 50 mm, and gain 60 dB. The images were subsequently analysed using MeatQtex software (Humeco). Animals were slaughtered at 312 days of age, with mean slaughter live weights (SLW) of 449.25 kg (G0), 437.25 kg (G1), and 465.87 kg (G2), and a mean carcass weight (CW) of 250 kg (G0), 243 kg (G1) and 272 kg (G2). Carcasses were classified according to the EUROP system as R+2+ for G0, U–2+ for G1, and U2+ for G2. All statistical analyses were performed using R Commander for Windows, version 4.3.2. No significant differences were found between treatment groups for Longissimus muscle area between the 12th-13th rib interface at weaning (ULMAw) and at slaughter (ULMAs). ULMAs values were significantly greater than ULMAw in all groups, with no significant differences among groups (G0: ULMAw 66.68 ± 1.71 vs. ULMAs 75.50 ± 6.38; G1: ULMAw 67.68 ± 5.38 vs. ULMAs 76.99 ± 4.96; G2: ULMAw 71.41 ± 4.85 vs. ULMAs 82.34 ± 4.40, $P < 0.001$). No significant differences were observed among treatment groups for subcutaneous fat thickness at the level of the 12th -13th rib interface at weaning (UFATw) and at slaughter (UFATs). UFATs values were significantly higher than UFATw in all groups, with no significant differences among groups (G0: UFATw 2.89 ± 0.19 vs. UFATs 3.68 ± 0.31; G1: UFATw 2.65 ± 0.21 vs. UFATs 3.38 ± 0.11; G2: UFATw 2.70 ± 0.19 vs. UFATs 3.69 ± 0.41, $P < 0.001$). ULMAs showed moderate to high positive Pearson´s correlations (95% confidence intervale, $P < 0.01$) with TP at slaughter ($r = 0.46$), CW ($r = 0.54$), dressing percentage ($r = 0.60$) and carcass conformation ($r = 0.67$), indicating that ULMAs values are a good indicator of overall muscular development in Rubia Gallega male calves. Moderate correlations between ULMAs and ADG ($r = 0.35$), between ULMAs and SLW ($r = 0.44$) were observed. In conclusion, R. communis oilseed supplementation did not modify dorsal subcutaneous fat thickness and Longissimus muscle area at the 12th -13th rib by ultrasound measurements in Rubia Gallega male calves. However, ultrasound Longissimus muscle area was a practical and reliable indicator of carcass weight, dressing percentage and carcass conformation, as shown by high correlation values.

A survey of dairy-beef calf management practices pre- and post-weaning, and post-turnout to pasture on Irish commercial farms

R. R. Male Here[1,2], M. Mcgee[1], P. Smith[1], T. Bourke[1], J. Smyth[1], S. Reilly[1], E. O'Riordan[1], D. Kenny[1], C. Mcaloon[2], B. Earley[1]

[1] Teagasc, Animal & Grassland Research and Innovation Centre, Grange, Dunsany, C15 PW93 Co. Meath, Ireland, [2] University College Dublin, School of Veterinary Medicine, Belfield, Dublin 4, Dublin, Ireland

The expansion of dairy cow numbers has led to an increase in dairy calves available for beef production in Ireland; however, information on dairy-beef calf management practices on Irish commercial farms remains limited. The aim of this study was to describe the management of Irish dairy-beef calves pre- and post-weaning, and post-turnout to pasture. A survey of 43 farms geographically distributed across Ireland was conducted using a combination of face-to-face and online questionnaires between February and August 2025. Farms were recruited through the online and farming media advertising, Teagasc farm advisory service, and public farming events. Participation in the survey was voluntary. Most farms reared both male and female calves (69%, 25/36) and purchased calves at 2-4 weeks of age (92%, 33/36) directly from multiple (median: 4) dairy farms (72%, 26/36). Predominant breeds of calves purchased were Aberdeen Angus (81%, 29/36), Hereford (58%, 21/36), and Holstein-Friesian (58%, 21/36). Calf health (79%, 27/34), price (62%, 21/34), and beef genetic merit (commercial beef value; 38%, 13/34) were the main purchase criteria. Upon arrival, access to water and forage (100%, 36/36), electrolytes (31%, 11/36), and calf milk replacer (67%, 24/36) was provided immediately. On all farms (36/36), calves were accommodated in group pens, with group sizes of ≤10 (48%, 16/33), >10-20 (21%, 7/33), >20-30 (21%, 7/33), and >30 (9%, 3/33) calves. Multiple criteria were used for grouping, including purchase batch (53%, 18/34), bodyweight (35%, 12/34), and age (21%, 7/34). Almost all farms (97%, 35/36) practiced calf vaccination (bovine respiratory (86%, 30/35) and clostridial (60%, 21/36) diseases), and of those, 66% (23/35) administered vaccines within 7 days post-arrival. Most farms fed calf milk replacer twice daily (81%, 29/36), with a daily milk volume of 5-6 L (83%, 30/36) at total solids concentrations of 12.5-15% (76%, 22/29). Pre-weaning, all farms (36/36) offered concentrate (mostly ad libitum; 83%, 30/36) and forage (all ad libitum). Gradual weaning was practiced on all farms (36/36), with half of the farms (17/34) weaning calves over at least 7 days. Multiple criteria were used for weaning, with age (60%, 21/35), concentrate intake (60%, 21/35), and bodyweight (49%, 17/35) being most prevalent. Predominant weaning target included age of 10-12 weeks (55%, 11/20), concentrate intake of 1.5-2 kg/day (86%, 18/21), and a bodyweight of 90-100 kg (71%, 10/14). Most farms weaned calves indoors (74%, 29/39), and among these, 93% (27/29) retained them indoors for 1-4 weeks before turnout to pasture. Calf turnout mostly occurred in multiple batches (75%, 30/40) from early March to early June (median: late April). All farms (40/40) continued concentrate feeding post-turnout, with 73% (29/40) offering 1.5-2 kg/day. Almost two-thirds of the farms (24/38) offered pelleted concentrate, with the remainder offering coarse ration (34%, 13/38), at pasture. On 22 farms (55%), concentrate feeding was continued throughout the entire grazing season. Most farms operated rotational grazing systems (83%, 33/40) and calves grazed separate pasture areas from adult cattle (69%, 27/39). A leader-follower grazing regime was practiced on 15% (6/39) of farms. This study identified variation in management practices of dairy-beef calves on Irish commercial farms. These findings may help to inform future research and to guide targeted knowledge-transfer initiatives for dairy-beef farmers.

Umbilical Cord Blood Profiling at Birth as a Predictor of Early Growth in Piglets

A. Solà-Navarro[1], E. Huenul[1], P. Salgado-López[1], J. F. Pérez[1], S. M. Martin-Orúe[1]
[1] Universitat Autònoma de Barcelona, Animal Welfare and Nutrition Service (SNiBA), 08193 Barcelona, Spain

Newborn piglets face substantial physiological challenges immediately after birth, including thermal stress, adaptation to extrauterine respiration, and high metabolic demands. Their survival and subsequent growth largely depend on their ability to respond effectively to these early-life stressors. Previous research suggests that physiological and behavioural differences between pigs with divergent early growth are marked by the suckling period and associate with persistent physiological alterations later in life. The objective of this study was to identify and evaluate non-invasive physiological parameters measurable at birth that could predict average daily gain (ADG) during the first week of life. The study included 40 randomly selected liveborn (Pietrain × (Landrace × Large White)) piglets from seven multiparous sows within a single farrowing batch on a 600-sow commercial farm operating with a 4-week batch management system. Umbilical cord blood was collected within ten minutes of birth, prior to colostrum intake, using a syringe and immediately analysed with a CG8+ cartridge on a portable i-STAT® analyser. Measured parameters included blood gases (partial carbon dioxide (pCO2) and partial oxygen), electrolytes (sodium and potassium), pH, glucose (Glu), ionized calcium, and haematocrit. Calculated values for total CO_2 (tCO2), bicarbonate (HCO^{3-}), base excess (BE), oxygen saturation, and haemoglobin were also obtained. Piglet body weight was recorded at birth, 24 hours, and 7 days to calculate ADG. Univariate linear regression analyses were performed to assess associations between umbilical cord blood parameters and weight gain. First-day weight gain (0–1 WG) was positively correlated with Glu ($r = 0.358$, $p = 0.031$) and first-week ADG ($r = 0.438$, $p = 0.012$). ADG during the first week was negatively correlated with BE ($r = –0.370$, $p = 0.043$), HCO^{3-} ($r = –0.393$, $p = 0.029$), and tCO2 ($r = –0.396$, $p = 0.030$). Notably, Glu was negatively correlated with BE ($r = –0.629$, $p < 0.001$), HCO^{3-} ($r = –0.585$, $p < 0.001$), and tCO2 ($r = –0.574$, $p < 0.001$). The positive correlation between 0–1 WG and Glu suggests that piglets with greater immediate energy availability at birth are better prepared for the required postnatal transitions. These piglets may exhibit greater vitality, facilitating earlier access to the udder and increased colostrum intake, which is reflected in higher weight gain within the first 24 hours. However, Glu was not significantly correlated with 0–7 ADG, suggesting that factors beyond initial colostrum intake also contribute to early growth. The negative associations between 0–7 ADG and multiple acid–base parameters provided by the i-STAT® analyser (BE, HCO^{3-}, and tCO2) indicate that acid–base status plays a significant role in early postnatal growth. The negative correlations between Glu and these parameters further suggests a metabolic advantage at birth for piglets with lower levels. Increases in HCO^{3-}, tCO2, and BE, calculated from pCO2 and pH, may reflect a transient episode of intrapartum hypoxia and associated metabolic stress, which could compromise the piglet's ability to adapt effectively to the competitive and demanding postnatal environment. This study demonstrates that specific umbilical cord blood parameters measured immediately after birth are significantly associated with early postnatal growth in piglets. Acid–base balance parameters and glucose concentration may serve as practical early biomarkers of neonatal performance, offering valuable tools for identifying piglets at risk of suboptimal growth.

Effects of maternal undernutrition on cardiac mitochondrial DNA (mtDNA) abundance and the cardiac transcriptome in Japanese Black fetuses

R. Yamamoto[1], T. Haginouchi[1], S. Takagi[1], T. Gotoh[1]
[1] Hokkaido University FSC, N11W10, Kita, 060-0811 Sapporo, Hokkaido, Japan

Maternal nutrition during gestation plays a critical role in fetal organ development and long-term physiological function. In cattle, prenatal undernutrition has been associated with impaired postnatal growth and increased susceptibility to metabolic and cardiovascular disorders. However, the molecular mechanisms underlying fetal cardiac adaptation to maternal undernutrition remain unclear in cattle. This study aimed to investigate the effects of maternal undernutrition on mitochondrial DNA (mtDNA) abundance and global gene expression profiles in the fetal heart of Japanese Black (Wagyu) fetuses. Multiparous Japanese Black cows were randomly assigned from conception to 8.5 months of gestation to either a high-nutrition group (HN; 120% of nutritional requirements, n = 6) or a low-nutrition group (LN; 60%, n = 6). Fetuses were collected near term, and left ventricular cardiac tissue was obtained for molecular analyses. Total DNA and RNA were extracted from each sample. Mitochondrial DNA copy number was quantified by qPCR using mitochondrial-encoded genes normalized to nuclear genomic DNA. Transcriptomic profiling was performed using RNA sequencing (RNA-seq), followed by differential gene expression and pathway enrichment analyses. The mtDNA copy number in fetal cardiac tissue was significantly lower ($P < 0.05$) in LN compared with HN, indicating reduced mitochondrial abundance under maternal undernutrition. RNA-seq analysis identified 1,847 differentially expressed genes (DEGs) between LN and HN using the criteria $|\log_2 \text{fold change}| > 2$ and $q < 0.05$. Pathway analysis demonstrated that genes involved in mitochondrial oxidative phosphorylation, the tricarboxylic acid cycle, and fatty acid β-oxidation were predominantly downregulated in LN, whereas genes associated with extracellular matrix organization, focal adhesion, and cellular stress responses were relatively upregulated in LN compared with HN. In conclusion, maternal undernutrition during gestation reduces mitochondrial content and induces coordinated transcriptomic alterations in the hearts in Japanese Black fetuses, characterized by suppression of energy metabolism–related pathways in the low-nutrition group.

Effects of maternal undernutrition on binucleate cell abundance and gene expression in the placenta of Wagyu (Japanese Black cattle)

S. Takagi[1], T. Haginouchi[1], R. Yamamoto[1], T. Gotoh[1]
[1] Hokkaido University, Experiment Farm, Field Science Center for Northern Biosphere, Kita 11, Nishi 10, Kita-Ku, Sapporo, 060-0811 Hokkaido, Japan

Maternal nutrition during pregnancy may influence fetal development through placental adaptation, but the nutritional responsiveness of placental phenotypes and their molecular correlates in beef cattle remain unclear. This study investigated whether sustained maternal nutritional restriction from pre-gestation through late pregnancy alters binucleated cell (BNC) abundance in placenta of Wagyu and whether corresponding differences in gene expression are detectable by RNA sequencing (RNA-seq). Primiparous Japanese Black cattle (n=12) were assigned to either a high-nutrition group (HN; 120% of nutritional requirements, n=6) or a low-nutrition group (LN; 60%, n=6) from pre-gestation until gestation day 260. Placentae were collected via cesarean section at 260 days of gestation. Hematoxylin and eosin staining was performed to morphologically identify BNCs. BNC abundance was quantified as the total number of BNCs counted from 10 microscopic fields (×400) per sample using BZ-X 1000 (KEYENCE, Osaka). Total RNA was extracted from each placenta for transcriptome analysis. Differentially expressed genes (DEGs) between groups were identified using DEGseq2 ($q < 0.05$). The BNC count was significantly larger in the HN group than in the LN group, indicating that long-term maternal nutrition influences trophoblast cell dynamics in the placenta. Differential expression analysis identified only three genes: COL6A5, KCP, and KRT17 ($q < 0.05$). These three genes are associated with structural organization of the extracellular matrix. However, the small number of detected genes suggests that gene expression changes are minor. Under the current sampling and analysis conditions, detectable transcriptome differences between nutritional groups are limited. Overall, maternal nutritional status was associated with distinct histological phenotypes, but RNA-seq detected only minor differences in gene expression. Although gene expression variability was small, changes in genes associated with extracellular matrix structural alterations may contribute to alterations in binuclear cell numbers.

Tributyrin supplementation reduces diarrhea frequency and severity in preweaning calves

A. Vigh[1], M. Müller[1], V. Thierer[2], J. Guyader[1]
[1] Evonik Operations GmbH, 4 Rodenbacher Chaussee, 63457 Hanau, Germany, [2] Viehweidhof, Zur Viehweid 1, 87775 Hausen, Germany

Neonatal calf diarrhea is one of the biggest health challenges in dairy cattle herds, causing substantial losses. In this regard, butyrate was shown to promote intestinal development, improve gut health and reduce the diarrhea incidence in young animals. This study investigated the effects of tributyrin as a butyrate source in milk replacer on diarrhea occurrence, growth performance, metabolic status and fecal microbial load in female dairy calves. Fifty female Holstein calves averaging 43.0±1.53 kg body weight (BW) at birth were divided in two experimental groups and fed a diet without (CON) or with 4.0 g/kg DM of tributyrin (TRIB; SpeoCare® T60, 60% tributyrin, Evonik Operations GmbH) mixed in a commercial milk replacer until weaning (~80 days of life). The calves were housed in individual pens during the first 3 weeks of life, in double pens the following 2 weeks (week 4-5), and collective pens (maximum 14 animals/pen) until the end of the trial (~150 days of life). The fecal consistency was evaluated daily until week 6 of life, with fecal scores from 1 to 4. Animals with fecal scores of 1 and 2 were defined as normal, while animals with fecal score of 3 (moderate diarrhea) and 4 (severe diarrhea) were defined diarrheic animals. Diarrhea frequency was calculated with the equation: diarrhea frequency (%) = [(number of diarrheic calves × days of diarrhea) / (total number of calves × days of measurement)] × 100. Calves BW was recorded at birth, at weaning, and at the end of the trial period and used for average daily gain (ADG) calculation. From each experimental group, 10 calves were randomly selected for blood and fecal sampling. Blood was sampled at birth, weaning and end of the trial period, and analyzed for total protein, hemoglobin, urea, glucose, insulin, beta-hydroxybutyrate, and glutathione peroxidase. Fecal sampling occurred at the end of week 1, 2 and 3, at weaning and at the end of the trial period. Plate count of total bacteria, lactic acid bacteria and coliform bacteria was done on the fecal samples. For statistical analyses, the qualitative data were analyzed using Pearson's square Qi test, while the quantitative data were analyzed based on a linear model using treatment and period (time) and their interaction as fixed effects. The initial measurements at birth were included as covariates. Least square means were compared using Tukey's test. Significance was declared when $P \leq 0.05$ and tendency with $0.05 < P \leq 0.10$. Supplementation with TRIB during the preweaning period significantly decreased the diarrhea frequency during the first week (-13%, $P<0.010$). More specifically, moderate diarrhea was reduced by 7% ($P=0.053$) and severe diarrhea by 6% ($P=0.066$) when compared to CON. Starting with week 2 the moderate diarrhea was not different between the two experimental groups; nevertheless, a significantly lower severe diarrhea frequency was registered with TRIB compared to CON during week 2 (-8%, $P<0.05$). Between week 3 and week 6, diarrhea frequency presented no significant difference between the two groups. No significant differences were registered in ADG or blood metabolites throughout the study. No significant differences were registered in fecal count of total bacteria or lactic acid bacteria between the CON and the TRIB groups. However, the coliform bacteria fecal load was significantly lower in the TRIB group during the whole study period ($P<0.05$; 6.34 and 7.07 $\log_{10}$ CFU/g for TRIB and CON, respectively). In summary, supplementing tributyrin during the preweaning period improved the health status of dairy calves by reducing diarrhea frequency and fecal coliform bacteria load.

Effect of early life high nutrition on hepatic metabolism, gene expression, and DNA methylation in beef cattle

S. Muroya[1], A. Saito[2], K. Ojima[3], T. Gotoh[4]
[1] Kagoshima University, Faculty of Veterinary Medicine, 1-21-24, Korimoto, 890-0065 Kagosima, Japan, [2] Zenrakuren, 1-3-2, Yoyogi, 151-0053 Shibuya, Tokyo, Japan, [3] NARO Institute of Livestock and Grassland Science, Division of Meat Animal and Poultry Research, 2 Ikenodai, 305-0901 Tsukuba, Ibaraki, Japan, [4] Hokkaido University, Graduate School of Agriculture, Kita-10, Nishi-11, 060-0811 Sapporo, Hokkaido, Japan

Early high nutrition potentially enhances growth and improves carcass traits of beef cattle. We hypothesized that this early nutritional effect is mediated by metabolic programming of liver, leading to modulation of endocrine and nutrient distribution. To investigate the underlying mechanisms of epigenetic modulation of gene regulation and metabolism in the liver, we examined the metabolome, transcriptome and epigenetic profiles of Japanese Black (JB; Wagyu) steers that were fed a high-nutrient milk diet in early life, using an integrated multi-omics approach. The steers were divided into two groups. The early roughage (ER) group (n = 11) was fed a standard amount of milk replacer until three months of age (mo), followed by only roughage from four to ten months. The early high overall nutrition (EHN) group (n = 12) was provided with three times the standard amount of milk replacer until three months of age, followed by a high-concentrate diet from four to ten months. From 11 to 31 months of age, all of the steers were fed only roughage. Liver samples from four EHN steers with the greatest final body weight (BW) and four ER steers with the lowest BW were used for subsequent analyses including CE-TOF/MS and LC-TOF/MS, RNA-seq, and RRBS. The body weight (BW) of EHN steers was higher than that of ER steers at 3, 10 and 31 months, as was their hot carcass weight ($p < 0.01$). EHN steers exhibited higher subcutaneous fat thickness and intramuscular fat content than ER steers ($p < 0.05$) for the carcass trait. EHN steers exhibited a liver metabolome profile with higher levels of carnitine, the precursor γ-butyrobetaine, glutamine and serine, and lower levels of acylcarnitines than ER steers. This suggests that acylcarnitine is transferred more efficiently into the mitochondria of EHN steers for accelerated β-oxidation. The results of RNA-seq and subsequent gene ontology analysis revealed that the expression of genes associated with pyruvate metabolism, gluconeogenesis, triglyceride homeostasis, lipid metabolism and the regulation of RNA polymerase activity was significantly altered. This was characterized by the upregulation of PC, APOA5, ANGPTL8, TGIF1, UHRF1 and HDAC5. Meanwhile, most of the downregulated genes were associated with the immune and inflammatory responses. Furthermore, the results of DNA methylation analysis using RRBS indicated that promoter-hypomethylated genes were associated with regulation of angiogenesis, axon guidance, regulation of mitochondrial outer membrane permeabilization, blood vessel morphogenesis, nerve system development, hepatocyte apoptotic process, chromatin remodeling, and genomic imprinting. Meanwhile, promoter-hypermethylated genes were associated with regulation of apoptotic process and regulation of cell proliferation. Although many genes with highly altered promoter methylation did not exhibit significant changes in gene expression, those involved in systemic homeostasis and energy metabolism (IGFALS, ACSF3 and ORM1) exhibited promoter region hypomethylation, which could result in increased gene expression. Collectively, EHN leads to a long-lasting metabolic shift towards high β-oxidation activity and modulates the regulation of genes involved in systemic energy metabolism in the livers of JB steers through metabolic gene imprinting.

Estimation of genetic heterogeneity of variance (environmental sensitivity) of milk yield traits and somatic cell count to predict resilience of dairy cattle

M. Haile-Mariam[1,2], M. Khansefid[1,2], M. Goddard[1,5], G. Nieuwhof[3], A. Gilmoure[4]
[1] Agriculture Science and Technology, Agriculture Victoria, Department of Energy, Environment and Climate Action (DECCA), 5 Ring Road, Bundoora, Vic 3083 Melbourne, Australia, [2] School of Applied Systems Biology, La Trobe University, 5 Ring Road, Bundoora, Vic 3083 Melbourne, Australia, [3] DataGene Limited 5 Ring Road, Bundoora, Victoria 3083, Australia, AgriBio, Centre for AgriBioscience, 5 Ring Road, Bundoora, Vic 3083 Melbourne, Australia, [4] Holman way, 11 Holman Way, NSW, 2800 Orange, Australia, [5] Faculty of Science, University of Melbourne, Parkville, Vic. 3010 Melbourne, Australia

Genetic selection offers a promising opportunity to improve resilience in dairy cattle because resilience-related traits show heritable variation. However, the lack of suitable phenotypes is a major barrier to developing genetic evaluation for resilience of dairy cattle. Variability in traits that are frequently recorded such as milk yield can be used to develop a breeding value for resilience. This study quantifies the genetic residual variability of sires based on milk yield traits and somatic cell count (SCC) and evaluates whether heterogeneity of variance at the sire level is associated with functional traits in Australian dairy cattle. Test-day data of over 760,000 Holstein (H) and 138,000 Jersey (J) cows were analysed using a Double Hierarchical Generalised Linear Model (DHGLM). In the DHGLM, mean (normal) and the dispersion (gamma) were analysed in a bi-variate mixed model including covariances between the mean and dispersion effects. We analysed three milk yield traits, fat & protein percent, fat to protein ratio and SCC to calculate sire solutions for trait dispersion. Sire solutions for dispersion of the traits were correlated with Estimated Breeding Values EBVs for functional traits as well as with exit by 180-days and exit by 180-days plus all deaths to assess their usefulness to predict resilience. Results show that the heritability of the dispersion of all the traits ranged from 0.02 (SCC and protein%) to 0.05 (fat % and fat to protein ratio). The genetic-level (sire) correlation between the mean and dispersion are higher (0.05 to 0.51) than the cow level (-0.1 to 0.34) correlations. Genetic correlation between the mean and dispersion were the highest for milk yield (MY) in H (0.51) and J (0.49). Accounting for sire by herd interaction for the mean did not affect sire solutions for dispersion; accounting for persistency of lactation, however, resulted in some re-ranking of sires for dispersion of the traits highlighting the importance of persistency on dispersion of different traits. The correlations between sire solutions for dispersion and EBVs for functional traits such as fertility, survival, etc. were low but mostly in the expected direction. For example, high sire solutions for dispersion of milk yield were associated with poorer fertility and increased mastitis incidence, and higher rate of exit by 180-days plus all deaths. Although these correlations between sire solutions for dispersion and EBVs were not strong enough to be used for predicting functional traits or developing breeding values for resilience, avoiding the use of sires with high dispersion solutions (i.e. the high sensitivity sires) may help to improve functional traits and potentially resilience. Further examination of the sire solutions for different dispersion traits showed significant differences in EBVs for functional traits between the least sensitive (bottom 25%) and most sensitive (top 25%) sires. There is interest to assess the relationship of sire solutions for dispersion traits with metabolic diseases (milk fever and ketosis) for which there is no genetic evaluation in Australia.

Deriving environmental variability indicators from herd-level milk production by calendar date for reaction norm models

R. Shi[1], N. C. Friggens[2], J. I. Ohlsson[3], T. Klingström[3], M. H. Pinard-Van Der Laan[1]
[1] Université Paris-Saclay, INRAE, AgroParisTech, GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France, [2] INRAE, PEGASE, 16 Le Clos Domaine de La Prise, 35590 Saint-Gilles, France, [3] Swedish University of Agricultural Sciences, Department of Animal Biosciences, VHC, Ulls väg 26, 750 07 Uppsala, Sweden

Dairy cows respond differently to changes in environmental quality, which can be characterized by both environmental level (ENV_l) and environmental variability (ENV_var). Most existing studies focus on genetic differences along ENV_l, for example, by using contemporary group estimates or daily average climatic indicators in reaction norm models. However, indicators specifically characterizing ENV_var in dairy cattle remain limited. The aim of this study was to derive an ENV_var indicator that is largely independent of ENV_l by using herd-level milk production by calendar date (HMPC) statistics. These indicators can subsequently be incorporated into reaction norm models to investigate genetic responses of traits such as resilience under variable environments. This analysis was based on data from 13 Swedish dairy herds from the network of the Gigacow project (Swedish University of Agricultural Sciences). After quality control, the dataset included 1,384,332 daily milk yield records from 3,937 lactations between 1 January 2021 and 31 December 2025. The studied herds had at least one year of milking records and a minimum of 20 daily milk yield records per date. The HMPC was derived separately for primiparous and multiparous cows. To derive ENV_l and ENV_var for individual cow-lactations, the relevant HMPC segments were obtained by aligning calendar dates with that cow's days in milk (DIM). The mean and standard deviation of HMPC were then calculated as indicators of ENV_l and ENV_var, respectively. To evaluate the relevance of ENV_l and ENV_var, individual cow-lactation DIM curves were combined with expected lactation curves derived from polynomial quantile regression models to obtain resilience traits, such as logarithm variance of deviations (LnVar) and average daily milk loss (ML_d). Associations between these resilience traits and both ENV_l and ENV_var were evaluated. The current results showed that no lactation-stage patterns were observed in HMPC, indicating that variation in HMPC largely reflected external environmental perturbations. A weak association between ENV_l and ENV_var was observed (Pearson correlation coefficient = -0.30), suggesting that the proposed ENV_var indicator is largely independent of ENV_l. Both LnVar and ML_d increased linearly with ENV_var, indicating greater milk deviations and milk loss under more variable environments. This relationship was stronger in multiparous cows than in primiparous cows (Pearson correlation coefficients of 0.87 and 0.53 for ML_d, respectively). These results demonstrate the feasibility of using the proposed ENV_var indicator to characterize environmental variability in dairy production systems. Future work will focus on investigating genetic differences in responses to ENV_var by incorporating this indicator into reaction norm models which will improve understanding of the genetic mechanisms underlying resilience to environmental variability. This work was funded by project European Partnership on Animal Health and Welfare (European Union's Horizon Europe Project 101136346 EUPAHW).

Integrating satellite environmental proxies to optimise genotype-by-environment interaction assessment for weaning weight in Namibian pasture-based beef systems

S. Vanvanhossou[1], S. König[1]
[1] Justus-Liebig-University Giessen, Institute of Animal Breeding and Genetics, Ludwigstraße 21b, 35390 Giessen, Germany

In open rangeland cattle systems, such as those found in Namibia, there is a need for innovative environmental covariates (ECs) that extend beyond traditional metrics like temperature–humidity index (THI) to model key production factors, including forage availability and animal health stressors. Such ECs enable a more comprehensive characterization of production conditions, thereby informing breeding strategies for enhanced animal resilience to environmental pressures. This study investigated genotype-by-environment interaction (G×E) for weaning weight (WW) in four Namibian cattle breeds along post-natal conditions defined by four ECs: normalized difference vegetation index (NDVI), precipitations (PREC), surface solar radiation (SSR) and THI. The NDVI as an indicator of vegetation and forage status was contrasted to PREC, whose effects on feed availability are modulated by soil properties and other climatic factors. The SSR, given its direct impact on animals' exposed environments, was compared with THI. The ECs were derived from satellite-based data retrieved via the Google Earth Engine platform using farm coordinates and averaged over a 90-day period following each calf's birth. Pedigree-based reaction norm models were fitted separately for Bonsmara (n = 26,624), Brahman (n = 25,125), Simbra (n = 14,984), and Simmentaler (n = 9,811), to regress the genetic parameters of WW on individual EC using first-order Legendre polynomials. Reactions norms and phenotypic plasticity were assessed to identify breed-specific patterns of animal sensitivity to the ECs. Pairwise correlations between NDVI and PREC (0.70–0.79) and between SSR and THI (0.77–0.86) were moderate to high, whereas correlations between NDVI and SSR (0.03–0.26) were low, suggesting that each EC captures distinct environmental conditions. Irrespective of the breed, direct and maternal heritabilities (h^2) for WW exhibited considerable variations along all EC gradients, with NDVI and THI showing the largest variations. Estimates of h^2 increased gradually from low to higher NDVI, indicating that improved feed resources enhance response to selection and maximal genetic gain. Conversely, h^2 decreased under moderate THI and increased under both extreme heat conditions. Both direct and maternal genetic correlations (rgEC) decreased significantly, reaching negative values with environmental divergence (direct rgEC: -0.25 – 0.39; maternal rgEC: -0.68 – 0.32 at extreme EC gradients). These findings indicate the presence of G×E across all ECs, but the variation of rgEC along the gradients differed with ECs and breeds. Simmentaler and Simbra cattle exhibited the lowest rgEC at extreme EC gradients compared to Brahman and Bonsmara. Analysis of reaction norm patterns revealed low to moderate correlations between the intercept and slope of direct genetic effects (-0.2 – 0.6), confirming substantial reranking of breeding values along most ECs. Moreover, higher slope-to-intercept genetic variance ratios (> 0.5), particularly with THI and SSR in Simmentaler and Simba, suggest important contribution of environmental sensitivity to overall genetic variation in these breeds. Overall, the evaluated ECs induced notable alterations of genetic parameters in Namibian breeds. Differences in environmental sensitivity across breeds and ECs reflect varying adaptive capacities to distinct stressors and highlight that no single covariate can fully represent the complexity of G×E.

Population reaction norms of three German dairy cattle populations regarding heat stress

A. K. M. Neufeldt[1], V. P. Haas[1], J. Bennewitz[1]
[1] University of Hohenheim, Institute of Animal Science, Garbenstrasse 17, 70599 Stuttgart, Germany

Heat stress events present a challenge for global livestock production. The consequences of climate change and more extreme weather events are already becoming apparent all over the world. In general weather in Europe is more localized. Southwest Germany, in particular, comprises different natural areas, with different local climate conditions. In this context we aimed to estimate heat stress effects in southwest Germany in the three most common dairy cattle breeds: German Holstein Friesian, German Fleckvieh, and German Brown Swiss. To quantify the environmental conditions inside stables, data of installed climate loggers inside stables as part of the EIP Project KlimaFit were used. Daily milk yield measurements from automatic milking systems at 46 farms were used as animal performance of 2,538 German Holstein Friesian, 1,829 German Fleckvieh, and 815 German Brown Swiss dairy cows and the climate data from the climate loggers were used as the environmental descriptor. Daily temperature and humidity measurements were used to build a daily Temperature-Humidity-index (THI), which acts as an indicator for the daily heat stress load inside the stables. In Contrast to the common approach in most studies the THI records were not clustered into predefined groups. Instead, treated as a continuous variable using a double hinge function transformation in order to increase the resolution in the higher THI range and capture effects in this critical region. Higher order Legendre Polynomials were used in the random regression reaction norm model to describe the genetic variation in milk yield along the trajectory. The higher order Legendre polynomials were significantly above zero, confirming the presence of genetic variability of heat stress milk yield depression. The critical of the reaction norm models were slightly different between the populations. The critical value for HF was around 55, for Fleckvieh 65, and for Brown Swiss it was around 69. In all three breeds the milk yield dropped nearly linearly exceeding a population individual critical point. No greater differences were observed throughout the reaction norm between the three breeds. The results indicate that heat stress is affecting dairy cattle in southwest Germany. Furthermore, the estimated genetic variances indicate that animals differ in their genetic ability to respond to varying thermal conditions. Additive genetic effects and heritability did change along the environment THI, u-shapes were observed and were comparable between the three breeds. Future breeding should consider enhanced heat stress resilience and tolerance, which is expected to become an important issue in livestock production systems due to progressing climate change conditions.

Genetic analysis on heat tolerance of fertility traits in Canadian Holstein cows

G. R. Dodd[1], F. S. Schenkel[1], C. F. Baes[1], F. Malchiodi[1,2], C. Richardson[3], F. Miglior[1,4]
[1] University of Guelph, Centre for Genetic Improvement of Livestock, 50 Stone Road East, N1G 2W1 Guelph, Canada, [2] Semex, 5653 Highway 6, N1H 6J2 Guelph, Canada, [3] AbacusBio International Ltd, Roslin Innovation Centre, Easter Bush Campus, University of Edinburgh, EH25 9RG Edinburgh, United Kingdom, [4] Lactanet, 660 Speedvale Ave W Unit 101, N1K 1E5 Guelph, Canada

Adaptability to changing environmental conditions is crucial for the long-term sustainability of dairy cattle production. While the genetics of heat tolerance in milk production have been extensively studied, those of fertility traits remain less well characterized. Time from first service to conception (FSTC) reflects a cow's ability to conceive at the first insemination and is used in Canadian national genetic evaluations as an indicator of reproductive efficiency. The objectives of this study were to estimate heat tolerance and evaluate possible genotype-by-environment interaction (GxE) for FSTC in Canadian Holsteins. Phenotypic data comprised 1,964,398 first-parity Canadian Holsteins across 10,313 herds with FSTC records collected between January 1, 2008 and December 31, 2024. Weather data were obtained from the NASA POWER database, including hourly ambient temperature and relative humidity corresponding to the latitude and longitude of each herd (https://power.larc.nasa.gov/; accessed 2026-02-11). Based on previous analysis, daily temperature-humidity index (THI) values were averaged over a window from 3 days prior to 2 days after the first insemination date associated with each FSTC record. A reaction norm model was fitted with an intercept term representing fertility performance under thermoneutral conditions and a slope term representing heat tolerance. A previously estimated threshold of THI 68 was assumed for the onset of heat stress effects, and a heat stress function (HSF) was defined for the slope as HSF = max(0, THI-68). Heritability estimated were 0.02 ± 0.003 for thermoneutral FSTC and 0.05 ± 0.02 for heat tolerance of FSTC. The genetic correlation between fertility and heat tolerance was moderately unfavorable (-0.31 ± 0.26), indicating GxE and a potential trade-off between reproductive performance and resilience to environmental pressures.

Phenotypic analysis of heat stress effects on enteric methane emissions in Holsteins

B. Amini[1], G. Dodd[1], C. Baes[1], F. Schenkel[1], C. Richardson[2], F. Malchiodi[1,3], F. Miglior[1,4]
[1] University of Guelph, Animal Biosciences, 50 Stone Road East, N1G 2W1 Guelph, Canada, [2] AbacusBio, Roslin Innovation Centre, South Bridge, EH25 9RG Edinburgh, United Kingdom, [3] SEMEX, 5653 Hwy 6, N1H 6J2 Guelph, Canada, [4] Lactanet, 660 Speedvale Ave W, N1K 1E5 Guelph, Canada

In response to climate change targets, reducing enteric methane (CH4) emissions has become a priority for the dairy sector. Genetic selection provides a scalable mitigation strategy, and mid-infrared spectroscopy (MIRS)-predicted CH4 is a practical proxy trait for large-scale genetic improvement. Concurrently, rising global temperatures are intensifying heat stress (HS), with well-documented consequences for dairy performance and profitability. The temperature humidity index (THI) combines ambient temperature and relative humidity to reflect an animal's thermal load. However, the way HS interacts with enteric CH4 emissions remains unclear. Thus, the objective of this study was to identify the THI threshold at which MIRS-predicted CH4 is affected by HS in Canadian Holsteins. The dataset included 743,106 test-day records from 524,832 first parity Holstein cows in mid-lactation, collected between 2018 and 2025. A univariate repeatability model was used to adjust the MIRS-predicted CH4 phenotype by accounting for all known sources of genetic and environmental variation to extract residual CH4. Average hourly THI was calculated from ambient temperature and relative humidity obtained from the NASA POWER database (https://power.larc.nasa.gov/; accessed 2026-02-12) and averaged across 24 hours to obtain daily THI. The accumulated effect of HS was examined over five time windows ranging from the test-day alone to the test day plus the four preceding days (i.e., 5-day average). A segmented polynomial regression was used to identify the breakpoint at which MIRS-predicted CH4 changes with rising THI. Estimated thresholds ranged from THI 67 to 70 across time windows. A 2-day average THI window showed the best model fit (R^2=0.69) and the greatest post-threshold slope (0.57 ± 0.10), making it the most informative window for capturing HS effect on CH4. The results of this study indicated that CH4 emissions increased above the THI threshold of 70, corresponding to HS conditions. These findings suggest that HS effects on MIRS-predicted CH4 occur more sharply within shorter time windows. In future analyses, the identified THI threshold will be used to assess the genotype-by-environment interactions through reaction norm models, characterizing individual MIRS-predicted CH4 performance below and above the threshold. Keywords: Heat stress, MIRS-predicted methane, Temperature humidity index

Genotype by environment interactions for methane emissions of dairy cows fed 3-nitrooxypropanol

A. Van Breukelen[1], S. Van Gastelen[2], B. Gredler-Grandl[1], R. Veerkamp[1], Y. De Haas[1]
[1] Wageningen University & Research, Animal Breeding & Genomics, Droevendaalsesteeg, 6700AH Wageningen, Netherlands, [2] Wageningen University & Research, Animal Nutrition, Droevendaalsesteeg, 6700AH Wageningen, Netherlands

Reducing methane (CH4) emissions of ruminant livestock is important as ruminants are the single largest CH4 emitter in the agricultural sector. Several methods exist to reduce enteric CH4 emissions of cattle and two of the most promising methods applied in practice are the provision of CH4 reducing feed additives and genetic selection for low CH4 emissions. It remains unclear if combining dietary strategies and genetic selection can result in a larger reduction of CH4 emissions, or that the two strategies interact and may negatively influence each other. Therefore, our aim was to investigate if genotype by environment (G x E) interaction is present between animal breeding and dietary strategies that aim to reduce enteric CH4 emissions. Data were available on enteric CH4 emissions of cows recorded by 'sniffers' (WD-WUR v1.0 and v2.0, manufactured by Carltech BV) from the feed bin of milking robots, where several cows were provided 3-nitrooxypropanol (3-NOP; marketed as Bovaer®, dsm-firmenich AG, Kaiseraugst, Switzerland) during the CH4 recording period. Records up to 405 days in milk were included of cows with a minimum breed fraction of 75% Holstein. In total, 55,998 weekly average CH4 measurements were included in the analyses from 5,102 cows on 52 farms, of which 2,446 measurements from 453 cows on 8 farms with 3-NOP supplementation. Of these, 171 cows on 4 farms had CH4 records with and without 3-NOP supplementation. The average CH4 concentration for all 453 cows receiving 3-NOP was 493 ppm, whereas the average CH4 concentration was 620 ppm for cows without 3-NOP supplementation. The genetic correlation between CH4 with and without 3-NOP supplementation was estimated with a bivariate animal model using a restricted maximum likelihood approach. The model included fixed effects for herd × year × week, 2nd order Legendre polynomials for age at calving (in days), parity × 3rd order Legendre polynomials for days in milk, second breed × 2nd order Legendre polynomials for the second breed fraction, and random effects for the genetic cow effect, two permanent environmental effects for the repeated measurements for each cow within and between parities, and the residual effect. The genetic correlation between CH4 recorded with 3-NOP supplementation and CH4 recorded without 3-NOP supplementation was 0.71 ± 0.18. This indicates that there is little G x E interaction, thus selection responses are expected to remain in the desired direction if selection decisions are made using datasets that mix measurements from periods with and without 3-NOP supplementation, albeit s.e. is still large. Further analyses will quantify differences in the CH4 mitigating response to 3-NOP for cows with a high or low genetic merit for CH4 emissions.

Towards a resilience selection index capturing health, longevity and heat tolerance in three German dairy breeds

F. Keßler[1], J. Bennewitz[1]
[1] University of Hohenheim, Animal Breeding and Genetics, Garbenstr. 17, 70599 Stuttgart, Germany

Resilience, defined as an individual's ability to cope with short-term external stressors and to recover as fast as possible, has become a central topic in animal breeding research in recent years. In various livestock species, different indicator traits for resilience have been studied. The most promising approaches are based on changes in longitudinally recorded traits, such as the variance and autocorrelation of daily milk yield in dairy cows. While variance reflects fluctuations in milk yield — where lower values can be interpreted as higher resilience — autocorrelation indicates recovery time, with values close to zero being desirable. Previous studies reported low to moderate heritabilities for resilience indicators and generally favorable correlations with, health, and functional traits, raising the question of how resilience can be integrated into breeding programs. Consequently, a resilience selection index combining multiple resilience indicators has been proposed. In this study, we build on the resilience selection index recommended by Keßler et al. (10.3168/jds.2024-25323) and studied how selection for resilience affects existing breeding values for health, longevity, and heat tolerance. The study was conducted within the KlimaFit project and is based on data from 56 dairy farms equipped with automatic milking systems in Baden-Württemberg, Germany, collected between 2022 and 2024. Data from 2,211 German Holstein, 3,445 German Fleckvieh, and 1,229 German Brown Swiss cows were analyzed. For each lactation per cow, a lactation curve was modeled using P-spline interpolation and limited to days 10 to 305. Based on daily milk yield, several resilience indicators were calculated: the variance of absolute daily milk yield (v); the variance (vd) and autocorrelation (rAuto) of deviations between observed and predicted absolute daily milk yield; the variance of daily milk yield relative to the 305-day yield (vr); and the variance of deviations between observed and predicted relative daily milk yields (vrd). Breeding values were estimated separately for each breed and resilience indicator using an animal model including fixed effects (herd-year-season, lactation number, age at first calving, and data completeness) and random additive genetic and permanent environmental effects. Breed-specific resilience selection indices were constructed by combining single resilience indicators with optimized weighting factors. Optimization aimed to maximize the expected selection response in health and fitness traits using an L-BFGS algorithm. Selection responses in health, fitness, and longevity traits resulting from selection on resilience were subsequently evaluated. Across all breeds, the correlated selection responses in health and fitness traits exceeded the correlated response in longevity. German Holstein showed the highest responses (approximately 0.22 for health and 0.20 for longevity), followed by German Brown Swiss (0.15 for fitness and 0.10 for longevity), while German Fleckvieh showed the lowest responses (0.10 for fitness and 0.05 for longevity). Currently we are in progress of combining the resilience selection index with heat tolerance. The latter one will be analysed using a Broken Stick model to quantify milk yield declines during heat waves. These results will be used to refine our selection index towards including heat tolerance. Overall, our results support the implementation of resilience-based selection across dairy breeds, as it positively affects health and longevity traits and might contribute to heat tolerance.

Recursive model approach to define nitrogen use efficiency in Holstein dairy cows

R. E. Jahnel[1], L. R. Schaeffer[1], L. M. Alcantara[1], B. O. Makanjuola[1], A. Flemming[2], F. S. Schenkel[1], F. Miglior[1,2], C. F. Baes[1]

[1] Centre for Genetic Improvement of Livestock, University of Guelph, Animal Biosciences, 50 Stone Road E, N1G 2W1 Guelph, Canada, [2] Lactanet Canada, 660 Speedvale Avenue W, N1K 1E5 Guelph, Canada

Improving nitrogen utilization in dairy production is essential for reducing environmental nitrogen losses and enhancing the sustainability of livestock systems. Nitrogen use efficiency (NUE), defined in this study as the proportion of nitrogen intake converted into milk protein, is a key indicator of both environmental and economic performance. On average, less than half of the nitrogen consumed by dairy cows is retained. Therefore, increasing NUE offers substantial potential to reduce nitrogen excretion, lower feed costs, and improve production efficiency. Because direct measurement of NUE is not feasible at scale, indicator traits that describe nitrogen intake, output, and mobilisation could offer a potential approach. Recursive structural equation models provide a suitable framework for defining NUE-related traits because they represent prospective causal relationships among these indicators. The objective of this study was to define and evaluate a genetically derived NUE-related trait suitable for genetic evaluation. Indicator traits included dry matter intake (DMI) as a proxy for nitrogen intake, milk urea nitrogen (MUN) as a measure of nitrogen excretion, and energy-corrected milk (ECM) plus metabolic body weight (MBW) to represent nutrient partitioning into production and maintenance. The dataset comprised 97,698 records from 2,399 first parity Canadian Holstein cows, with 39,822 animals in the pedigree. Four-trait repeated-record models were implemented in ASReml 4.2. Models included fixed effects of herd-year-season and age at first calving, and classes for days in milk. Genetic, permanent environmental and residual variance components were estimated across days in milk (DIM) 5 to 305. Additionally, repeated records models were fitted using test day records within five lactation stages (early to late). The NUE-related trait was defined using a structural equation model in which MUN was modelled as a nitrogen-output trait conditional on nitrogen intake (DMI) and the energy sinks (ECM and MBW). Heritability estimates for NUE-related trait were moderate across time periods, ranging between 0.23±0.05 and 0.34±0.02. Milk urea nitrogen and DMI heritabilities were low to moderate (0.18±0.05–0.24±0.05 and 0.15±0.03–0.20±0.03, respectively). Heritabilities for ECM were moderate (0.21±0.03–0.27±0.03), while heritabilities for MBW were moderately high (0.38±0.04–0.48±0.06). Repeatability estimates for the NUE-related trait ranged between 0.32±0.04 and 0.37±0.03. These estimates indicate the potential for genetic improvement of the proposed NUE-related trait. Due to the recursive model approach, the NUE-related trait was genetically independent of DMI, ECM and MBW. Genetic correlations between the NUE-related trait and MUN across lactation was averaged 0.70 and ranged between 0.68 and 0.93 across individual lactation periods, indicating that nitrogen utilisation varies across lactation stages. A genetically defined NUE-related trait offers a practical tool to reduce nitrogen emissions through genetic selection while maintaining production. If validated in larger and more diverse datasets, our proposed approach could support incorporation of nitrogen-surplus reduction into routine genetic evaluation and breeding objectives, providing a practical lever to improve environmental performance alongside existing selection for feed and methane efficiency.

A New Multivariate Index for Resilience Selection in the Nelore Breed

V. A. Ligori[1], L. F. C. Araújo[1], G. H. C. Borges[2], L. E. F. Zadra[1], J. N. S. G. Cyrillo[1]
[1] Institute of Animal Science, Animal Science, Rodovia Carlos Tonani, km 94, 14174-000 Sertãozinho, Brazil,
[2] São Paulo State University (UNESP), Animal Science, Via de Acesso Prof. Paulo Donato Castellane, s/n, 14884-900 Jaboticabal, Brazil

Animal resilience is described by three indicators related to the growth curve: logarithm of residual variance (LNVAR), autocorrelation (RAUTO), and skewness (SKEW), which differ in biological interpretation, scale, and variance, making isolated selection and joint interpretation difficult. This study aimed to construct and evaluate a multivariate genomic index for resilience by comparing a simple standardized index and the optimal Hazel index. (Co)variance components and Genomic estimated breeding values (GEBVs) were obtained for 5,294 Nelore cattle using Bayesian inference. Because the three indicators have distinct biological interpretations, a biological reorientation was first applied (T_LNVAR = −LNVAR; T_RAUTO = −|RAUTO|; T_SKEW = −|SKEW|), ensuring that higher values consistently represented greater resilience. Since the indicators also differed in scale and variance, Z-score standardization was applied (mean = 0; SD = 1) to allow direct comparability. Two indices were then constructed: (i) a simple index (I_RES), calculated as the arithmetic mean of the standardized GEBVs, and (ii) the optimal Hazel index (I_H), derived from $b = P^{-1}a$, where P is the phenotypic (co)variance matrix and a is a vector of equal economic weights. The resulting optimal weights were applied to the standardized GEBVs. The indices were evaluated in three analytical blocks. First, I_RES was assessed through correlations with individual indicators, expected genetic gain (ΔG), and Top 10% male ranking. Second, I_H was evaluated through analysis of optimal weights, ΔG, accuracy, Top 10% ranking, and sensitivity tests removing one indicator at a time. Third, both indices were compared through correlation between indices, Top 10% overlap, ΔG differences, and relative contribution of each indicator. Under equal weighting, SKEW showed the highest correlation with I_RES (0.69), followed by LNVAR (0.65) and RAUTO (0.58), indicating greater relative influence of SKEW on the final score. The expected genetic gain (ΔG) reflected this correlation pattern, with stronger responses associated with indicators more closely related to the index, and the Top 10% ranking defined animals superior under equal-weight selection. When applying Hazel's methodology, the (co)variance structure redistributed the relative importance of indicators, with SKEW showing the highest correlation with I_H (0.70), followed by RAUTO (0.65), while LNVAR presented the lowest contribution (0.56). This reweighting was reflected in ΔG, where RAUTO presented the highest isolated genetic gain (0.58) under I_H. The accuracy of I_H reached 0.80, and sensitivity analyses demonstrated structural robustness, maintaining correlations above 0.85 even after removing any single indicator. The Top 10% ranking under I_H identified animals selected according to optimal weighting. Finally, comparison between indices revealed a high overall correlation (r = 0.99), indicating similar ranking hierarchy; however, Top 10% overlap between I_H and selection based on each indicator individually ranged from 26.5% to 42.6%, indicating that single-trait selection would not identify genetically balanced individuals, and differences in ΔG patterns demonstrated that Hazel's weighting modifies the expected selection response by redistributing emphasis among resilience components. Overall, the proposed multivariate index proved robust and reliable for genomic selection, with the optimal Hazel index improving the distribution of genetic emphasis among resilience components and promoting more balanced genetic progress.

Genomic Insights into Genotype × Feed Interactions for Feeding Behaviour, Efficiency and Carcass Traits in Different Pig Breeds

M. F. Bellersen[1], E. Jonas[2,3], I. Brinke[2], A. Kiefer[2], E. Tholen[2], C. Große-Brinkhaus[1]
[1] University of Göttingen, Animal Breeding and Genetics, Albrecht-Thear-Weg 3, 37075 Göttingen, Germany, [2] University of Bonn, Institute for Animal Science, Endenicher Allee 15, 53115 Bonn, Germany, [3] Association for Bioeconomoy Research (FBF e.V.), Adenauer Allee 174, 53113 Bonn, Germany

Due to environmental pollution and the excretion of unused feed nutrients, feed efficiency in pig production is a highly important topic. Current research topics focus especially on nitrogen (N) and phosphorus (P). However, the pigs' feed efficiency is influenced by numerous intrinsic and extrinsic factors. On the one hand, the nutrient composition of the feed can be adjusted, and on the other hand, the animal's genotype also contributes to this variation. The interaction between these different factors can lead to genotype×feed interactions (G×E). The aim of this study was to assess the influence of breed-specific genomic characteristics on pigs' responses to different feeding regimes. Therefore, two feeding trials were conducted to evaluate the effects of a N/P-reduced feeding strategy on feeding behaviour, feed efficiency and carcass composition traits. Two feeding groups were evaluated, where one group received a control (CON), and the other group a N/P-reduced feed (RED). In total, 1,052 pure bred landrace boars (PB) and 796 crossbreed Piétrain×F1 pigs (CB) (393 males and 403 females) were evaluated. Phenotypes were recorded in the performance test stations of the BHZP GmbH for PB and of the Landesanstalt Schwarzenau for the CB. Six feeding behaviour, six efficiency and ten carcass traits were examined for PB, and six efficiency and seven carcass traits for CB. Genomic DNA was isolated from skin or muscle tissue samples collected routinely after slaughter. All pigs in the study were genotyped using the Porcine 70k ggp porcine Illumina© HD array. Quality control (QC) was performed using PLINK, accounting for a call rate > 0.95 and a minor allele frequency < 0.05. SNPs were annotated on the Pig Sscrofa 11.1, and a Genome-Wide Association Study (GWAS) was performed using the R-package rrBLUP. After QC, 55,378 SNPs for PB and 68,816 SNPs for CB remained in the analyses. First, these data were analysed by considering the feeding group as a fixed effect in the model. This was followed by an analysis within each feeding group, where the data were divided by feeding group. To account for multiple testing, p-value adjustments were performed with Bonferroni correction and the false discovery rate control. A total of 265 and 235 significant SNPs across 12 chromosomes were identified for PB and CB, respectively. For feeding behaviour, 15 significant SNPs were identified. For efficiency traits 42 and 33, and for carcass traits 208 and 202, significant SNPs were identified in PB and CB, respectively. Indeed, the majority of these numbers in CB are for the trait drip loss (125 SNPs). For the within-feeding-group analyses of feeding behaviour, PB animals showed 15 SNPs in both, CON and RED, and all of these were identical. Similar observations were made for feed efficiency in PB, where the CON revealed 29 SNPs, as well as for the RED. In CB animals, the CON revealed a much higher number of significant SNPs (51), whereas the RED showed only 5 significant SNPs associated with feed efficiency traits. In the evaluation of carcass traits, 128 and 46 significant SNPs in CON and 23 and 51 significant SNPs in RED were identified for PB and CB animals, respectively. The next step is to investigate the identified regions for candidate genes and functionally relevant variants.

Deep phenotypes of growing Charolais cattle divergent in residual feed intake fed two contrasting diets

H. Nguyen-Ba[1], A. Van Der Linden[2]
[1] Université Clermont Auvergne, INRAE, VetAgro Sup, UMR 1213 Herbivores, Route de Theix, 63122 Saint-Genès-Champanelle, France, [2] Animal Production Systems group, Wageningen University & Research, PO Box 338, 6700 AH Wageningen, Netherlands

Improving feed efficiency (FE) is a major goal to preserve resources and reduce environmental impacts of animal production. Residual feed intake (RFI) is a promising genetic selection metric due to its low correlation with performance indicators, with lower-RFI animals being more efficient. However, RFI classification is poorly reproducible when a high-starch (HS) diet is replaced by a high-fiber (HF) diet, indicating a genotype × environment (G×E) interaction. Deep phenotypes of FE, representing inner meta-mechanisms, may relate more closely to genotype than RFI but remain unexplored in beef cattle. This study estimated deep phenotypes of low- and high-RFI Charolais bulls fed HS or HF diets and assessed G×E interactions. Deep phenotypes were estimated using the mechanistic, dynamic model LiGAPS-Beef, a genetic algorithm, and measured phenotypes. LiGAPS-Beef simulated bulls with a daily timestep based on animal genotype, climate and available feed quality and quantity. Data from an in vivo trial with low-RFI (n =16) and high-RFI Charolais bulls (n = 16) fed HS or HF diets were used to calibrate the model. Four measured phenotypes (body protein and lipid content at d0, d84, and d200, daily DMI and fortnightly LW recordings), were compared to simulated phenotypes of individual bulls. Using the genetic algorithm (R package GA), differences between simulated and measured phenotypes were minimized by adjusting 7 deep phenotype values via relative root mean squared errors (rRMSE). Traits adjusted were net energy for maintenance (NEm), Gompertz curve slope (DPAR), maximum feed intake capacity (PHFEEDCAP), efficiency of protein and lipid accretion (PROTEFF and LIPIDEFF), maximum carcass fraction (CFRMAX), and maximum total body weight (TBWMAX). ANOVA tests compared these traits between the two RFI groups and diets. Pearson correlations (r) were used to explore their relationships with measured FE, RFI, and 285 muscle metabolites quantified at slaughter by mass spectrometry (MxP Quant 500 Assay, Biocrates). After minimization, rRMSE across the four phenotypes was 43%, corresponding to an average of 10.6% per phenotype, indicating measured and simulated values were relatively close. Average values of deep phenotypes were 258.1 ± 13.3 kJ NE $kg^{-0.75}$ d^{-1} for NEm, 0.84 ± 0.08 for DPAR, 120.2 ± 3.5 g DM $kg^{-0.75}$ d^{-1} for PHFEEDCAP, 0.63 ± 0.14 for PROTEFF, 0.59 ± 0.12 for LIPIDEFF, 0.46 ± 0.02 for CFRMAX and 1303 ± 74 kg for TBWMAX. All the deep phenotypes were positively ($r > 0.5$) or negatively ($r < 0.5$) correlated ($p < 0.05$) with measured FE during the RFI classification test (d0 to d84), except for PROTEFF ($p = 0.4$). No significant correlations were observed between measured RFI and the deep phenotypes. Consistently, deep phenotypes did not differ significantly between the two RFI groups. In contrast, diet had a strong effect on deep phenotypes, as all estimated values differed significantly ($p < 0.001$) between the HS and HF diets. All of the deep phenotypes were significantly correlated with numerous muscle metabolites, notably those of lipid metabolism such as Phosphatidylcholines and Lysophosphatidylcholines ($r > 0.6$ or $r < -0.6$, $p < 0.001$). In conclusion, although diet effects were still strongly reflected in the seven estimated deep phenotypes, these traits showed strong associations with FE and metabolical indicators. This highlights the potential for further exploration of deep phenotypes in breeding programs aimed at improving FE. Future research is required to link individual deep phenotypes to the animals' metabolic pathways.

Environmental and Spatial Drivers of Genetic Variation in the Rubia Galega Cattle

N. Mejuto-Vázquez[1,2], R. Rodríguez-Bermúdez[1], P. Martínez[2], M. Hermida[2]
[1] Universidade de Santiago de Compostela, Anatomía, Produción Animal e Ciencias Clínicas Veterinarias, Av. Carvalho Calero, s/n, 27002 Lugo, Spain, [2] Universidade de Santiago de Compostela, Zooloxía, Xenética e Antropoloxía Física, Av. Carvalho Calero, s/n, 27002 Lugo, Spain

Understanding the relationship between genetic variation and environmental heterogeneity is essential for interpreting population structure and informing breeding strategies in livestock. This study investigated whether spatial and environmental factors contribute to the genetic structuring of the Rubia Galega (RG) cattle breed, a native beef population from northwestern Spain that has undergone recent reproductive intensification. We hypothesized that, despite the overall weak genetic structure previously reported for the breed, geographic distance and environmental gradients could still explain subtle patterns of genetic differentiation.Genomic data from 5,275 RG cattle genotyped with a medium-density SNP array (46,280 markers after quality control) were analysed. To evaluate isolation by distance, pairwise genetic differentiation among municipalities was calculated using FST estimates, and geographic distances were obtained from municipal coordinates using the Haversine formula. The relationship between both matrices was assessed through Mantel tests with 1,000 permutations and bootstrap confidence intervals. Sensitivity analyses were performed by excluding municipalities located outside Galicia and by restricting the dataset to animals likely derived from natural mating in order to reduce the potential influence of artificial insemination. In addition, redundancy analysis (RDA) implemented in the VEGAN R package was used to explore the association between allele frequencies and environmental variables, including altitude and temperature-related metrics, together with spatial coordinates. Multicollinearity among predictors was assessed using variance inflation factors, and model selection was conducted through a backward permutation-based procedure.Mantel tests revealed a weak but significant positive correlation between genetic and geographic distances ($r = 0.225$; $p < 0.01$), indicating a moderate pattern of isolation by distance. When municipalities outside Galicia were excluded, the correlation decreased but remained significant, suggesting that part of the signal is influenced by the most distant populations. Analyses restricted to animals likely derived from natural mating produced comparable correlation values despite a substantial reduction in sample size, supporting the robustness of the spatial signal. The RDA model identified mean temperature, minimum temperature, and latitude as significant predictors of genetic variation; however, the proportion of explained variance was small (adjusted $R^2 = 0.015$), indicating a limited influence of environmental gradients on population structure.Overall, these results suggest that the genetic structure of RG cattle is extremely weak but not entirely absent. Subtle spatial patterns are detectable and likely reflect a combination of demographic processes, gene flow, and management practices rather than strong local adaptation. The findings highlight the importance of integrating spatial and multivariateapproaches when interpreting genomic data in livestock populations with high connectivity, and provide useful insights for refining breeding and conservation strategies in the breed.

Effect of temperature and humidity index on the performance of hyperprolific sows at first service

L. Espinoza-Aguirre[1], J. Romo-Rubio[1], J. Romo-Valdez[1], J. Portillo-Loera[1], A. Romo-Valdez[1], U. López-Arroyo[1], J. Uriarte[1]

[1] Universidad Autonoma de Sinaloa, Facultad de Medicina Veterinaria y Zootecnia, Boulevard San Ángel 3880, 80246 Culiacan, Mexico

To determine the influence of temperature and humidity index (THI) on the performance of hyperprolific sows at first service, reared in a warm environment, a prospective comparative observational study was conducted in northwestern Mexico. Four hundred ninety-seven first-time sows from the the PIC Camborough® line preselected as future breeders from the moment of birth were used. The sows were classified into three temperature and humidity index (THI) groups, ranging from 84 to 148 d and from 149 to 268 d of age (≤74, >74 <78 and ≥78 <84). ANOVA was applied to the performance data ($p \leq 0.05$). In gilts that were in an THI ≥74 between 84 and 148 d of age, an older age at puberty (235 vs. 215 d; $p = 0.001$) and at service (268 vs. 238 d; $p = 0.001$) was observed compared to those that were in an THI ≤74; similarly, in sows in an THI ≥74 between 149 and 268 d of age, the age at puberty (239 vs. 220 d; $p = 0.008$) and the age at service (268 vs. 247 d; $p = 0.001$) increased. The observed results allow us to conclude that a THI ≥74 delays the age at puberty and at service in gilts. This variable should be considered in a selection and management program for hyperprolific first-time sows, raised in warm environments, with the aim of increasing the percentage of first-time sows served at an age less than 240 d. Keywords: Gilt, growth rate, THI, puberty, age at service.

Estimation of genetic parameters for egg weight across the laying cycle in hens

M. Sanchez-Diaz[1], N. Ibañez-Escriche[2], L. Varona[1], D. López-Carbonell[1], D. Cavero[3], C. Casto-Rebollo[4]
[1] Facultad de Veterinaria, Universidad de Zargoza, Miguel Servet 177º, 50013 Zaragoza, Spain, [2] Institut de Ciència, Universitat Politècnica de Valencia i Tecnologia Animal,, Camí de Vera S/N, 46022 Valencia, Spain, [3] H&N International GmbH, Am Seedeich 9, 27472 Cuxhaven, Germany, [4] Lohmann Breeders GmbH, Am Seedeich 9, 27472 Cuxhaven, Germany

Egg weight is a key trait in modern laying hen breeding programs, especially under extended production systems that reach up to 90 or 100 weeks of age. Maintaining a stable egg weight throughout the laying cycle is essential for market value, production efficiency, and egg quality. The objective of this study was to estimate heritability and genetic correlations for egg weight at different stages of the laying cycle in purebred and crossbred commercial populations, using a multi trait approach. Data were obtained from two pure lines and their reciprocal crossbred populations. Egg weight was recorded at 28, 40, 70, and 90 weeks of age. Purebred hens were housed individually under nucleus conditions, while crossbred hens were kept in commercial environments and recorded as cage means. All the hens from one cage share the same sire. Egg weight at each age and in each genetic type was considered a different trait, resulting in eight traits analyzed simultaneously using a sire multi trait model. Variance components were estimated with a Bayesian approach based on Gibbs sampling. Descriptive results showed that egg weight increased with age in all lines. Line B consistently produced heavier eggs than Line A. Crossbred hens produced heavier eggs than purebred hens at all ages, reflecting heterosis and genetic complementarity. Differences between reciprocal crosses suggested the presence of maternal and non additive genetic effects. Between 70 and 90 weeks, egg weight tended to stabilize in the pure lines, which agrees with current breeding goals aimed at avoiding excessive egg size at the end of the cycle. Heritability estimates in purebred lines were high across all ages, ranging from 0.57 to 0.87, indicating strong genetic control of egg weight, even at late stages of production. In crossbred populations, heritability was lower than in purebreds, ranging from 0.42 to 0.71. Across populations, the heritability estimates were relatively high. These elevated values may be partly explained by the structure of the sire model and the group housing of crossbred hens (75% full sisters), where common environmental and non-additive effects could have inflated the sire variance and, consequently, the additive genetic variance. Genetic correlations between adjacent ages were high and decreased as the time interval increased, this pattern may indicate some changes in gene expression over the laying cycle. Genetic correlations between purebred and crossbred performance were moderate to high for most ages, indicating that selection in pure lines can effectively improve egg weight in commercial crossbreds. However, correlations were lower at 90 weeks, possibly due to environmental differences and increased biological stress in extended production. In conclusion, egg weight shows substantial genetic variation throughout the laying cycle, including late production stages. These results support the use of multi trait genetic evaluations and the integration of purebred and crossbred information to improve long term egg production efficiency.

(Epi)genomic regulation of phenotype diversity and plasticity in cattle

V. Baddela[1], J. Vanselow[1], G. Moreira[2,3], C. Charlier[3], D. Becker[1], G. Plastow[4], C. Klein[5], C. Kühn[1,6,7]
[1] Research Institute for Farm Animal Biology, Wilhelm-Stahl-Allee2, 18196 Dummerstorf, Germany, [2] Université Paris-Saclay, , 78350 Jouy-en-Josas, France, [3] University of Liège, Avenue de l'Hôpital 11, 4000 Liège, Belgium, [4] University of Alberta, , T6G 2H1 Edmonton, Canada, [5] Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Höltystraße 10, 31535 Neustadt, Germany, [6] Friedrich-Loeffler-Institut, Südufer 10, 17493 Greifswald-Insel Riems, Germany, [7] University Rostock, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany

Cattle husbandry in Europe increasingly moves forward to new farming systems due to animal welfare demands like outdoor contact and changes in landscape use (e.g. grassland). However, this development comes with environmental challenges e.g. heat stress or novel or recurring pathogen exposure in addition to or on top of already existing intrinsic factors like e.g. metabolic imbalances in high-yielding dairy cows. This generates needs for adaptation at the population (via selection) and individual level (via epigenetic modulation on top of an individuals' genetic makeup). Understanding the molecular level of genetic and epigenetic regulation will help evaluating (patho)physiological response mechanisms to biotic and abiotic noxes and indicate potential mitigation options. Main current extrinsic and intrinsic challenges in cattle comprise management stress, infectious pathogens and early lactation energy deficit of dairy cows. Tissue-, ontogenetic-stage and breed-specific distribution of regulatory regions within the genome are the precondition for phenotypic variation and tailored response pattern to such challenges. Thus, respective comprehensive inventories of the bovine genome for core physiological tissues were established within many global and international projects. Particularly within the Functional Annotation of Animal Genomes (FAANG)-associated global and European consortia maps of epigenetic marks for open chromatin and methylation sensitive pattern were assembled. Results demonstrated a match between e.g. metabolic tissue activity and methylation level when lactating mammary gland exhibited the lowest and subcutaneous tissue of male adults the highest whole-genome methylation level. Bovine embryos at 7-8 days of age revealed differences at the transcript as well as methylation level either associated with direct mimicking effects of subclinical maternal ketosis or with effects of heat stress on sperm used for in-vitro embryo production. Interestingly, subsequent heat stress models provide tentative indication for long-term transgenerational effects arising during spermatogenesis. Epigenomic marks during ontogenesis or in early life bear the potential for prediction of phenotype to assist selection or induce countermeasures to ameliorate negative environmental effects. Particularly long-term acquired epigenomic marks provide opportunities for objectively monitoring exposure to adverse extrinsic or intrinsic factors and might provide e.g. summarizing readouts for animal wellbeing and animal welfare potential.

Exploring blood methylome differences in dairy cow breeds under feed restriction

G. Costa Monteiro Moreira[1,4], J. A.a. Pires[2], V. Costes[3], F. Ali[1,4], H. Jammes[1,4], H. Kiefer[1,4]
[1] Université Paris Saclay, UVSQ, INRAE, BREED, 78350 Jouy-en-Josas, France, [2] Université Clermont Auvergne, INRAE, VetAgro Sup, UMRH, 63122 Saint-Genès-Champanelle, France, [3] ELIANCE, LPA Epsilon, 75015 Paris, France, [4] Ecole Nationale Vétérinaire d'Alfort, BREED, 94700 Maisons-Alfort, France

Understanding DNA methylation changes induced by nutritional stress is essential to decipher the epigenetic mechanisms underlying adaptive capacity and resilience to metabolic challenges in dairy cows. Here, we investigated the impact of short-term feed restriction (FR) on whole blood DNA methylation profiles in Holstein (HOLS, n = 18) and Montbéliarde (MONT, n = 18) multiparous cows. As part of the GenTORE project (Pires et al., 2025; PMID:39521419), cows underwent a nutritional challenge consisting of a sequence of four 4-day feed restriction periods, during which feed allowance was restricted to 50% of individual NEL requirements calculated before the challenge. The first FR was initiated at 87 ± 9 DIM. Whole blood samples collected before (d0) and after (d4) this first FR wave were used to profile DNA methylation using the RUMIGEN EpiChip targeting 44,053 CpG sites. Cell-type proportions were estimated using a deconvolution approach based on an in-house reference dataset. CpGs with a standard deviation < 0.01 or > 20% missing values were removed, and B-values were converted to M-values. Differential methylation analysis was conducted using a Breed × Time linear model implemented in limma, including the combined Breed x Time factor and estimated cell-type proportions as covariates. Repeated measures (paired d0–d4 samples) were accounted for by estimating within-animal correlation and fitting cow as a blocking factor. Technical/batch effects were evaluated and included in the model when they varied within animal. The following contrasts were tested: (i) FR effect within MONT (d4 vs d0); (ii) FR effect within HOLS (d4 vs d0); (iii) breed differences at d0; (iv) breed differences at d4; and (v) the breed × FR interaction. P-values were adjusted for multiple testing using the Benjamini–Hochberg procedure (FDR < 5%). Deconvolution analysis indicated that short-term FR significantly altered lymphocyte and neutrophil proportions ($p < 0.05$) in both breeds, reflecting immune responsiveness to nutritional stress and supporting their inclusion as covariates in the differential analysis. For the FR effect within MONT and HOLS breeds, no differential methylation sites (DMCs) were detected, indicating no short-term DNA methylation changes in response to FR in either breed. In contrast, 2,185 and 1,292 DMCs were detected between breeds at d0 and d4, respectively, with 904 DMCs consistently observed across both time points, highlighting breed-specific epigenetic differences. Interestingly, these 904 DMCs target 185 genes, encompassing genes associated with immune system regulation (e.g., ARG2, ZBTB1, F2RL1, ARG2, RNASE6). Overall, these results indicate that short-term FR has limited effect in blood methylome but reveal baseline epigenetic divergence between HOLS and MONT breeds. These breed-specific signatures may contribute to differences in metabolic adaptation and resilience, warranting further investigation under prolonged or repeated nutritional challenges, and in response to the transition from late gestation to early lactation.

Environmental modulation of blood DNA methylation in Jersey cattle with shared genetic background

G. Sahana[1], V. Costes[2], E. Karaman[1], R. B. Stephensen[1], C. Patry[3], M. S. Lund[1], H. Kiefer[4], Z. Cai[1]
[1] Aarhus University, Center for Quantitative Genetics and Genomics, C.F. Møllers Alle 3, 8000 Aarhus, Denmark, [2] Eliance, 149 Rue de Bercy, 75012 Paris, France, [3] Valogene, 149 Rue de Bercy, 75012 Paris, France, [4] Université Paris-Saclay, UVSQ, INRAE, BREED, 78350 Jouy-en-Josas, France

Understanding how environmental conditions shape the bovine epigenome is essential for advancing precision breeding and management strategies. We investigated genetic and environmental contributions to DNA methylation in Jersey cattle using a half-sib design. Blood samples were collected from 440 cows, daughters of 23 Danish Jersey bulls, raised in two contrasting production environments: Denmark (DK; n = 223) and South Africa (SA; n = 217). In addition, semen samples from 18 Danish Jersey bulls were included for typing for methylation. Genomic DNA was extracted from blood or ear clip samples and genotyped using the Eurogenomics SNP array. Only autosomal SNPs were considered for downstream analyses. Quality control was performed using PLINK v1.9, where individuals and SNPs with low call rates were excluded (–mind 0.10, –geno 0.10). SNPs with a minor allele frequency (MAF) below 1% were removed. Sporadically missing genotypes were imputed using Beagle v5.5. After quality control, the final genotype dataset consisted of 45,180 SNPs. For population structure analysis, linkage disequilibrium pruning was applied using PLINK (–indep-pairwise 50 5 0.2), resulting in 4,881 SNPs used for principal component analysis (PCA). DNA extracted from whole blood and semen samples was epigenotyped using the RUMIGEN EpiChip. Methylation data were obtained for 44,053 epigenetic markers. Probes showing zero variance across samples were removed, leaving 42,823 probes for further analysis. Missing methylation values were imputed using the per-probe mean and were used for downstream analyses. Differences in methylation levels between DK and SA cows were tested for each probe using a t-test. Genotype-based principal component analysis (PCA) showed no population stratification between DK and SA cows, with daughters clustering by sire, confirming a shared genetic background. In contrast, PCA of blood DNA methylation profiles revealed a moderate separation between DK and SA cows, and clustering by sire was absent. Overall methylation levels were higher in Danish cows, with a greater representation of both hypo- and hypermethylated CpG sites. The top 25 CpGs significantly different in DK and SA cows showed higher average methylation levels in cows from DK compared to cows from SA Africa. Although we observed a moderate country-specific separation in PCA, clustering based on the top 100 differentially methylated CpGs did not result in a clear separation of cows by country. These results demonstrate that bovine blood DNA methylation from highly similar genetic backgrounds is strongly modulated by environmental conditions, highlighting the epigenome as a sensitive interface between genotype and environment. Ongoing work will explore associations between methylation variation and phenotypic traits in Danish Jersey cows. Overall, the study supports the integration of epigenomic information into dairy cattle breeding programs to improve biological understanding of complex traits and to advance precision breeding and management strategies.

Intergenerational and transgenerational match/mismatching effects of ancestor calving months on lactation curves in Simmental cattle

N. P. P. Macciotta[1], L. Degano[2], D. Vicario[2], C. Dimauro[1], A. Cesarani[1,3]
[1] University of Sassari, Dipartimento di Agraria, Viale Italia 39a, 07100 Sassari, Italy, [2] ANAPRI, Via Ippolito Nievo 19, 33100 Udine, Italy, [3] University of Georgia, Department of Animal and Dairy Science, 425 River Road, 30602 Athens, United States

The impacts of climate change are becoming an increasing concern for the livestock sector, even in temperate areas. Inter and transgenerational studies in dairy cattle shown that the calving season of female ancestors—used as an indicator of the environmental conditions experienced during pregnancy—can influence the performance of their female descendants. In particular, negative effects of heat stress experienced during pregnancy on offspring performances have been observed. A possible explanation of these results is the occurrence of epigenetic inheritance. According to the match/mismatch theory suggested for interpreting epigenetic programming effects, matched ancestor pregnancy/offspring production environmental conditions may result in offspring advantages compared to mismatched ones. Aim of this work was to investigate the effect of matched/mismatched environmental conditions on milk yield of Italian Simmental cattle breed. A total of 1,119,392 Test Day (TD) records of 125,252 lactations of 59,182 Simmental cattle were analyzed. For each cow, data from the great granddam (GGD) were available. Data were analyzed with a linear model that included parity, combination between GGD and cow calving seasons (SEA_combination), and the interaction between days in milk class and SEA_combination as fixed effects and animal and herd-test date combination as random effects, respectively. The SEA_combination factor was included in the model for accounting for match/mismatch conditions. SEA_combinations affected significantly TD milk yield ($P<0.001$). The lowest least squares means of TD records were observed when GGD calved in autumn or winter (i.e., the best condition) and the cow calved in summer (i.e., the worst condition). On the contrary, largest TD means were obtained for GDD calving in summer and autumn (best condition) and cow calving in summer (worst condition). Results of the present study confirm the importance of the combination between calving and production season of the cow together with calving season of the ancestors in affecting production performances.

Impact of late gestation heat stress on progeny's health in dairy cows

E. Vanbergue[1], G. Costa Monteiro Moreira[3], L. Brun-Lafleur[1], D. Plouzin[2], B. Vaillant[2], V. David[1], M. Brochard[1]
[1] French Livestock Institute, 149 rue de Bercy, 75012 Paris, France, [2] Ferme expérimentale Trinottières, La futaie, 49140 Montreuil sur le Loir, France, [3] INRAE, Rue Manufacture, 78350 Jouy en Josas, France

Heat stress (HS) experienced by gestational dairy cows has been shown to impact on their offspring, particularly on both passive and developing immune competence of the calves. We evaluated the impact of a vaccine challenge on the immune response of in utero HS heifers. The objective of the study was to describe the immune response of heifers exposed to acute (experiment 1) and chronic (experiment 2) HS in utero, in relation to their dams' strategies to cope with HS, and to investigate epigenetic signatures associated with these responses (experiment 3). In experiment 1, 24 Holstein dairy cows and their progeny were monitored, and in experiment 2, 12 dams/heifer couples were monitored. In experiment 3, all dams/heifer couples were monitored to investigate the impact of HS challenge on the epigenomic profile of blood-derived immune cells. To classify the dams according to their adaptation strategies to cope with HS, a Hierarchical Classification on Principal Components (HCPC) was performed on dams centered indicators : ruminal temperature, activities (ruminating, eating, resting and panting behavior), milk production, milk fat content, milk protein content, serum cortisol, serum non esterified fatty acids, serum thyroxin, calves 'weight and serum immunoglobulin of calves. In experiment 1, algorithm discriminated five clusters based on cows' adaptation to HS and in experiment 2, two clusters were discriminated. To classify the heifers according to their response to the immune challenge, a HCPC was performed on cytokines IL1-β, IL-6, IL-8 and IL-10 longitudinal response, specific antibodies for BPI3, BRSV, and Mannheimia haemolytica before vaccination and after vaccination, and specific antibodies for AdenoV and Mycoplasma bovis along with health-related variables and growth variables . In experiment 1, the HCPC revealed four subgroups with distinct cytokines and antibodies patterns and growth outcomes. In experiment 2, the HCPC revealed 2 different subgroups. In experiment 3, DNA methylation was profiled using the RUMIGEN EpiChip to estimate the proportions of three major immune cell types (lymphocytes, monocytes and neutrophils) before and after the vaccination challenge, and to identify potential epigenetic biomarkers. A contingency table between dams' clusters and heifers' clusters did not show any link between the two. Neither did the description of maternal clusters with the heifer's specific variables. However, a significant (pvalue<5%) difference in the proportion of lymphocytes was detected before and after vaccination in heifers born from the more affected cows, whereas this pattern was not observed in heifers born from the less affected cows. Although limited, differential methylation analysis comparing the methylome profiles of heifers born from more affected cows before and after the vaccination challenge revealed four CpGs co-localized with a candidate gene related to immune system function. Our work has highlighted that animal responses to the vaccine challenge varied, but these do not seem to depend on how their dams coped with HS during late gestation. Nevertheless, epigenomic analyses suggest that prenatal HS exposure may modulate immune cell dynamics during later-life immune challenges. Immune responses depend on several factors, both innate and environmental, among which the intergenerational impact of HS appears to have little influence in our region.This project has received funding from the European Union's Horizon 2020 programme for research and innovation under grant agreement no. 101000226.

Epigenome-wide association of DNA methylation with phenotypic traits and environment in French Holstein cows

A. Asset[1], V. Costes[1,3], G. Potier[2], M. P. Sanchez[4], F. Besnard[3,4], C. Fouere[3,4], S. Fritz[3,4], C. Patry[3], G. Foucras[6], H. Jammes[1], C. Richard[2], V. Gelin[2], L. Le Berre[3], A. To date, large-scale epigenome-wide association studies (EWAS) in livestock remain scarce due to the lack of high-throughput method to obtain DNA methylation data. In this work, we harnessed the RUMIGEN EpiChip, a cattle-specific DNA methylation array, to investigate whether variation in blood DNA methylation is associated with agronomic performance and reflects exposure to different conditions in dairy cows. An EWAS was conducted in 4,608 French Holstein cows from 261 herds. Blood DNA methylation was quantified at 44,053 CpG sites using the RUMIGEN EpiChip; 38,859 probes were retained after quality control. Thirty-three traits were analysed as yield deviations from the national genetic evaluation system, including milk production and composition, fertility, udder health and morphology. Environmental variables were available for 2,945 cows and comprised grazing duration, ration type, dry-off management and herd target age at first calving. Associations between CpG methylation (M-values) and traits were tested using linear models including technical effects, estimated leukocyte proportions, age and the first five genomic principal components to account for population structure. Multiple testing was controlled using Bonferroni correction (adjusted pvalue < 0.05). Significant associations were predominantly detected for milk traits: 72, 61, 52, 35 and 34 CpGs were associated with fat content, protein yield, milk yield, fat yield and protein content, respectively. Fertility traits showed fewer signals (32 CpGs for heifer conception rate and ≤ 2 for other traits), while most morphological traits displayed limited associations. In contrast, environmental factors were associated with a substantially larger number of CpGs: grazing duration (1,121 CpGs), ration type (690), target age at first calving (465) and dry-off management (61). Associated CpGs were distributed across multiple chromosomes, suggesting widespread epigenomic responsiveness to management practices. Overall, our results demonstrate that blood DNA methylation is linked to both production performance and farming conditions in dairy cattle. The stronger signals observed for environmental variables support the sensitivity of the bovine methylome to management-related exposures. Although causality cannot be inferred, DNA methylation may represent an intermediate regulatory layer connecting genotype, environment and phenotype.

Seasonal investigation of circulating microRNAs in two Sicilian cattle breeds to evaluate the response to heat stress

S. Tumino[1,2], A. Antoci[1], M. Carlentini[1], G. Chessari[1], A. Criscione[1], S. Bordonaro[1,2], D. Marletta[1,2]

Global warming and the more complex phenomenon of climate change represent the most relevant and topical emergencies worldwide. Projections suggest that Europe will warm significantly in the coming decades, especially in Mediterranean regions, which are already experiencing the impacts of global warming. Livestock systems are often considered among the main drivers of global warming and, at the same time, suffer the negative effects of climate change. In particular, hot climate and heatwaves strongly compromise the productive and reproductive capacities of dairy cows. In this context, native breeds raised in Mediterranean regions often show greater adaptability to warm climates than breeds bred in temperate environments. The response to heat stress is a complex biological process involving the activation of molecular pathways and the regulation of gene expression at the transcriptional and post-transcriptional levels. MicroRNAs (miRNAs), small endogenous non-coding RNAs, are important post-transcriptional regulators and are involved in numerous biological processes, including response to environmental stress. The objective of this study was to analyze seasonal variations in circulating miRNA profiles of two native Sicilian cattle breeds, Modicana and Cinisara, reared in extensive system, and to identify breed-specific molecular responses. A total of 36 serum samples from the two Sicilian cattle breeds, sampled during the winter and summer of 2025, were analyzed. The QIAseq miRNA library kit was used for library preparation, followed by sequencing on the Illumina NovaSeq X Plus platform in 150-bp single-end mode. Differential expression analysis was performed with DESeq2, in which miRNAs with a false discovery rate (FDR) lower than 0.05 and |log2 fold change| ≥ 1 were considered significantly differentially expressed. A total of 36 miRNAs were significantly differentially expressed between the seasons in the Modicana breed, and 9 miRNAs were detected in Cinisara. In Modicana, several miRNAs identified (including miR-29 family members, miR-145, and miR-2285) have previously been linked to heat stress responses in bovine mammary tissue and blood circulating fractions. Moreover, miR-30-P1d_5p, which was upregulated in summer in this breed, belongs to the miR-30 family, previously associated with heat stress responses in cattle serum and fibroblasts, as well as in oxidative stress and immune-related pathways. Finally, worth noting is miR-423, which is suggested to regulate chronic heat stress responses in Holstein cows, and was found to be downregulated in the summer season in Modicana. In Cinisara, miR-155, a key regulator of immune and inflammatory processes, shows downregulation in summer. Three miRNAs (miR-335-5p, miR-193-P1a-5p and miR-3432-5p) are found in both breeds, but miR-335-5p and miR-193-P1a-5p are regulated differently in each season. The distinct circulating miRNA signatures observed between Modicana and Cinisara suggest different molecular strategies for maintaining physiological homeostasis under summer heat conditions, which could provide new insights into breed-specific adaptation to climate stress.
This study was carried out within the Agritech National Research Center and received funding from the European Union Next-GenerationEU (PIANO NAZIONALE DI RIPRESA E RESILIENZA (PNRR)–MISSIONE 4 COMPONENTE 2 INVESTIMENTO 1.4 – D.D. 1032 17/06/2022 CN00000022) as well as from the project “Gen. Al.Tec.”; Linea 1—PIAno di inCEntivi per la RIcerca di Ateneo 2024/2026.

Seasonal effects on bull sperm-borne sncRNA profile

P. Dey[1,2], V. Costes[3], A. Bonnet[3], C. Le Danvic[3], E. Sellem[1,2]
[1] Université Paris-Saclay, AP-HP, UVSQ, INRAE, BREED, Domaine de Vilvert, 78350 Jouy-en-Josas, France,

[3] Eliance, 149 Rue de Bercy, 75012 Paris, France

Investigation of seasonal variations in the small non-coding RNA (sncRNA) profile of Holstein bull sperm offers a window into their functionality, especially considering that ejaculated sperm are transcriptionally silent. As non-seasonal breeders, this may hold particular economic importance to improve breeding strategies in the dairy industry. The objective of this study was to characterize seasonal expression profiles of bull sperm-borne sncRNAs, establishing a foundational overview of their temporal dynamics. Semen samples from 21 Holstein bulls from SYNETICS (France) were collected in July, September and December and ranging between 11-24 months old in July. Total RNA was then extracted from all 63 sperm samples and subjected to UMI deep sequencing on Illumina HiSeq2000 (Qiagen, 20 M single-reads (75 bp) per sample). After quality control, reads were processed and annotated using PAQmiR, an in-house pipeline based on miRDeep2 that also enables tsRNA, rsRNA and piRNA annotation. Differential expression analysis was performed using R(DESeq2), which involves performing a likelihood ratio test to identify sequences that showed a significant (Benjamini-Hochberg, adjusted p-value <0.05) change in expression across all 3 seasonal periods. Next, hierarchical clustering was conducted to group significant sncRNAs with shared expression patterns. Gene targets for the miRNAs in each cluster were retrieved using TargetScan v8.0 to identify the significantly enriched (Benjamini-Hochberg, False Discovery Rate <0.05) KEGG pathways and biological processes. After sequencing and annotation, expressed sncRNAs comprised 36.4% of miRNAs, 30.1% of tsRNAs, 10% rsRNAs, 12.9% piRNAs and 10.6% of other sequences. Differential expression analysis revealed 2581 sequences clustered into 4 groups based on their shared expression trends. Interestingly, dominant sncRNA expression varied by cluster: miRNA (34.4%, Cluster 1), piRNA (80.1% – majority of which have a 5' 1U bias, Cluster 2), other sequences (38.6%, Cluster 3) followed closely by tsRNA (31.1%, Cluster 3), and rsRNA (36.4%, Cluster 4). miRNA targets were analysed to identify functionally enriched pathways and processes. Functional enrichment analyses show that the calcium signalling pathway and metal ion transport processes that are known to play an important role in sperm motility and capacitation were statistically enriched. By providing a comprehensive seasonal catalogue of sncRNA subtypes, this study contributes to enhance knowledge on molecular response to seasonal shifts.

Changes over time, individual variability and environmental influence on blood cell counts in healthy heifers

P. Martin[1], D. Descamps[2], A. Bachelet[3], E. A. Richard[4], R. Lefebvre[1], V. Costes[7], F. Ali[5,6], G. Costa Monteiro Moreira[5,6], H. Jammes[5,6], C. Ferret[2], S. Riffault[2], F. Blanc[1]

Calf immunity is of primary importance in cattle production because of the influence of calf health on the subsequent performances and welfare. In order to better understand this complex process and its long-term effects, a vast longitudinal experiment has started at the INRAE Le Pin research facility, aiming to monitor over 800 female calves and relate biological parameters to health, environmental, genetic, and performance data. As a first step, we investigated temporal changes, individual variability, and environmental influences on blood cell counts in the first healthy heifers. Considered animals were purebred Holstein (n=72) and Normande (n=20) females, born between February 2024 and May 2025, sampled at around 3, 14, 70 and 150 days of age and with no recorded health events. Blood cell counts was determined by using an automated hematology analyzer at the LABÉO veterinary laboratory. Levels of the different blood cell parameters were analyzed using linear mixed-effects models to determine the influence of calf's breed, year of birth, birth ease (human assistance or not), birth weight, management of the dam (heifer, indoor intensive system, grazing system) and difference between the real and the theoretical sampling days. Additionally, for a subset of blood samples, genomic DNA was extracted and used for epigenetic profiling with the RUMIGEN EpiChip. A deconvolution approach was conducted from the DNA methylation values to infer the proportion of neutrophiles, lymphocytes and monocytes present in each sample. These estimated cell counts were compared with those measured by LABÉO. First results show that leukocyte counts increased over time ($P < 0.001$), mainly driven by a sustained rise in lymphocyte populations ($P < 0.001$), while neutrophil, monocyte, and eosinophil proportions declined ($P < 0.001$). Basophil counts increased progressively ($P < 0.001$). Red blood cell indices were also strongly affected by age at sampling ($P < 0.001$), reflecting progressive erythrocyte remodeling. Birth weight significantly influenced several hematological parameters, with lighter calves displaying distinct erythrocyte and leukocyte profiles. Most significant covariate effects were observed at 3 days of age, particularly for red blood cell indices, whereas fewer associations persisted later. Breed effects were transient, mainly detectable at 3 days and reappearing selectively at 70 days, while year-of-birth effects were limited to early basophil-related differences. A large remaining variability existed that was not explained by the environmental effects, suggesting that, aligning with the literature reports, there could be a genetic influence on blood cell counts. Next step will be to integrate more immune parameters to better characterize the trajectory of healthy calves.

Diversity of Toll signalling pathway adaptors as a source for breeding for health traits in Czech Red Pied cattle

K. Novák[1], K. Samaké[2], T. Valčíková[3]
[1] Institute of Animal Science, Department of Genetics and Breeding of Farm Animals, Přátelství 815, 104 00 Prague, Czech Republic, [2] Charles University, Department of Genetics and Microbiology, Viničná 5, 128 43 Prague, Czech Republic, [3] Czech University of Life Sciences, Faculty of Agrobiology, Food and Natural Resources, Kamýcká 129, 165 06 Prague, Czech Republic

The diversity in the innate immune genes represents a source of variants that can be used for targeted breeding for health and general resilience. Consequently, the variation in the genes encoding the members of the Toll signalling pathway has been screened in the population of Czech Red Pied cattle. Although the breed is a part of the group of Simmental breeds, the differences due to the starting cattle population before the crossing in the 19th century are still indicated by mtDNA diversity. A range of adaptors that interact with the main members of the pathway represent an interest due to the presence of highly conserved regions Toll/IL-1R/R (TIR) and death domains (DD). These regions serve for the formation of complexes like myddosomes and enable the transfer of the signal downstream. Most of new mutations in these regions strongly affect the immune response and are not fixed in the population. The MYD88 gene (myeloid differentiation primary response gene 88) for the adaptor MyD88 was used as a representative of this group of adaptors. The pooled genomic DNA samples from 150 bulls of the CRP production population were sequenced using Illumina HiSeq technology. These data were complemented in the course of hybrid sequencing with the results of PacBio technology. Due to a high GC content (up to 90% locally, 69% in the proximal 500 nucleotides), and high autocomplementarity, an optimised PCR system had to be developed to obtain pooled amplicons for genotyping. Diversity found in MYD88 in frame of the CRP population was extremely low. Only 12 SNPs and 1 insertion with frequency above 0.05 were found throughout the entire gene sequence of 4457 bp on chromosome 22, where only 10 SNPs were located in mRNA.. Only one polymorphism was found in the coding sequence, albeit with a low frequency 0.036. Nevertheless, the nonsynonymous change 11648941C>T leads in this case to a substitution Ser>Phe in the product. Functional consequences can be expected due to the localization of this polymorphism in the centre of the TIR region. It is assumed that the triple interaction with TIR regions of TLR and Mal in myddosomes should prevent the persistence of the new mutation in a population. On the other hand, the presence of a polymorphism 2853C>G changing glutamine for histidine was found in the interacting TIR region of TLR2 in this population and functional complementation is not excluded. Notably, a substantially higher diversity of MYD88 was found in the conserved nucleus herd of the historical CRP cattle, namely 58 SNPs and 1 insertion causing 11 amino acid substitutions. Also a conserved population of the indigenous Czech Red cattle harboured 128 SNPs and 1 insertion leading to 44 aa substitutions. An association study based on the targeted genotyping of the 10 intragenic SNPs and additional SNPs in the adjacent regions is carried out. The main traits checked for correlation are the traits used for the calculation of breeding value index, including early reproductive disorders and calving ease, which are known to be affected by the Toll pathway. The ongoing reconstruction of haplotypes in the MYD88 gene will improve resolution of the association study. The number of published studies on bovine MYD88 is very limited to date, in contrast with the numerous described effects in model species. It is expected that the role of MYD88 polymorphism in animal health will be described in a comparative degree.

Dynamics of sheep sperm sncRNAs during maturation, from testis to ejaculated sperm

I. Bourassi[1,2], V. Costes[3], L. Jouneau[1,2], A. Frambourg[1,2], A. Chauveau[1,2], P. Chavatte-Palmer[1,2], E. Sellem[1,2]
[1] Université Paris-Saclay, UVSQ, INRAE, BREED, 78350 Jouy-en-Josas, France, [2] Ecole Nationale Vétérinaire d'Alfort, BREED, 94700 Maisons-Alfort, France, [3] Eliance, 149 Rue de Bercy, 75012 Paris, France

Ejaculated sperm contain a diverse repertoire of small non-coding RNAs (sncRNAs). These constitute a heterogeneous group of subfamilies, such as miRNAs, piRNAs, tRNA and rRNA fragments (tRFs and rRFs respectively). Their roles in fertility are not yet fully understood, although they are essential for the proper functioning of spermatogenesis. Surprisingly, spermatogenesis sncRNAs aren't fully discarded at the end of the processes and a part of the ejaculated sperm content is acquire during the epididymis journey and in interaction with seminal plasma. Several studies suggest the involvement of these sncRNAs in embryonic development via their transfer to the oocyte during fertilization, but their biological functions in this context remain to be elucidated. To study their potential roles in early embryonic development, it is therefore important to thoroughly characterize their expression dynamics along the male reproductive tract. To date, no comprehensive catalog of sperm sncRNAs based on localization has been established in sheep. This study aims to fill this gap by describing the dynamics of sheep sperm sncRNAs. Ejaculated sperm were collected from four fertile rams, as well as from the testis and the epididymis (caput, corpus and cauda). The extracted RNA was sent to Qiagen for library construction and 75-bp single-end UMI sequencing with a target depth of 20 million reads per sample. The sequences were then quantified and annotated using the PAQmiR pipeline. The results showed that the sncRNA profile undergoes significant changes from testis to ejaculated sperm: while piRNAs dominate the testis (49.0% of total expression), ejaculated sperm displays a high a miRNA-driven expression landscape (48.4%), despite only 4% of the sequence diversity. Of these, 81.3% were identified as known miRNAs primarily originating from Ovis aries (52.7%), followed by Mus musculus (14.6%) and Homo sapiens (11.64%), while 18.6% were classified as putative novel miRNAs, all of which originated from 1216 canonical miRNAs. A differential expression analysis (DESeq2) based on the source of acquisition, as well as functional analyses and a comparison with the bovine species are currently underway.

Age, genetics, laying intensity, and housing conditions affect DNA methylation of the oxytocin receptor in female chicken

C. Reimer[1], S. Weigend[1], C. Klein[1]
[1] Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Hoeltystr. 10, 31535 Mariensee, Germany

Animal welfare monitoring is rapidly becoming a critical concern, with an ongoing search for biomarkers. DNA methylation has the potential to serve as such a biomarker. Therefore, we tested the hypothesis, whether hens of genetically distinct layer lines display divergent methylation patterns at selected behavioral genes in response to housing conditions. L68 and BLA (brown layer lines, low and high laying intensity respectively) and G11 and WLA (white layer lines, low and high laying intensity respectively) were used in a cross over-design. Blood samples were collected from 2 day old chicks and at 454 ± 31 days of age (for each condition n=6 samples were collected; all female). Adult animals were raised in groups until the 16th week of age after which they were either housed in individual cages (one animal per compartment) or small groups of 10 animals with access to group nests, perches, litter, pecking blocks, and an additional sand tank for dustbathing. DNA methylation at the OXT, OXTR, POMC, ESR1, HTR1A, HTR2A, and HTR3A gene were determined using direct bisulfite-PCR sequencing. Methylation levels at individual CpG sites between young and old animals for each gene were compared using t-tests. A three-way ANOVA followed by Tukey's post hoc test was used to determine an interaction between genetics, housing condition, and laying intensity. A two-way ANOVA analysis followed by Tukey's post hoc test was used to test for interaction between genetics and laying intensity for each housing condition separately. False discovery rate (FDR) correction was implemented for each analysis. OXTR was the only gene displaying consistent differences in DNA methylation depending on age, genetics, laying intensity, and housing. The largest effect of age on methylation was evident for OXTR, with adult animals displaying significantly higher methylation than 2-day old chickens. While methylation levels for OXTR did not differ between chicks, significant differences in methylation levels were detected for OXTR when comparing samples from adult animals. Three-way ANOVA revealed a significant interaction effect of laying intensity x housing and a significant interaction effect of genetics x housing on the majority of CpG sites. For some CpG sites, a significant interaction effect of all three factors was present. A follow up two-way ANOVA examined the effects of genetics and laying intensity for each housing condition. For samples obtained from animals housed in a layer cage, except for one CpG site, no effect of laying intensity on mean methylation levels was detected, while genetics had a significant impact on the majority of CpG sites. For samples obtained from animals subjected to group housing, laying intensity and genetics had a significant effect on the majority of CpG sites. When comparing differences between group housed animals versus animals housed in an individual cage, no differences were detected for BLA (brown, high producing), while for L68 (brown, low producing) the majority of CpG sites displayed significantly higher levels of methylation for animals housed in groups, while WLA (white, high producing) presented consistently higher methylation levels in samples obtained from animals housed in an individual cage. Our findings provide evidence that genetics, in interaction with the environment, significantly influences DNA methylation of the OXTR gene. Several studies in humans have shown that OXTR methylation is sensitive to environmental cues. In particular, early-life adversity can increase methylation at specific regulatory CpG sites. Future studies will focus on validating OXTR as a biomarker for animal welfare monitoring.

The effect of ambient temperature during first 10 days after parturition of female calves on their milk production during the first lactation

V. Tančin[1,2], L. Mačuhová[1], M. Uhrinčať[1], M. Vršková[1], J. Mačuhová[3]
[1] 1National Agriculture and Food Centre, Hlohovecka 2, 95141 Lužianky, Slovakia, [2] Slovak University of Agriculture in Nitra, Tr. A. Hlinku 2, 94976 Nitra, Slovakia, [3] Institute for Agricultural Engineering, Vöttinger Str. 36, 85354 Freising, Germany

Temperature conditions are important for calves' development, health, and welfare especially during the late prenatal and early postnatal periods, under both low and high ambient temperatures. The aim of this study was to evaluate the effect of ambient temperature conditions during the first 10 days after parturition of female dairy calves on their milk production during first lactation. Selected dairy farm focuses on the intensive breeding of Holstein cows. After calving, the female calves were moved within the farm to individual hutches with small fens and fed whole milk. The daily outdoor temperatures during first 10 days after parturition were obtained from a nearby meteorological station. Based on the average temperature, the following temperature groups were created: A: bellow 0 $_{o}$C (N=82), B: 0-15 $_{o}$C (N=422), C: 15-22 $_{o}$C (N=168); and D: over 22 $_{o}$C (N=119). From farm databases, there were available data of 791 dairy cows born within year 2015-2018 for evaluation on their first lactation performance, including milk yield (kg) and fat, protein, and lactose production (kg and %) per 305 days of lactation. The effect of temperature group on milk yield and milk composition was analysed using linear models (PROC MIXED, SAS) with Tukey-adjusted least squares means; differences were considered significant at $P \leq 0.05$. Temperature group had a significant effect on milk yield ($P = 0.0026$). Milk yield differed significantly between Group B (8843±2173 kg) and Groups A (8380±1976 kg) and D (8508±2383 kg). A significant effect of temperature group was also observed on all milk component yields in kg ($P = 0.0024$, $P = 0.0015$, and $P = 0.0012$ for fat, protein, and lactose yield, resp.). For all these parameters, values differed between Groups B and D. Additionally, differences between Groups A and B were observed for protein and fat yields in kg. No significant effects ($P > 0.05$) of temperature group were found for milk composition in %. In conclusion, ambient temperatures below 0$_{o}$C and over 22$_{o}$C during first 10 days of life of female calves' can negatively influence milk production in their first lactation. Supported by "Agroecological Transition of the European Dairy Farming System" (TEDY; CUP I53C24002990006) and by grant LIFE23-IPC-SK-NatAdaptSK.

Prenatal thermal environment of calves and their milk production and composition in first lactation

L. Mačuhová[1], V. Tančin[1,2], M. Uhrinčať[1], M. Vršková[1], J. Mačuhová[3]
[1] NPPC, Department of Animal Production, Hlohovecká 2, 951 41 Lužianky, Slovakia, [2] University of Agriculture in Nitra, Tr. A. Hlinku 2, 949 76 Nitra, Slovakia, [3] Institute for Agricultural Engineering and Animal Husbandry, Vöttinger Str. 36, 85354 Freising, Slovakia

Maternal heat stress can have lifelong negative effects on offspring, including impaired immune function and reduced productive performance. The aim of this study was to evaluate the effect of the average ambient temperature during the last 30 days before calving on milk yield and milk composition during the first lactation. The study was conducted using data on milk yield (kg) and milk composition (fat, protein, total fat and protein, and lactose; expressed in kg and %, resp.) from 791 cows on a commercial Holstein dairy farm located in western part of Slovakia. The animals were divided into four temperature groups according to the average ambient temperature during the last 30 days before calving: Group 1: t < 0 °C (N = 63); Group 2: t = 0 – 14.99 °C (N = 402); Group 3: t = 15 – 21.99 °C (N = 215); and Group 4: t ≥ 22 °C (N = 111). The effects of temperature group on milk yield and composition were analysed using linear models (PROC MIXED, SAS) with Tukey-adjusted least squares means; differences were considered significant at P ≤ 0.05. Regarding milk composition (%), a statistically significant effect of temperature group was found for fat (P = 0.0146). Significant differences in fat percentage were detected only between Groups 1 and 2 and between Groups 1 and 3. For milk yield, a significant difference was observed between Groups 2 (8,791.13 ± 2,181.01 kg) and 4 (8,417.01 ± 2,384.90 kg). Regarding milk composition (kg), a significant effect of temperature group was observed for fat (P = 0.0440) and lactose (P = 0.0202). The lowest fat (376.31 ± 62.85 kg) and lactose yield (416.00 ± 72.46 kg), were recorded in Group 4, whereas the highest fat was observed in Group 1 (402.95 ± 68.85 kg), and the highest lactose (437.33 ± 62.35 kg) in Group 2. Maternal exposure to environmental heat stress during the last month of prenatal development may lead to lower milk yield and reduced fat, protein, and lactose production (kg) during the first lactation. Supported by “Agroecological Transition of the European Dairy Farming System” (TEDY; CUP I53C24002990006) and by the grant “LIFE24-IPC-SK-NatAdaptSK-101202890-2“.

Genetic correlations between clinical mastitis, metritis and ovarian cysts in Polish HF cows

P. Topolski[1], W. Jagusiak[1,2], T. Suchocki[1,3]
[1] National Research Institute of Animal Production, Department of Cattle Genetics and Breeding, Krakowska 1, 32-083 Balice, Poland, [2] University of Agriculture in Krakow, Department of Genetics, Animal Breeding and Ethology, Mickiewicza 24/28, 30-059 Krakow, Poland, [3] Wroclaw University of Environmental and Life Sciences, Department of Genetics,, Kozuchowska 7, 51-631 Wroclaw, Poland

Genetic correlations between clinical mastitis (MA), metritis (ME) and ovarian cysts (OC) in the population of Polish Holstein-Friesian (PHF) cows were estimated. The dataset for health traits was created on the basis of PLOWET database developed by the National Research Institute of Animal Production and included phenotypic data collected in 4 experimental dairy farms. Phenotypic evaluation of health traits of the cows was carried out between 2016 and 2025 and was based on veterinary registration. The dataset used in our study comprised 12,492 records of cows. Gibbs sampling algorithm implemented in the BLUPF90 package was used for the computations. The linear observation models included additive random effects of animal, fixed effects of herd-year-season of calving subclass (HYS) and lactation stage, fixed regressions on cow age at calving and fixed regressions on cow age at the time the disease was diagnosed. Cow and bull pedigrees contained two generations of ancestors i.e. parents and grandparents. Genetic correlation coefficients were ranged from 0.48±0.019 (MA vs OC) and 0.55 ±0.026 (MA vs ME) to 0.73 ±0.012 (ME vs OC). The magnitude of the obtained coefficients of genetic correlation are in the range of coefficients published in the papers of other authors and indicate the possibility of including these results in the national cattle improvement program e.g. to optimize selection indexes.

Transcriptomic analysis to identify genes involved in physiological and immune responses to heat stress challenges in Romanian Holstein lactating cattle

D. Gavojdian[1], V. M. Ber[1], A. E. Mizeranschi[2], M. Mincu-Iorga[1], I. Nicolae[1], D. E. Ilie[2]
[1] Reseach and Development Institute for Bovine, Sos. Bucuresti - Ploiesti, km 21, 077015 Balotesti, Romania, [2] Research and Development Station for Bovine Arad, Calea Bodrogului 32, 310059 Arad, Romania

Heat stress (HS) was shown to negatively impact production, reproduction and health of all livestock species, while having the largest impact on lactating dairy cattle, which are particularly susceptible as the high yields production generate increased metabolic heat loads. The aim of the current study was to investigate genes and molecular mechanisms involved in physiological responses to heat stress challenges in lactating Romanian Holstein dairy cows, throughout a transcriptomic analysis. For this reason, RNA sequencing (RNA-Seq) was performed on whole-blood samples collected from seven multiparous Romanian Holstein cows, under HS (average temperature-humidity index (THI) = 77.5) and thermoneutral (TN, average THI = 31) conditions. Across all analysed samples, RNA-Seq generated a total of 1,070,066,390 raw reads, with an average of approximately 76.4 million reads per sample. Significantly differentially expressed genes (DEGs) were annotated against public databases. Functional enrichment analysis was conducted using clusterProfiler (v4.14.6), identifying enriched Gene Ontology (GO) terms and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways associated with the thermal stress response. Significance tests were performed with the functions enrichGO and enrichKEGG, using default thresholds (0.05 for p-values and 0.2 for q-values). Gene annotations were obtained from the R package. A number of 487 DEGs were identified, of which 447 genes were downregulated and 40 genes were upregulated, during the HS exposure compared to TN episode. The consistency for the down-regulated genes associated with immune function (e.g. CD200, PAX5, BACH2, ANKRD42), metabolic health (e.g. SMAD3, PPARGC1B, NOX1, CCDC30, LCLAT1), and reproductive performance (e.g. AMHR2, ADAM20, CCDC170) underlined the interconnectedness of these biological functions. The simultaneous down-regulation of transcription factors (e.g. PAX5, BACH2) involved in central biological processes such as immune cell differentiation and function, suggests a coordinated weakening of the adaptive immune system, potentially increasing susceptibility to various infectious diseases during HS challenges. The contrasting patterns of gene expression, characterized by a predominant downregulation of genes important for reproduction-related functions and complex adaptive immune processes, alongside the upregulation of immediate protective and antiviral responses, suggests a biological prioritization of survival over reproduction and productivity. These findings provide detailed molecular insight into the physiological challenges faced by heat-stressed lactating Romanian Holstein dairy cows.

Hormonal induction enhances functional differentiation in bovine mammary organoids

E. Mussard[1], S. Belvederesi[1], C. Kjeldgaard Larsen[2], M. Ladefoged Kjelsgaard[2], L. Bach Larsen[2], N. Aagaard Poulsen[2], S. Purup[1]
[1] Aarhus University, Animal and Veterinary Sciences, Blichers Allé 20, DK-8830 Tjele, Denmark, [2] Aarhus University, Food Science, Agro Food Park 48, 8200 Aarhus N, Denmark

Bovine mammary organoids are an innovative in vitro 3D model for studying lactation biology. To accurately model the mammary gland, organoids must reproduce its cellular architecture and hormonal responsiveness. Organoids should also support the synthesis and secretion of milk components. We hypothesised that lactogenic treatment promotes functional differentiation in bovine mammary organoids leading to enhanced structural organization and upregulation of genes involved in differentiation and lactation. This study aims to investigate the lactogenic differentiation in bovine mammary organoids by comparing the effects of proliferative and differentiation culture conditions using confocal microscopy, milk-related gene expression analysis and secretome profiling. Bovine mammary epithelial organoids were generated from mammary epithelial fragments isolated from the mammary gland of non-pregnant heifers. The organoids were cultured for 20 days in MammoCult™ commercial medium, or for 10 days in MammoCult™ followed by 10 days of lactogenic differentiation. This protocol included a 4-day hormone pre-treatment with estradiol and progesterone, followed by 6 days of bovine pituitary extract (BPE) treatment. All media were supplemented with hydrocortisone at a higher concentration during lactogenic induction. Organoids were stained for confocal microscopy, and gene expression was analyzed by qPCR. Imaging using confocal microscopy showed, in both conditions, that the apical localization of the tight junction protein ZO-1 was oriented towards the lumen. The organization of the ZO-1 network was more well-defined in the organoids cultured with lactogenic treatment than in those cultured in MammoCult™. Preliminary data on gene expression analysis showed that lactogenic treatment increased progesterone and oestrogen receptor expression (PGR and ESR1, respectively), reflecting responsiveness to the hormonal treatment. The lactogenic treatment also modulated the expression of milk protein genes, including β-casein (CSN2) and κ-casein (CSN3), and led to increased lactoferrin (LTF) gene expression which is consistent with the induction of lactogenic differentiation. Taken together, the preliminary findings suggest that lactogenic treatment enhances structural organization of bovine mammary organoids and promotes the modulation of the genes involved in the lactation. Further analysis of gene regulation and expressed proteins secreted into the lumen of organoids will be performed together with comprehensive mass spectrometry-based proteomic profiling to identify milk-associated proteins. These approaches will provide a more detailed characterization, helping to establish bovine mammary organoids as a physiologically relevant model for lactation biology. This organoids model represents a promising tool for understanding mammary function and the production of cell-based milk components.

Genome-wide DNA methylation profiling in a German Black Pied Cattle trio

A. C. Schmidt[1], G. A. Brockmann[1], E. M. Strucken[1]
[1] Humboldt-Universität zu Berlin, Albrecht Daniel Thaer Institut, Invalidenstr. 42, 10115 Berlin, Germany

DNA methylation regulates gene expression, imprinting, and genome stability. Although reprogramming occurs during gametogenesis, some regions retain parental signatures. This study characterized methylation variations in a German Black Pied Cattle (DSN) trio and its overlap with known imprinted genes. Blood DNA (no cell count available) from a bull (8y), a dam (4y), and their male offspring (6w) was sequenced using PacBio HiFi long-read sequencing (Revio) for direct detection of 5-methylcytosine (5mC) without additional chemical treatment. CpG methylation was quantified at single-base resolution, and methylation levels calculated as the proportion of methylated versus total cytosine reads. Long reads (15–20 kb; Q30 >99.9%) were aligned to the bovine reference genome. Methylated cytosines were assigned to Differentially Methylated Regions (DMRs) using a Bayesian hierarchical model (DSS; Feng et al. 2014), which normalized the data for spatial correlation between sites, read depth, and biological variability. DMRs were annotated relative to promoters (±2 kb), CpG islands and shores, UTRs, exons, introns, and repeats. Genes overlapping DMRs were used for Gene Ontology (GO) enrichment analysis. The average sequencing depth across all animals was 31.92 ±2.75. After normalization, approximately twice as many DMRs were observed between sire–calf (138,034) as between dam–calf (60,214). Mean DMR length and CpGs number were 216 ±245 bp with 9.7 ±9.5 CpGs (sire–calf), and 189 ±188 bp with 10.6 ±13.1 CpGs (dam–calf). The calf generally showed lower methylation levels than both parents across regulatory elements. Promoter methylation was similar to the dam, while 5′UTRs were more methylated in the dam. Compared to the sire, the calf showed reduced methylation levels across promoters, UTRs, gene bodies, and repetitive regions. GO enrichment analysis of genes differentially methylated between sire–calf or dam–calf pairs revealed, in both comparisons, molecular functions significantly associated with binding and protein binding ($p<0.002$). Genes showing similar methylation in one parent–offspring pairing but not the other were significantly enriched ($p<0.05$) for cell morphogenesis, neuron projection guidance, negative regulation of Ras and small GTPase signaling, GTPase activator/regulator activity, synapse and junction components (dam–calf pattern); and regulatory and intracellular signaling processes, phosphatidylinositol-mediated pathways, synaptic and membrane components, cytoskeletal organization, and binding, ion-binding, and GTPase regulatory activities (sire–calf pattern). Assuming that methylation patterns unique to the dam–calf pair indicate maternal imprinting and those unique to the sire–calf pair indicate paternal imprinting, classical paternal imprints such as ATP2C2, EGFL7, THRB remained consistent in the DSN trio. Despite the expected 50% methylation of imprinted regions in somatic cells, genes maternally imprinted in humans or mice, including ANO1, CELF4, CHST8, CTNNA3, FBRSL1, FKBP6, OSBPL5, and SMOC2, appeared paternally imprinted in DSN, while CDH18 and MEAK7 showed the opposite pattern. Genes with complex imprinting conservation, such as GNAS and GRB10, were maternally imprinted in sheep, cattle, or rats but paternally in DSN. Several DMRs overlapped with QTLs for production and conformation traits in DSN, including ABCC5 and FGF12 (milk and protein yield; BTA1), SLC15A5 (fat content), CLEC4A, CD163 (birth weight; BTA5), and RORA (body weight; BTA10). While restricted by a single trio and the lack of blood cell count data, this study demonstrates the utility of long-read sequencing for bovine methylation analysis, though results require cautious interpretation.

Navigating the Promise and Pitfalls of Phytochemically Diverse Pastures for Multifunctional and Sustainable Livestock Systems

A. Serkan[1]
[1] *Oregon State University, College of Agricultural Sciences, Withycombe Hall 333, 2921 SW Campus Way Corvallis, OR 97331, United States*

Pastures are increasingly recognized as multifunctional agroecosystems, extending beyond their traditional role as sources of animal feed. Confronted by environmental degradation, input cost volatility, and societal demands for sustainable food systems, pasture-based livestock production must concurrently support productivity, ecosystem services, and environmental stewardship. This expanded mandate necessitates re-evaluating pasture design not only in terms of yield and nutritive value, but also in terms of biochemical functionality, ecological resilience, and animal health outcomes. Phytochemically diverse pastures that incorporate legumes and bioactive-rich forb species offer a promising pathway toward such multifunctionality. Plant secondary compounds, including phenolics, tannins, and terpenoids, have been associated with improved rumen function, enhanced immune responses, reduced enteric methane emissions, mitigation of nitrate leaching, and increased antioxidant capacity of animal-derived products. However, despite growing interest, significant knowledge gaps remain regarding the concentration-dependent, species-specific, and interactive effects of these compounds within complex, mixed-species swards. These complexities limit our ability to intentionally design phytochemically optimized pastures. Another challenge is sustaining botanical and phytochemical diversity in grazed systems. Selective grazing, competition, soil fertility gradients, and climatic variability often reduce forb abundance, undermining long-term sward stability. Realizing the benefits of phytochemically enriched pastures therefore requires not only biological understanding, but also adaptive and novel grazing and management strategies that maintain diversity over time. This presentation will synthesize recent research on temperate forb species rich in bioactive compounds and their effects on animal performance, health, rumen function, and greenhouse gas mitigation, while also discussing practical strategies for integrating and sustaining these species in multifunctional pasture systems. These approaches contribute to multifunctional livestock systems capable of delivering environmental, production, and socio-economic benefits in rural landscapes.

Agroecological characterization of alpine pastures from visible to invisible: linking pasture use, vegetation, soil chemistry, and microbial communities.

S. Raniolo[1,2], C. Pornaro[1], E. Basso[1], S. Da Re[1], A. Ceppatelli[1], L. Giagnoni[1], A. Squartini[1], E. Sturaro[1]
[1] University of Padova, DAFNAE, viale dell'Università 16, 35020 Legnaro, Italy, [2] University of Padova, TESAF, viale dell'Università 16, 35020 Legnaro, Italy

Alpine grasslands, classified as High Nature Value Farmland for their rich biodiversity, are vital agro-ecosystems supporting extensive livestock systems. This study investigates agroecological relationships in two alpine summer pastures in the Eastern Italian Alps: one grazed by sheep following three years of abandonment, and another historically grazed by dairy cows. During summers 2023 and 2024, we monitored grazing via GPS tracking to quantify pasture use intensity. Vegetation surveys using the Braun-Blanquet method identified multiple classes across both pastures. Topsoil samples were analysed for nitrate, ammonium, and organic carbon contents, as well as microbial communities via qPCR and sequencing. qPCR targeted nitrogen-cycle genes (nifH for fixation, amoA for nitrification, and nirK, nirS, and nosZ for denitrification) to assess functional potentials. Sequencing characterized community composition, with functional diversity inferred via FAPROTAX. In terms of pedological conditions, the nitrate:ammonium and organic carbon:nitrate ratios showed opposite trends and varied significantly across vegetation types and pasture-use intensities. These patterns were partly corroborated by distinct microbial community compositions and nitrogen/carbon-cycle functional potentials. Our findings highlight the interplay among pasture use, vegetation, and soil properties, including chemical status and microbial attributes, with key implications for nutrient cycling. This evidence supports agroecology-based strategies for sustainable management and conservation of alpine.

Integrating locally adapted legumes into multifunctional and extensive Mediterranean livestock systems

I. Poulopoulou[1], P. Kechagia[2], T. Hadjigeorgiou[1], P. Bebeli[2], I. Hadjigeorgiou[1]
[1] Agricultural University of Athens, Animal Science, Iera Odos 75, 11855 Athens, Greece, [2] Agricultural University of Athens, Crop Sciencer, Iera Odos 75, 11855 Athens, Greece

Livestock farming systems in Mediterranean regions are increasingly challenged by climatic variability, feed market volatility, and environmental constraints. Strengthening feed autonomy and diversifying locally adapted forage resources are essential strategies for enhancing the resilience and multifunctionality of extensive livestock systems. In this context, alternative legume crops may play a key role in supporting sustainable and rural livestock production. Bitter vetch (Vicia ervilia), an ancient Mediterranean legume, represents a promising protein source for low-input and extensive livestock farming. Its tolerance to drought and marginal conditions, combined with favourable nutritional characteristics, makes it particularly suitable for small ruminant systems operating under grazing-based and mixed crop–livestock contexts. The aim of this study was to evaluate the nutritional value of six indigenous populations of bitter vetch and assess their potential contribution to resilient livestock feeding strategies. The trial was conducted under Mediterranean conditions (December 2018–June 2019). Seed and straw samples were analysed for dry matter (DM), crude protein (CP), neutral detergent fibre (NDF), and acid detergent fibre (ADF) to determine their suitability for ruminant diets and their potential role in reducing reliance on imported protein feeds. Bitter vetch seeds exhibited high crude protein concentrations (17.9–23.6% DM) and relatively low fibre fractions (NDF 24–30% DM; ADF 4.2–6.0% DM), indicating strong potential as a locally produced protein source. Straw contained moderate protein levels (6.2–9.7% DM) and fibre values (NDF 56.9–63.2% DM) consistent with its use as roughage in extensive feeding systems. The combined utilisation of seeds and straw allows flexible incorporation into ruminant rations, supporting both energy and protein supply under low-input conditions typical of Mediterranean grazing systems. Beyond its direct nutritional value, the integration of bitter vetch into crop–livestock systems may enhance multifunctionality at farm and landscape levels. As a legume, it contributes to biological nitrogen fixation, improving soil fertility and supporting soil health. Crop diversification through the inclusion of locally adapted legumes can reduce dependency on external feed inputs, strengthen system resilience under drought, and support biodiversity-friendly management of agricultural land. By reinforcing feed self-sufficiency and stabilising production under climatic stress, bitter vetch can contribute to the long-term viability of extensive livestock systems and the sustainability of rural territories. Its integration into Mediterranean farming systems represents a practical pathway towards resilient, multifunctional livestock production that supports ecological functioning while maintaining productive and socio-economic roles within rural landscapes.

Western Italian Alps are losing upland cheese production

M. Coppa[1], C. Costamagna[1], L. M. Battaglini[1]
[1] University of Turin, Department of Agricultural, Forest and Food Sciences, Largo P. Braccini 2, 10095 Grugliasco, Italy

Upland dairy products are known for their specific features: the specificity of pasture botanical composition contributes to increase their polyunsaturated fatty acid content, and they express a diversified sensory profile, characterized by intense and floral notes. Their cheesemaking technology also largely varies across regions and relays on historical practices and local traditions, conferring to upland cheeses their uniqueness. However, mountain areas, especially in Western Italian Alps, are also characterized by considerable limitations in land-use, due to harsh climatic conditions, lack of infrastructures (roads, buildings) and services. Difficult working conditions, challenges in recruitment, wildlife conflicts, and insufficient generation renewal are menacing the maintenance of upland cheesemaking production. While a significant decrease in dairy production is widely perceived in mountain areas, quantitative data remain scares. The aim of this research was to take a census of upland active on farm cheesemaking plant in the Western Italian Alps and to compare data collected with the 2003 historical census aiming at quantifying trends of the last 20 years. We used a 425 km section of the Italian Alpine Club Walk "Sentiero Italia CAI" (crossing all the Alps) as a transect for the census. This transect crossed 15 valleys, and the whole Cuneo and half of the Torino provinces. Each upland pasture management unit (UPMU) crossed by the walk was identified and active on farm cheesemaking dairy plant were surveyed to characterise the farm, the herd and the cheesemaking production. Data form the same UPMU from the 2003 census were compared to those collected in 2025. On the total of 109 UPMU on the transect, 52 had an active cheesemaking plant in 2003, while only 35 remained active in 2025, with a reduction of 14.7%. Most of the remaining milk processing farms are accessible by roads and are equipped with barn and building. Here, the number of dairy cows milked on the farms was on average 33 vs. 36 in 2003. While total transhumant cattle numbers remained stable, there was an 8.0% increase in non-milking cattle (beef cattle, heifers, or dry cows). The total number of sheep and goats decreased of about -22% and -33%, respectively, mainly due to predation pressure and extra work needed for flock defence. The workforce on cheesemaking farms (mainly farmer's relatives) was 23% higher in 2025 than in 2003, probably because of the extra workforce demanded for modern farm management and for herds defence from wolf attacks. Cheese production on the UPMUs with an active cheesemaking plants decreased of about -7.3%, but when considering also the missed cheese produced in 2003 on those upland pasture management unit that stopped milk processing, the decrease was much consistent (-36.4%). In conclusion, even if the presented data are preliminary and partial, it is evident that Western Italian Alps lost about one third of the upland cheese in the last 20 years. The remaining cheesemaking farms on upland are those with adequate infrastructure and with large families capable of providing the required workforce. Urgent policy intervention is needed to invest in infrastructures (roads ad buildings), and facilitate employment to preserve upland cheesemaking production.

Added value of grassland based dairy farming systems: the Trentingrana PDO production in Eastern Italian Alps.

A. Ceppatelli[1], S. Da Re[1], M. Berton[1], E. Benedetti Del Rio[1], S. Raniolo[1], E. Sturaro[1]
[1] University of Padova, DAFNAE, Viale dell'Università 16, 35020 Legnaro, Italy

Mountain grassland-based dairy livestock farming is associated with the provision of several positive environmental externalities, also ensuring the management of marginal pastures and supporting local tourism activities. These systems are normally characterised by a stronger link with the territory when compared to conventional ones located in plain areas, contributing to support the local economy. Therefore, specific indicators are needed to maximise the positive contributions of these systems and mitigate the negative ones. This study aims at investigating mountain grassland-based dairy farming, to develop tailored indicators to maintain its link with the territory and its positive associated externalities. Farm structure and management data were collected from 23 grassland-based dairy farms under the Trentingrana PDO cheese certification scheme, located in three mountain areas (Val di Fassa, Primiero, Val di Non) in the province of Trento (Italy). A Principal Component Analysis, conducted to select the most representative variables, identified 4 indicators: altitude, farmland area, share of permanent grasslands (PG), loose housing. These indicators were combined with farm locations data to perform a K-means clustering, obtaining 3 clusters. Additional indicators for geo-morphological and landscape features and ecosystem services were computed using the software QGIS. A one-way Anova was then performed to investigate differences between the clusters. Cluster 1 represented mid-altitude farms (961m asl), with medium surfaces (35 ha), the largest herds (75 cows), total share of loose housing, the highest milk yield (11715 kg Energy Corrected Milk – ECM – /cow/year), the lowest field slope (8.66°) and no agrotourism activity. Cluster 2 described mid-altitude (802 m asl), smallest farms (22ha and 24 cows), with farm surfaces totally managed as permanent grasslands, medium share of loose housing (50%), the lowest milk yield (8088 kg ECM/cow/year), medium field slope (10.81°) and 44% of farms with agrotourism activity. Cluster 3 referred to farms located at the highest altitude (1523 m asl), managing the widest surfaces (69 ha), with medium-sized herds (45 cows), the lowest number of cuts on PG (1.7), farm surfaces totally managed as permanent grasslands, medium share of loose housing (65%), medium milk yields (10087 kg ECM/cow/year), the highest field slope (13.64°) and 67% of farms with agrotourism activity. Clusters were similar for the other factors considered, including milk price and additional ecosystem services indicators. In conclusion, farms belonging to Cluster 1 were reasonably located in more favourable areas, adopting a higher level of intensification carried out with increased herd size and milk yields, but without diversifying their activity through agrotourism. Farms belonging to Cluster 3 were situated in less favourable areas, located at the highest altitude and with fields characterised by the highest slope, but were able to maintain high production levels, also diversifying their activity by integrating agrotourism to a certain extent. Farms grouped into Cluster 2, despite being located in favourable areas, managed the smallest surfaces and herds, obtaining the lowest production levels and still adopting a medium share of tie-stall housing, therefore maintaining a more traditional production system. The above-mentioned indicators will be integrated with impact categories (Life Cycle Assessment and nutrients excretion data) and ecosystem services indicators, to monitor the multiple relationships between dairy farming and agroecosystems in the Trentingrana PDO cheese production chain.

Site-adapted farming systems in mountain regions: a synthesis of key characteristics, transformations and challenges

M. K. Schneider[1], C. M. Pauler[1]
[1] Agroscope, Animal Production Systems, Reckenholzstr. 191, 8046 Zürich, Switzerland

The diversity of environmental conditions in mountain regions has created a large diversity of locally adapted farming systems. Common to many systems are the challenges in harvesting and transporting forage, which favours grazing over mowing and transhumance over stationarity. Moreover, communal ownership is frequent to use labour and infrastructure more efficiently. Recent decades have seen important transformations of demographic and agricultural structures in European mountain regions. In general, the number of people working in agriculture decreased while farm sizes increased. Managing larger units and more land requires investments into infrastructure and machinery. These investments, in turn, require the specialization of animal production and of forage conservation as well as a rationalization of work processes by mechanization. The professionalization and rationalization of farm operations potentially decouple farming systems from the local conditions: Forage production is concentrated on flat and productive sites, manageable with machinery. Highly productive livestock allows higher output at lower number of heads but is less suited to graze low-productive sites and is thus supplemented with concentrates or herded on the best sites only. Summarizing a series of recent own studies we identify key elements of site-adapted farming systems in mountain conditions: (1) livestock diversity and productivity aligned with the diversity of environmental conditions and the productivity of available farm land, (2) closed nutrient cycles and circular flows to prevent the degradation of the natural grassland ressources, and (3) non-agricultural activities to valorize non-provisioning ecosystem services produced by farming. We illustrate these key elements with examples from the Alps and other mountain ranges.

Lamb meat production in marginal areas: a comprehensive carbon footprint assessment accounting for soil carbon sequestration

E. Sabia[1], C. Pacelli[1], A. Di Trana[1], R. Paolino[1], A. Coppola[1], C. Cosentino[1], L. Vignozzi[1], A. Braghieri[1]
[1] University of Basilicata, Department of Agricultural, Forest, Food, and Environmental Sciences, viale dell'Ateno Lucano, 85100 Potenza, Italy

In much of the Mediterranean basin, sheep farming is predominantly oriented towards dairy production, with ewes selectively bred to enhance milk yield. However, in certain marginal areas of southern Italy, such as the Basilicata region, sheep husbandry is mainly practiced for lamb meat production. Against this backdrop, the present study aimed to evaluate the environmental performance of lamb meat production in marginal areas, focusing on the carbon footprint (CF) and explicitly accounting for carbon sequestration. Five lamb meat farms, representative of the reference geographical area, were selected for the analysis. All farms are managed under extensive production systems, characterized by a wide reliance on grazing resources, limited use of external energy inputs, and the complete absence of both organic and inorganic fertilizers. The main breeds reared are the Gentile di Puglia sheep and the local crossbred. On average, the farms cover 167 ± 44 hectares, with 218 ± 32 adult ewes per farm. Annual lamb sales amount to 192 ± 21 head, with an average live weight (LW) of 18 ± 1 kg. The CF was quantified using a Life Cycle Assessment approach in accordance with ISO 14040-44 standards, applying a cradle-to-farm-gate system boundary. Emissions were expressed as kg CO_2 equivalent and calculated using the open-source software openLCA (v.2.6), supported by the AGRIBALYSE and Ecoinvent databases. The Environmental Product Declaration (EPD 2018) impact assessment method was used. Two functional units were considered: LW (kg) and land area (ha). Soil carbon sequestration (SCS) was estimated using the crop residue approach and subsequently deducted from the overall CF. The average of CF amounted to 14.2 ± 3.3 kg CO_2 eq per kg of LW and 452 ± 111 kg CO_2 eq per ha (mean ± SD). When SCS was included in the accounting framework, the overall environmental impact decreased by 30%. The main contributors to total emissions were biogenic CH_4 (64%), followed by N_2O (29%) and fossil CO_2 (7%). Overall, the findings highlight the central role of enteric methane in determining the CF of extensive lamb production systems and demonstrate the substantial mitigation potential associated with SCS in grazing-based farms. Properly accounting for soil carbon dynamics is therefore essential to avoid overestimating the climate impact of low-input, pasture-based systems. In addition, the relatively low CF observed per unit of land area reflects the limited external inputs and the extensive nature of these production systems, confirming their low environmental intensity at the regional level. This aspect is particularly relevant in marginal areas, where sustainable livestock management can contribute not only to food production but also to landscape conservation and the provision of various externalities and ecosystem services. Overall, the study provides a first benchmark for lamb meat production in Southern Italian marginal areas and supports the environmental value of extensive sheep farming when its multifunctional role is fully acknowledged.

Effect of breed on the health and welfare of semi-extensively reared dairy goats in Greece

A. Zemou[1], S. Vouraki[2], G. Batikas[1], A. Gelasakis[3], G. Banos[1,4], G. Arsenos[1]
[1] Aristotle University, University Campus, 54124 Thessaloniki, Greece, [2] University of Ioannina, Kostakioi, 47100 Arta, Greece, [3] Agricultural University of Athens, Iera Odos 45 Street, 11855 Athens, Greece, [4] Scotland's Rural College, Easter Bush, Midlothian, EH25 9RG Edinburgh, United Kingdom

Dairy goat farming plays a vital socioeconomic role in marginal regions, though sustainability is often hindered by animal health and welfare challenges in semi-extensive farming systems. The objective here was to assess the effect of breed on health and welfare traits of semi-extensively reared dairy goats in Greece. A total of 1,210 goats from seven farms were used. Goats belonged to Eghoria (n=418), Skopelos (n=429), and Damascus (n=363) breeds. Health and welfare traits of individual goats were recorded monthly across two consecutive milking periods. Health records included milk somatic cell count (SCC), total viable count (TVC), and parasitism with gastrointestinal nematodes (GIN). Welfare records included body condition score (BCS), horn injuries, ocular and nasal discharge, head injuries and lesions (collectively analysed as head problems), skin injuries and lesions, body and udder abscesses, udder asymmetry, and overgrown claws. Breed effects on the studied traits were analysed using mixed linear and non-linear models in R. In addition to breed, models included the fixed effects of period of kidding, age at kidding and days from kidding, and the random effects of animal and farm. Significant breed differences ($P<0.05$) were identified for BCS, udder asymmetry, and head problems. Specifically, Skopelos goats had higher BCS compared to Eghoria and Damascus goats. The odds for udder asymmetry were three and two times higher for Eghoria and Damascus, respectively, than Skopelos goats. Head problems were ten-times more likely in Damascus and Eghoria relatively to Skopelos goats. These results highlight significant breed-specific differences in dairy goat welfare traits, and a comparatively better welfare status in Skopelos goats, likely reflecting their better adaptation to semi-extensive farming conditions. Collection of data was funded by the European Commission Seventh Framework Program (FP7 Food, Agriculture and Fisheries, Biotechnology) for the project Sustainable Organic and Low Input Dairying (SOLID), grant number FP7-KBBE-266367.

Adoption of regenerative management practices in Mediterranean Dehesa Livestock Systems and their contribution to ecosystem services

P. Gaspar[1], A. Horrillo[2], A. Rodríguez-Ledesma[1], M. Escribano[2]
[1] Universidad de Extremadura, Departamento de Producción Animal y Ciencia de los Alimentos, Avda. Adolfo Suárez s/n, 06007 Badajoz, Spain, [2] Universidad de Extremadura, Departamento de Producción Animal y Ciencia de los Alimentos, Av. de la Universidad s/n, 10003 Cáceres, Spain

Mediterranean Dehesa Systems are multifunctional extensive livestock systems based on the sustainable use of pastureland, trees and natural resources. They play an important role in biodiversity conservation, wildfire prevention, climate regulation and rural employment. Regenerative management practices may further enhance their environmental performance and resilience. However, the degree to which these farms are implementing regenerative techniques remains unclear. The objective of this study was to evaluate the adoption level of regenerative practices in dehesa livestock farms and to assess their potential contribution to ecosystem services. A survey was conducted on 52 livestock farms in Extremadura (Spain) during 2021–2022. A structured questionnaire collected information on soil management, organic matter cycling, grazing strategies, tree management and biodiversity-related actions. Adoption rates were analysed descriptively to identify patterns across management domains. Results show a coexistence of traditional and conventional practices, with limited implementation of specific regenerative techniques. In organic matter management, 53.8% of farms use pruning residues for browsing, whereas composting (3.8%) and biochar production (0%) are almost absent. Additionally, 19.2% still burn residues. Conventional tillage is used by 19.2% of farms, while minimum tillage (9.6%) and no-till (3.8%) remain marginal. Although 53.8% practice pasture rotation, 75% rely on large fixed paddocks, and adaptive grazing tools such as mobile fencing (11.5%) and electric fencing (17.3%) are underused. Regarding ecosystem services, 61.5% of farms use grazing for wildfire prevention, highlighting their contribution to landscape management. Tree planting (30.8%) and beekeeping (42.3%) indicate diversification strategies linked to biodiversity support. However, ecological infrastructures such as hedgerows and corridors are scarce (7.7–9.6%). Furthermore, 30.8% of farms report severe erosion, yet corrective measures are rarely implemented. Dehesa livestock systems maintain a strong ecological base and already provide relevant ecosystem services. Nevertheless, the structured adoption of regenerative soil and grazing management remains limited. Enhancing technical training and knowledge transfer could strengthen system resilience, improve environmental outcomes and reinforce the role of extensive livestock farming in sustainable rural development.

Multifunctional extensive small ruminant farming in Amorgos island (Greece): implications for rural development and ecosystem services

A. Kominakis[1], M. Goliomytis[1], M. Koveos[1], I. Hadjigeorgiou[1]
[1] Agricultural University of Athens, Department of Animal Science, Iera Odos 75, 11855 Athens, Greece

Extensive small ruminant farming systems in Mediterranean insular regions represent multifunctional production models that simultaneously sustain rural livelihoods and deliver essential ecosystem services. This study assesses the structural, productive and environmental characteristics of sheep and goat farming in Amorgos Island (Greece), within the framework of a rational livestock management plan. Primary data were collected through structured interviews with 16 representative farms, complemented by genomic analysis of indigenous sheep, official livestock registry and arable crop statistics. The system is predominantly extensive (87.5%), based on year-round utilizing rough grazing on steep slope rocky hills as well as flat land cultivated parcels by sheep and goats. Local breeds dominate, selected mainly for environmental adaptability and resilience under low-input conditions. Reproductive performance is satisfactory (fertility ~83–84%), adult mortality remains below 5%, and animals exhibit extended productive longevity, reflecting adaptation to local constraints. Beyond food production, the system provides other significant ecosystem services. Continuous grazing contributes to shrub biomass control and wildfire risk mitigation, while manure deposition enhances soil fertility in both rangelands and small arable plots. The preservation of autochthonous genetic resources strengthens system's drought tolerance and climate resilience. Moreover, grazing maintains heterogeneous agro-pastoral landscapes that support biodiversity conservation. Economically, livestock production is closely linked to local tourism and short supply chains, with a high proportion of meat and dairy products marketed directly or through family businesses. However, challenges include ageing farmers, limited succession, drought-induced pasture decline and reliance on purchased feed. Overall, the Amorgos case demonstrates how multifunctional extensive livestock systems can reinforce rural cohesion, prevent land abandonment and enhance ecosystem services in Mediterranean marginal environments.

Effects of Pasture Diversification Strategies on Milk Production in Dairy Cows

L. Carmona-Flores[1], M. Bionaz[1], D. E. Prado-Tarango[1], K. La Terra[1], J. Cruickshank[1], S. Ates[1]
[1] Oregon State University, Animal and RangelandScience, 112 Withycombe Hall, 2921 SW Campus Way, OR97333 Corvallis, United States

Pasture diversification is increasingly promoted because of its agronomic, nutritional, and environmental benefits. However, establishing and maintaining pasture diversity remains challenging because of edaphic and environmental constraints, as well as the generally lower persistence of forbs relative to grasses. Diversification through mixed cover crops and herbal leys may provide a practical strategy to enhance pasture diversity and improve animal performance. This study evaluated the effects of pasture diversification through the inclusion of forbs alone or in combination with herbal leys on milk yield, milk composition, nitrogen partitioning, and methane emissions of grazing dairy cows during spring 2026. Pastures were established in a randomized complete block design with four replicates. Thirty-six mid-lactation Jersey cows (19 primiparous and 17 multiparous) blocked for parity, body weight, and milk yield grazed one of three pasture systems: (1) simple pasture, (2) diverse pasture, or (3) diverse pasture supplemented with herbal leys. Diversification through the inclusion of forbs alone was limited because of substantial volunteer annual ryegrass invasion; however, the addition of herbal leys increased forb content in the pastures to 37% as compared to 14% in simple and 19% in diverse pastures. Cows grazing the diverse + herbal ley treatment produced numerically greater ($P = 0.11$) milk yield (16.3 L/d) compared with cows grazing the simple (14.8 L/d) and diverse pastures (15.2 L/d). Milk composition was not affected by pasture treatments (all $P > 0.05$). Measurements related to environmental outcomes, including enteric methane emissions, and animal health parameters are currently being analyzed. Summer and fall grazing evaluations will also be conducted in 2026 to determine the influence of seasonal variation in pasture conditions. Overall, these preliminary findings suggest that incorporating herbal leys can successfully increase forb abundance and may enhance milk production in pasture-based dairy systems, even when conventional diversification approaches are constrained by grass competition and climatic conditions.

Towards a New Selection Index for Holstein Cattle in Pasture-Based Production Systems: Stakeholder Perspectives from a Survey

A. Breiholz[1], N. Volkmann[2], S. Voßgerau[3], D. Hinrichs[4], N. Kemper[2], G. Thaller[1], N. Krattenmacher[1]
[1] Institute of Animal Breeding and Husbandry, Kiel University, 24118 Kiel, Germany, [2] Institute for Animal Hygiene, Animal Welfare and Farm Animal Behavior, University of Veterinary Medicine Hannover, Foundation, 30173 Hannover, Germany, [3] Rinderzucht Schleswig-Holstein eG, Rendsburger Str. 178, 24537 Neumünster, Germany, [4] University of Kassel, Faculty of Organic Agriculture, Section of animal breeding, 37213 Witzenhausen, Germany

Pasture-based dairy cow management systems are associated with animal welfare and resource efficiency. However, the number of such farms in Germany has declined in recent years, despite increasing societal and political expectations. Currently, no national selection index explicitly reflects the breeding priorities of farmers operating pasture-based dairy systems. To address this gap, a nationwide survey was conducted to assess the role of grazing in German dairy farming, identify key challenges and explore stakeholder perspectives on breeding goals relevant to grazing systems. Using an online survey, dairy farmers received questions regarding socio-demographic characteristics, farm structure, grazing management, motivations for or against grazing, challenges associated with grazing and their ideas concerning breeding of Holstein Friesian (HF) cows suitable for pasture-based production systems. The questionnaire included multiple choice items, Likert-type scales and adaptive question paths. Responses from 329 participants collected between March 2025 and January 2026 were used for a preliminary descriptive analysis. Among respondents, 84 % practiced grazing, with most farms located in Northern Germany. HF was the predominant breed, and the average herd size was slightly higher than the national average of animals per herd. Most farms offered more than six hours of daily pasture access to lactating cows, while full grazing without supplementation (4 %) was rare. Rotational grazing systems were most common, only young stock was mainly kept on full pasture. The main reasons for grazing were animal health aspects (95 %) and personal conviction (91 %), followed by reputation (71 %). External drivers such as certification (34 %) or milk price premiums (43 %) seem to play a minor role. In contrast, farms without grazing primarily reported economic disadvantages (83 %), increased labor (77 %) and a lack of pasture close to the farm (75 %) as main barriers. Farmers with grazing cows were asked whether they see merit in the development of a new breeding value specifically designed to fit the needs of farms with grazing cows, and nearly 50 % expressed interest. Using a participatory approach, HF farmers with an interest in breeding who had their own ideas about pasture genetics (n = 20) as well as experts from breeding organizations (n = 10) were asked to evaluate the relative importance of various traits for HF kept on pasture. In addition to traits included in the German total merit index (RZG), body condition score and feed efficiency should also be considered. Furthermore, not only the relative breeding value for milk, but also those for milk components were of interest. Based on the survey conducted among farmers, milk traits (milk yield: 17.3 %; milk components: 11.2 %) received the highest weighting, followed by longevity (23.1 %), feed efficiency (11.7 %) and conformation (10.9 %). Although the indices designed by the individual farmers varied to some extent, the overall index was similar to expert assessments but differed from the RZG, particularly in the emphasis placed on milk production traits and health. The study indicated a demand for the development of a specifically tailored selection index for pasture-based dairy production as it is already established in other countries.

Emerging practices and perceptions of regenerative agriculture across pioneering Dutch dairy farms

J. Threels[1], E. Bokkers[1], E. De Olde[1]
[1] Wageningen University, Animal Production Systems, De Elst 1, 6708WD Wageningen, Netherlands

Dutch agriculture, and particularly the dairy sector, is confronted with several sustainability challenges regarding biodiversity, soil quality and nitrogen excretion. A transition towards more regenerative agriculture (RA) has been suggested as one way to address these challenges. However, there is no generally accepted scientific definition of RA yet. Therefore, this study aims to identify the characteristics and applied practices of regenerative dairy farming and how this compares to the general dairy production practices in the Netherlands. Interviews with 28 RA pioneering farms were carried out. These farms voluntarily participated in a large research programme (ReGeNL) on supporting RA in the Netherlands. They are applying (combinations of) innovative practices that distinguish them from the conventional Dutch dairy farms and have the potential to improve their regenerative capacity. Examples of such practices are grazing and feed extensification, technical innovations such as a mobile pasture milking robot, integration of agroforestry and shortening of value chains. Two rounds of interviews were carried out. The first round aimed to get a general understanding of the farm system (e.g., size of the operation, origin story of the farm, general distribution of production) and their perception of RA (e.g., why did they start with RA on their farm?; what themes are most relevant to them now and in the future?). The second round consisted of getting a detailed dairy cow management overview (e.g., calf weaning process, feed and grazing management, medical intervention plan). Preliminary analysis of the first-round interviews showed an average farm size of 98.8 ha (41 – 200 ha) with 88 lactating dairy cows (30 – 230 cows), where the average Dutch dairy farm cultivates 60 ha and milks 119 dairy cows. Additionally, the farmers' perspective on RA mainly comprised the improvement of natural closed cycles on farm, which often coincided with minimizing reliance on external inputs. The theme deemed most important in moving towards RA was soil health (for its regulatory and cycling capacity) followed by the theme animal (in relation to health, production and welfare). Overall jointly listed as third by the farmers are the themes economy and biodiversity. The preliminarily results of the second interview round showed strong variation across pioneering farms. For example all farms practice grazing, but the types varied from rapid rotational strip grazing to kurzrasen, with variable occupation ranging from 2 to over 100 animals/ha on occasion. Grazing strategy varied throughout the season depending on grass availability. Total grazing duration varied between farms ranging from 720 h (the minimum to label milk as pasture-based) to 4200 h annually. Whereas in the Netherlands, about 80% of dairy farms implement grazing, reaching an average annual grazing duration of 1301 hours. Furthermore, diet composition varied strongly between the interviewed farms, for example concentrate provision ranged from 0 kg (on a purely grass-based farm) to 30 kg per 100 kg milk yield (Dutch average: 30.5 kg). Finally, the breed composition on these farms varies substantial resulting in herds of up to 6 different breeds, with only about half of the farms having Holstein cows as one of the main breeds in the herd, where the overall Dutch herd stock consists for 90% of Holstein Friesian. In conclusion, RA dairy farms displayed distinct characteristics compared to the average Dutch dairy farm, most notably a shared tendency towards extensification. Nevertheless, considerable variation existed in the approaches of individual farms, which was linked to differences in available land, knowledge, and financial resources.

The potential of grass biorefinery on dairy farms

M. Hoogterp[1], A. Klop[1], S. Jebbink[1], A. Evers[1], J. De Boer[1], G. Van Duinkerken[1]
[1] Wageningen Livestock Research, De Elst 1, 6708WD Wageningen, Netherlands

The dairy sector is under increasing pressure to close nutrient cycles, reduce environmental impact, and develop innovative on-farm revenue models. Biorefinery of grass might offer a promising solution. Grass refinery is a physical process in which fresh grass is pressed and separated in two fractions. A liquid fraction (press juice), which is rich in protein and can be used in feeds for monogastrics or in human food products. And a fibrous fraction, which can be ensiled (press cake) and remains on the dairy farm, or can be valorised in other sectors like construction or the paper industry. By replacing part of the conventional grass silage in the ration with press cake from biorefined grass, both nitrogen (N) intake and N excretion can be reduced and N efficiency can be increased, without compromising animal performance. Grass biorefining is technically available, but its practical implications for closing nutrient cycles on dairy farms and farm economics have hardly been investigated or quantified. The objective of this study was to assess the effects of grass biorefining on nutrient cycling and the economic performance of dairy farms for three farm types. The effects of grass biorefining were assessed with the DairyWise model and the Annual Nutrient Cycle Assessment (ANCA) model for three typical Dutch dairy farms: an intensive dairy farm on clay soil (C farm) and two more extensive dairy farms on peat (P farm) and sandy soils (S farm). The initial situation was compared with a scenario in which grass biorefining is applied on five hectares of grassland per farm. The impacts on farm management, economic results, and sustainability indicators were assessed. The model analysis indicated that related to farm management the application of grass biorefining affects the amount of available roughage, because of dry matter allocation in the press juice. On the other hand, the refinery process improved the digestibility of the press cake, resulting in a favorable ileal digestible protein level and a reduced rumen degradable protein balance. To compensate for the loss of roughage, the C farm bought more maize silage where the extensive P and S farm sold less surplus of grass silage. Grass biorefining reduced the amount of concentrates per cow per year, with 39, 11, and 68 kg for the C, P and S farm, respectively. However, especially for the C farm more protein rich concentrates were needed. Regarding fertilization, grass refining showed both positive and negative effects on the required input and composition of mineral fertilizers, depending on the farm situation. From an economic perspective, applying grass biorefining on five hectares of grassland resulted in a positive balance of € 810, € 560 and € 750 per hectarefor the C, P and S farm respectively. The positive effect of grass biorefinement on farm income came from compensation for land use and the press juice, reduced contractor costs and manure disposal costs, although this might be partly offset by decreased roughage sales and increased storage needs, again, depending on the farm situation. For sustainability indicators, grass biorefinery led to a reduction in ammonia and greenhouse gas emissions (methane and nitrous oxide). With grass refinery, ammonia emissions reduced 2, 4 and 3% for the C, P, and S farm, respectively. This modeling study provided insights into the practical implications and key considerations of grass biorefinement on dairy farms. Validation under real farm conditions is required to determine how these model results translate into farm-specific constraints, practices, and results. In conclusion, grass biorefining is a promising strategy to enhance nutrient efficiency and farm profitability.

Winter grazing by dairy cows: a viable solution for climate change adaptation

V. Brocard[1], D. Benoit[2], C. Caraes[2], S. Schetelat[1], G. Trou[2], E. Tranvoiz[2]
[1] Institut de l'Elevage, monvoisin, 35650 Le Rheu, France, [2] Chambre d'Agriculture de Région Bretagne, RP M Le Lannou, 35000 Rennes, France

With climate change, grass growth in western France is expected to increase in late autumn and late winter, periods when soil bearing capacity is not always sufficient for grazing. This can lead to a large stock of grass biomass which, if not utilized before spring, reduces pasture quality. This study aims to assess whether winter grazing by dairy cows could be a suitable solution for utilizing this grass. It also seeks to determine whether this forage could help improve winter rations in organic farming systems, which are often deficient in protein due to the lack of satisfactory solutions for on-farm production of protein concentrates. Trials conducted over three winters (2022–2025) at the Trévarez organic experimental farm (Western France, Chamber of Agriculture of Brittany and Idele) aimed to characterize winter grass and evaluate the impact of winter grazing on pastures (growth, composition, potential degradation, trampling). The results showed that the median grass density was 245 kg Dry Matter (DM) ha^{-1} cm^{-1}. Average growth was 4 kg DM ha^{-1} day^{-1}, corresponding to 360 kg DM ha^{-1} accumulated over three months (mid-November to mid-February). Winter grass consisted of more than 80% grasses at the leafy stage, which explains its good nitrogen value (20–22% crude protein in DM, with an average DM content of 15%). Winter grazing did not reduce annual yield but delayed the spring regrowth of the pasture by about two weeks. The experiment also studied the response of a lactating herd grazing grass–legume pastures during winter as a complement to an indoor ration consisting of ad libitum grass silage and 5 kg DM of maize silage. An experimental group of 25 lactating cows grazed for 3 hours per day, in two grazing rotations, during the three winters between December and February. The performances were analysed with an ANOVA model with R Studio software (tests with $\alpha = 5\%$). With grazed grass intake estimated using the Inrae HerbValo method at 2.6 kg DM cow^{-1} day^{-1}, these cows produced on average significantly 1.8 kg cow^{-1} day^{-1} more milk for two winters out of three (no significant effect at $p<0,05$ during the third winter) than the control group that remained indoors on the same basal ration. This was associated with a reduction in grass silage intake of 1 kg DM $cow^{-1}day^{-1}$. Overall intake increased and the nitrogen balance of the ration improved slightly: 85 vs. 80 g PDI per UFL (Intestine Digestible Protein per Energy Unit, INRAe 2018) for the non-grazing control group. No effects were observed on milk components, body condition, or animal health. From an economic perspective, 3 hours of grazing for a herd of 75 dairy cows would increase the margin over feed costs by about €2,100 per month in two winters out of three. Winter grazing may therefore be a way to better balance the protein supply of winter rations, particularly in organic dairy farming. However, this practice requires well-designed farm tracks and must be adapted to pedo-climatic conditions (stocking rate and grazing duration adjusted to soil bearing capacity and cumulative rainfall). Winter grazing could thus represent an opportunity to utilize the grass available in late autumn and make better use of the effects of climate change, especially in livestock regions with an oceanic climate.

Adapting Dairy Cattle Grazing Systems to Climate Change: The Role of Agroforestry

M. Mele[1]
[1] *University of Pisa, Dipartimento Scienze Agrarie, Alimentari, Agro-ambientali, Via del Borghetto, 80, 56124 Pisa, Italy*

Climate change alters the thermal environment of grazing animals, affecting their productivity, health, reproduction, and feed conversion efficiency. In addition, the quality and quantity of forage in grassland systems are strongly influenced by the increasing frequency of extreme weather events. Consequently, targeted strategies in pasture and grazing management, supplementary feeding, and the use of alternative forage crops are needed to address the challenges posed by climate change. Agroforestry represents a land-use strategy that can help mitigate climate change while providing environmental, economic, and social benefits. The literature indicates that agroforestry systems may alleviate heat stress by improving microclimatic conditions and enhancing thermal comfort for grazing animals. However, factors such as tree canopy and trunk density, the arrangement and orientation of tree rows, and the density of scattered trees must be carefully considered in system design, as they influence heat stress risk by modifying solar radiation, air temperature, humidity, and wind circulation. In agroforestry systems, herbage biomass is primarily reduced due to limited light availability and, to a lesser extent, competition for nutrients. However, effects on nutritive value differ between grasses and legumes. Under shaded conditions, crude protein content tends to increase in grasses but decrease in legumes, while fibre content generally remains stable or declines. Grass–legume mixtures can enhance both yield and forage quality through complementary species interactions. Adopting optimal grazing management that accounts for shade, forage yield, and nutritive value is therefore essential to improve animal productivity. Agroforestry systems can also provide tree fodder to mitigate the effects of summer drought and heatwaves on herbaceous forage. Dairy cows can consume leaves and young shoots less than 8 mm in diameter, either directly from the tree or through branch foddering. Feeding livestock with leaves and shoots harvested from species such as maples (Acer spp.), ashes (Fraxinus spp.), lindens (Tilia spp.), elms (Ulmus spp.), poplar (Populus spp.) and white mulberry (Morus alba) is a traditional practice in several European regions. Given the increasing frequency of droughts and heatwaves that negatively affect forage yield and quality, the contribution of forage trees could become strategically important in counteracting the effects of climate change. The nutritional value of tree foliage is comparable to, and often higher than, that of many herbaceous forage species. Moreover, in many species, tree leaves contain significant levels of tannins, polyphenols, and other secondary metabolites that may help reduce gastrointestinal parasite burdens and mitigate methane emissions. Overall, integrating trees with forage crops or grasslands in agroforestry systems represents a promising strategy to address climate change challenges, particularly those related to drought and heatwaves.

Herbage mass and pasture allowance affect grazing behavior more than milk production in dairy cows grazing polyphytic pasture in southern Chile

R. G. Pulido[1], I. Calvache[1,3], E. Herrera[2], J. P. Keim[2], O. A. Balocchi[2]
[1] Universidad Austral de Chile, Ciencia Animal, PO Box 567, 5190000 Valdivia, Chile, [2] Universidad Austral de Chile, Producción Animal, PO Box 567, 5190000 Valdivia, Chile, [3] Universidad de Concepción, Producción Animal, Barrio Universitario, 4070386 Concepción, Chile

This study evaluated the effects of herbage mass (HM) and pasture allowance (PA) on milk production, dry matter intake (DMI), and grazing behavior of dairy cows grazing a polyphytic pasture during autumn in southern Chile. The pasture was mainly composed of Lolium perenne L., Trifolium repens L., and Bromus valdivianus Phil. The experiment was conducted at the Dairy Research Station of Universidad Austral de Chile (UACh), Valdivia, Los Ríos Region, Chile, during April and May 2025 (61 days), using rotational strip grazing across three paddocks with a total area of 9 ha. Grazing was delayed from late February to achieve the target HM. The basal diet consisted of polyphytic pasture supplemented with pasture silage (5.0 kg DM/cow/day, offered immediately after afternoon milking), commercial concentrate (4.5 kg DM/cow/day, offered in two equal portions during milking), rolled corn (1.8 kg DM/cow/day), mineral salts (0.25 kg DM/cow/day), and water ad libitum. Thirty-six clinically healthy Holstein Friesian dairy cows (28 multiparous and 8 primiparous), with somatic cell counts <200,000 cells/mL, milk production of 26.9 ± 1.25 L/day, days in milk (DIM) of 38.0 ± 4.17, and average body weight (BW) of 530 ± 4.9 kg, were assigned to one of four treatments in a 2 × 2 factorial arrangement: two HM levels [2,200 kg DM ha−1 (standard HM, SHM) or 3,000 kg DM ha−1 (high HM, HHM)] and two PA levels [17 kg DM cow−1 day−1 (low PA, LPA) or 25 kg DM cow−1 day−1 (high PA, HPA)], with nine cows per treatment.The variables evaluated included milk yield recorded at each milking throughout the experiment; milk fat, protein, and urea concentrations analyzed during the last week of each month from three consecutive milkings; grazing behavior recorded over a 24-h period on two occasions; and DMI determined during weeks 3 and 7 of the experiment. Data were analyzed using a generalized linear model. No HM × PA interaction was detected for milk yield (25.9 ± 1.23 kg cow−1 day−1) or milk protein concentration (3.78 ± 0.06%; $p > 0.05$). However, milk fat concentration showed a significant interaction ($p < 0.05$), with SHM_HPA showing the highest value (4.35 ± 0.97%).Pasture DMI differed according to PA level, with cows under HPA consuming 5.7 kg DM animal−1 day−1 compared with 3.9 kg DM animal−1 day−1 under LPA (SEM = 0.264). Total DMI was also greater under HPA than under LPA (17.6 vs. 16.0 kg DM cow−1 day−1; SEM = 0.36). Grazing time and idling time were affected by the HM × PA interaction ($p < 0.05$), whereas rumination time was not. The main effects showed differences only for HM in grazing time (407 vs. 370 min for SHM and HHM, respectively) and time spent on other activities (469 vs. 531 min for SHM and HHM, respectively). Although HM and PA had limited effects on milk yield and milk composition, these management factors influenced grazing behavior and pasture intake, indicating that cows adjusted their grazing activity in response to pasture availability rather than increasing milk output. Project financed by FONDECYT 1240451.

Milk urea concentration ranges suitable as indicators of nitrogen utilization in grazing dairy cattle

M. Mangwe[1,3], C. Reed[2], R. Bryant[3], S. Davis[4], G. Scott[4], C. Phyn[2], D. Pacheco[5]
[1] DairyNZ Limited, PO Box 8506, 7608 Lincoln, New Zealand, [2] DairyNZ Limited, Private Bag 3221, 3240 Hamilton, New Zealand, [3] Lincoln University, PO Box 85084, 7647 Lincoln, New Zealand, [4] Fonterra Co-operative Group Limited, PO Box 9045, 3240 Hamilton, New Zealand, [5] Bioeconomy Science Institute, Private Bag 11008, 4442 Palmerston North, New Zealand

Bulk milk urea (MU) concentration is widely used as an indicator tool to support diet formulation, improve nitrogen (N) utilization and reduce surplus urinary nitrogen (UN) excretion from dairy cattle managed under confinement systems. However, there is limited information on appropriate use of MU concentration ranges under pasture-based systems. This study used three datasets to determine lower and upper bulk MU concentrations in pasture-fed dairy cows: 1) contemporaneous (i.e. group mean) measurements of individual cow MU concentration and UN excretion from a cow phenotyping study (n=131); 2) measurements of herd bulk MU concentration from a 1-year observational study including four visits to 38 commercial farms in New Zealand (n=150); and 3) treatment means of individual cow MU concentration and UN excretion from a meta-analysis of 26 publications (n=76). Specific data available, animal management and measurement approaches varied across and within datasets, enabling identification of consistent trends across relevant, diverse contexts. Milk urea (mg/dL) was analysed by spectral or enzymatic methods, with UN excretion (g N/d or % N intake) estimated by urine spot sampling, sensors or total daily collection. Dietary energy and protein requirement and supply variables were estimated using milk production, live weight, feed composition and calculated or measured DM intakes. Relationships between MU concentration, UN excretion and variables that indicate either a deficit, a balance (where animal N requirements are met), or a surplus of dietary protein in lactating dairy cows were examined for each dataset. Pairwise correlation analyses (CORR procedure) to estimate linear Pearson (r) and non-linear monotonic Spearman (rs) correlation coefficients were performed in SAS (v9.4). Deciles of MU data were obtained (UNIVARIATE procedure in SAS), and variables of interest plotted and compared across deciles using one-way ANOVA and Tukey HSD testing in R (v4.2.0). Results indicated that N supply parameters, including dietary crude protein concentration, rumen degradable protein (RDP) balance and metabolizable protein (MP) balance, were positively correlated with MU concentration and UN excretion. By estimating the supply of RDP and MP relative to the animal requirements, we obtained a range of MU concentrations between 17 to 22 mg/dL as indicative of dietary N supply being close to animal requirements (i.e. balance); however, there was no consistent negative association between MU concentration below this range and milk production parameters. Thus, low MU values should be interpreted cautiously and not assumed to reflect dietary protein deficiency on their own. Increases in MU concentrations were linked with increases in daily UN excretion (expressed as g/N, % N intake, or relative to milk N output) and decreases in N use efficiency (milk N output/N intake). Milk urea concentrations exceeding the range of ~25-33 mg/dL were indicative of dietary N supply exceeding cow requirements and therefore increasing the likelihood of higher UN excretion. However, high variability in the datasets limited the development of predictive equations for UN losses based on MU concentration. Bulk MU can be used alongside other information to identify opportunities to optimize pasture and supplementary feed management, improve N use efficiency and reduce environmental risks of N losses from grazing dairy systems.

Effect of increasing lucerne-to-maize silage proportion in diets on performance of dairy cows

S. Hu[1], R. Delagarde[1], N. Edouard[1], Y. Huang[1]
[1] INRAE, Institut Agro, Pegase, 16 Le Clos, 35590 Saint-Gilles, France

The use of lucerne silage in dairy cow feeding systems has regained interest due to its numerous agronomic and zootechnical advantages. Combining lucerne silage with maize silage appears to be a promising feeding strategy, while using less protein-rich concentrate and increasing protein self-sufficiency. However, interactions between the two forages may influence feed intake and the nutritional value of the diet, and incorporation rate of lucerne silage in the diet may affect these interactions. This study aimed to evaluate the effect of 3 different proportions of lucerne and maize silages (25:75, 50:50, and 75:25; referred to as L25, L50, and L75, respectively) in forage-only based diets on voluntary dry matter intake (DMI), milk production, and enteric methane emissions in dairy cows. A total of 24 mid-lactation Holstein cows were assigned to a double 3 × 3 Latin square design with three treatments and three consecutive periods of 4 weeks. The DMI was lower on L25 (16.9 ± 0.39 kg/d, mean ± SE; $P < 0.001$) than on L50 (18.8 ± 0.39 kg/d) and L75 (19.1 ± 0.39 kg/d), probably partly due to the lower crude protein content of the L25 diet (93 vs 139 g CP/kg DM on average). Cows fed L50 produced more milk (20.4 ± 0.57 kg/d; $P < 0.05$) than those fed L25 (19.3 ± 0.57 kg/d), while L75 showed an intermediate value (19.9 ± 0.57 kg/d). A similar pattern was observed for energy-corrected milk yield ($P < 0.05$), which was higher with L50 (20.0 ± 0.51 kg/d) compared with L25 (18.8 ± 0.51 kg/d) and L75 (19.2 ± 0.50 kg/d). Milk fat and protein contents did not differ among treatments, averaging 39.0 ± 1.12 g/kg for fat ($P = 0.12$) and 29.5 ± 0.44 g/kg for protein ($P = 0.06$). In contrast, milk fat yield was higher for L50 (800 ± 23.2 g/d; $P = 0.02$) than L25 (750 ± 23.2 g/d) and L75 (764 ± 23.1 g/d), and protein yield was greater for L50 (608 ± 16.8 g/d; $P = 0.04$) compared with L25 (569 ± 16.8 g/d), L75 being intermediate (584 ± 16.7 g/d). Daily methane production tended to be higher for L50 (419 ± 11.1 g/d) than for L25 (414 ± 11.1 g/d) and L75 (398 ± 11.0 g/d; $P = 0.051$). Methane production per kg of DMI decreased from 23.7 ± 0.55 g/kg for L25 to 21.5 ± 0.55 g/kg for L50 and 20.3 ± 0.55 g/kg for L75 ($P < 0.001$). Methane emissions per kg of milk was highest in L25 (21.8 ± 0.57 g/kg) and lowest in L75 (20.1 ± 0.56 g/kg), with intermediate values in L50 (20.8 ± 0.57 g/kg; $P < 0.05$). Overall, this study confirmed interactions between the two forages, with the L50 providing the most favorable balance by ensuring higher feed intake and milk production while reducing methane emissions, whereas increasing lucerne to 75% offered no additional production benefits. These results highlight the potential of optimising forage composition of mixtures to enhance both productivity and environmental sustainability.

Co-ensiling whole crop corn with increasing percentages of common beans (Phaseolus vulgaris)

M. Hünerberg[1], J. Hummel[1]
[1] University of Goettingen, Department of Animal Sciences, Kellnerweg 6, 37077 Goettingen, Germany

Growing corn together with crops that are more attractive to insects, particularly pollinators, is discussed as measure to improve the impact of corn silage production on insect biodiversity. Common beans (Phaseolus vulgaris) are relatively well-suited to be cropped together with corn for that purpose, as common beans (CB) are very attractive to insects, easy to establish, robust, and grow fast enough to not be outcompeted by the corn crop. However, CB are higher in crude protein (CP) and ash content compared to corn, which could buffer a fast drop in silage pH and have negative consequences on overall silage quality. This study was designed to investigate the impact of increasing percentages of CB inclusion on the quality and aerobic stability of mixed crop corn silage. Whole crop corn (variety: Ronaldinio) was ensiled with 0% (CON), 10% (10CB), 30% (30CB), 50% (50CB; dry matter [DM] basis) Phaseolus vulgaris (variety: Meraviglia de Venezia). Per treatment, three PVC-mini silos (3.4 L) were manually filled and compacted to 250 kg DM/m3 using a pneumatic press. The mini silos were sealed by rubber lids held on by metal clamps. Each silo had a gas relief valve. The silos were stored at 16.5 ± 1.5°C and opened after 8 wk of ensiling. Silages were subsampled and analyzed for crude nutrients, pH, and fermentation acids. In addition, the DM loss (DML) was calculated. As indicator for aerobic stability, heat loss from the silages over 14 d of aerobic exposure was recorded using Thermochron iButtons (Embedded Data Systems, Lawrenceburg, KY, USA). Data were analyzed using the mixed model procedure (PROC MIXED) of SAS (version 9.4). The model included the fixed effects of treatment. Mini silo was included as random effect. The impact of increasing concentration of CB on silage quality was examined using linear and quadratic orthogonal contrasts. Significance was declared at $P<0.05$. As expected, adding CB led to a linear increase in crude protein content of the silages ($P<0.01$; CON: 6.6%, 10CB: 7.7%, 30CB: 10.2%, 50CB: 12.2% CP, DM basis). In contrast, the energy content of the silages decreased linearly ($P<0.01$; CON: 11.25, 10CB: 11.19, 30CB: 10.86, 50CB: 10.76 MJ ME/kg DM). Silage pH increased linearly when CB were added ($P<0.01$) but was below pH 4 in all treatments (CON: 3.85, 10CB: 3.86, 30CB: 3.88, 50CB: 3.90). Acetate concentrations response to increasing percentages of CB in the silages also increased linearly ($P<0.01$), while butyrate concentrations tended to linearly increase ($P=0.09$). Total heat loss (i.e., area under the curve) over 14 d of aerobic exposure was higher when CB inclusion increased (linear: $P<0.05$). In addition, the first heat loss of the silages containing CB occurred earlier (d 4 to 5) compared to the CON (d 7). In conclusion, cropping corn together with CB might have positive impact on insect biodiversity but silage quality has to be monitored carefully, as fermentation quality and aerobic stability of these polycrop silages (corn plus CB) might be negatively affected.

Degradation Kinetics of Forage Monocultures and Multispecies Swards Harvested at Two Maturity Stages

R. Valencia[1], C. Reynolds[1], J. Hammond[1], L. Crompton[1]
[1] University of Reading, SAPD, PO Box 237, Earley Gate, RG6 6AR Reading, United Kingdom

Multispecies swards are promoted in grassland-based ruminant systems to enhance productivity and resilience under variable management and environmental conditions. Alongside species composition, maturity at harvest strongly influences forage nutritive value: less mature forage generally has higher crude protein (CP) and digestibility and lower fibre concentration. However, how forage maturity interacts with species composition to influence ruminal dry matter (DM) and CP degradation is less clear. Therefore, we evaluated the effects of forage species on the response of DM and CP degradation kinetics to harvest maturity.A field experiment established in spring 2023 included 8 forage species treatments: monocultures of perennial ryegrass (G1), timothy (G2), white clover (L1), red clover (L2), chicory (H1), and plantain (H2); a mixture of all 6 species (6Sp); and high-nitrogen (N) perennial ryegrass (G1-highN). All treatments received 100 kg N ha^{-1} annually, except G1-highN (200 kg N ha^{-1}). Treatments were replicated in three plots (n=3), except G1-highN (n=5). Plots (4 × 12.5 m) were split into early (5 harvests) and late (4 harvests) cutting subplots. Forage for rumen degradation analysis was collected at the second harvest on 29 May 2024 (early cut; 28 d regrowth) and 10 July 2024 (late cut; 56 d regrowth). Four rumen-cannulated Holstein dry cows were used for in situ incubations. Dried and milled (2 mm) forage samples were incubated in the rumen using Dacron bags for 0, 3, 6, 12, 24, 48, and 72 h, and residues were analysed for DM and CP. Degradation kinetics were modelled to estimate the soluble fraction (a), potentially degradable fraction (b), fractional degradation rate (c), potential degradability (PD=a+b) and undegradable fraction (U=100−a−b). Estimated fractions and degradation rate were analysed using linear mixed models in SAS (PROC MIXED), with forage species treatment, maturity, and their interaction as fixed effects, and plot, cow, and incubation batch as random effects.Forage species significantly affected all DM kinetic parameters ($P<0.001$), with significant forage species × maturity interactions for a, b, PD, and U ($P<0.01$). Increased forage maturity at harvest reduced PD across species ($P<0.001$), with larger declines observed in herbs (H1, 87.4 to 68.2%, early to late cut) and legumes (L1, 87.1 to 75.2%) than in grasses, including G1-highN (84.9 to 81.5%). Legume and herb monocultures exhibited higher c values (0.10 to 0.13 h^{-1}) than grass monocultures (0.07 to 0.08 h^{-1}; $P < 0.001$), indicating faster ruminal DM degradation. However, maturity did not affect c ($P=0.823$), indicating that maturity altered degradation extent and not rate. The 6Sp showed PD comparable to grasses at early cut and similar maturity-related reductions to most monocultures. For CP, forage species and maturity affected a, b, PD, and U ($P<0.001$), whereas c was unaffected ($P>0.05$). Early cut increased CP PD and reduced U. Legumes showed the highest CP PD at both cuts (L1, 92.3 to 81.9%; L2, 90.5 to 80.4%, early to late cut), while herbs exhibited larger maturity-related declines (H1, 86.1 to 62.5%; H2, 68.5 to 53.7%). Grasses showed smaller reductions (G1, 80.9 to 67.5%; G1-highN, 84.7 to 76.3%; G2, 78.6 to 73.5%). The 6Sp maintained intermediate CP PD and a smaller maturity-related increase in U than herbs.Overall, forage species and maturity altered DM and CP degradation primarily through changes in the degradable fraction. Legumes had greater ruminal protein degradability, whereas herbs were more sensitive to advancing maturity. The 6-species mixture moderated maturity-related shifts in degradability, indicating functional stability within grassland-based systems.

Red clover in grass silage-based dairy systems: A meta-analysis

P. Huhtanen[1], G. Baduge[2], M. Vaga[3], S. Krizsan[2]
[1] Natural Resources Institute Finland (Luke), Animal Nutrition, Production Systems, 31600 Jokioinen, Finland, [2] University of Inland Norway, Department of Agricultural Sciences, 2322 Hamar, Norway, [3] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, SE-75007 Uppsala, Sweden

Red clover (RC; Trifolium pratense) is a high-yielding legume capable of fixing atmospheric nitrogen (N), making it an important component of crop rotations and grasslands by helping reduce reliance on fossil-based N fertilisers. Additionally, protein degradation from cutting to ensiling and later in the rumen is lower in RC than in grasses due to the activity of the enzyme polyphenol oxidase. The aim of the study was to evaluate the effects of replacing grass silage (GS) with red clover silage (RCS) on milk production and nutrient supply. This meta-analysis compiled data from published studies, including 85 silage observations from digestibility trials, 33 dietary comparisons with a total of 94 treatments from production experiments, and 16 treatments from four digesta flow studies. Digestibility trials were conducted at MTT Agrifood Research Finland, using sheep, while production and flow data were extracted from published studies on dairy cows. Data were analysed using a mixed model procedure of SAS with study as a random effect and the proportion of RCS (0 – 1 on DM basis) as the independent variable. Compared with GS, RCS had lower NDF of 370 ± 15.2 g kg^{-1} DM vs. 570 ± 10.3 g kg^{-1} DM ($P < 0.01$) and higher soluble fibre concentration, mainly pectin, resulting in faster degradation of digestible fibre. However, the higher indigestible NDF content in RCS compared to GS 109 ± 9.7 g kg^{-1} DM vs. 85 ± 6.7 g kg^{-1} DM ($P < 0.05$) generally contributed to lower total tract digestibility of NDF 620 ± 15.9 vs. 726 ± 11.1 g kg^{-1} ($P < 0.01$), while OM digestibility was not significantly different between silages 704 ± 12.6 vs. 723 ± 8.8 g kg^{-1} ($P = 0.22$). Replacing GS with RCS increased forage and total dry matter intake by 1.7 and 1.6 kg d^{-1}, respectively ($P < 0.01$). Responses to RCS were positive, particularly when fed in mixtures with GS, with milk production increasing by 2.40 kg d^{-1} with increasing replacement of GS by RCS in the diet ($P < 0.01$). However, milk protein and fat concentrations declined by 0.80 and 2.82 g kg^{-1}, respectively ($P < 0.01$) with increasing replacement of GS by RCS, likely due to dilution from increased yield when feeding RCS in the diets. Metabolisable protein intake increased by 209 g d^{-1} ($P < 0.01$); however, N utilisation efficiency decreased by 64 g kg^{-1} ($P < 0.01$) as GS was replaced by RCS in the diet, likely due to higher dietary crude protein levels, which increased N excretion and limited effective use of metabolisable amino acid (AA). Consistent with this, omasal flow of total AA increased by 706 g d^{-1} ($P = 0.03$) with increasing replacement of GS by RCS. Methane (CH_4) emission responses were small and inconsistent, with no significant difference in daily CH_4 production between low and high RCS diets by 463 vs. 475 g d^{-1} ($P = 0.13$). Overall, production of RCS offers agronomic and nutritional advantages but requires careful formulation to optimise N efficiency and milk protein synthesis in dairy systems.

A comparison of Good Agriculture Practices (GAPs) for sustainable dairy farming in South Africa with the RISE 3.0 (Response-Inducing Sustainability Evaluation) tool

T. Blignaut[1,3], E. Van Marle-Köster[1], H. Meissner[2]
[1] University of Pretoria, Animal Science, Lynnwood rd Hatfield, 0002 Pretoria, South Africa, [2] MILKSA, Veale street Nieuw Muckleneuk, 0081 Pretoria, South Africa, [3] Dairy standard Agency, Esdoring Nook Highveld Techno Park, 0157 Centurion, South Africa

Good Agriculture Practices (GAPs) is a central framework to promote sustainable agriculture through environmental stewardship, animal welfare, social responsibility and food safety. In South Africa, the adoption of GAPs is driven by the Dairy Standard Agency (DSA), using structured audit frameworks to evaluate on-farm compliance. The real-world efficacy of DSA_GAP Sustainability audits in promoting sustainable outcomes and the alignment with other sustainability assessment tools remains largely unexplored. The RISE 3.0 is recognised as an indicator-based method for benchmarking sustainability on dairy farms. DSA_GAP audits mainly assess compliance with structured, risk-based standards and regulatory requirements, while RISE 3.0 audits evaluate broader sustainability performance through a indicators-based, outcome-focused assessment across environmental, social, and economic aspects. This study aimed to assess the effectiveness of GAPs in achieving sustainability goals through a comparative analysis of the DSA_GAP Sustainability assessment audit and RISE 3.0 evaluation reports. From 512 dairy farms evaluated in the GAP analyses representing TMR, pasture based and hybrid farms in four regions, 24 farms with verified records and sufficient RISE 3.0 report outcomes across environmental, social responsibility, product compliance, and risk management topics, were considered. Spearman correlations were estimated across 13 comparative theme combinations based on the GAP and RISE sub-theme scores and correlation strengths interpreted using the Asuero et al. (2006) scale. Across of themes, correlations were weak p=0.405 (environment – material) to moderate p=0.466 (social responsibility). In the Social Responsibility theme, a weak moderate correlation (0.348) was found for Animal Husbandry, while no significant correlation was found with Animal Welfare. For the Risk/Economic theme, both Risk Management and Documentation and Information showed weak and non-significant monotonic associations with DSA_GAP Sustainability scores ($\rho < 0.31$; $P > 0.05$). The results demonstrate selective alignment between DSA_GAP Sustainability and RISE 3.0 indicators, primarily within social responsibility and material-use dimensions, while most environmental and risk-related sub-themes show weak or inconsistent monotonic relationships. Although most sub-themes did not reach statistical significance, the overall positive directional trend across themes suggests conceptual alignment between compliance-based GAP implementation and broader sustainability performance. These findings support international evidence that structured management practices contribute positively to environmental and social sustainability outcomes and confirm that certification-based and performance-based frameworks capture overlapping but non-identical dimensions of sustainability. In practice, assessment approaches that combine compliance-based GAP audits with performance-based environ mental metrics could offer a more comprehensive view of farm-level sustainability.

AgroServ: an integrated multi-RI platform supporting agroecological transition in cattle production

R. Baumont[1], D. Baldo[2], M. Boër[2], S. Dramé[2], P. Florent[1], H. Ibrahim[3], R. Pieruschka[3]
[1] INRAE, UMR Herbivores, Route de Theix, 63122 Saint-Genès-Champanelle, France, [2] AnaEE ERIC, Central Hub, 1, av. de la Terasse, 91190 Gif-sur-Yvette, France, [3] IBG-2 Plant Sciences, Forschungszentrum Jülich, 54428 Jülich, Germany

Agriculture today faces a complex set of pressures, with agricultural lands threatened in two aspects: the impact of climate change and the environmental and social consequences of current agricultural practices. To address these challenges, AgroServ, funded by the EU's Horizon Europe program (grant No. 101058020), was launched as a transdisciplinary initiative bringing together researchers, industry, policymakers, and farmers. With 73 partners in over 20 countries, AgroServ provides 143 research services through 12 research infrastructures (RIs). These RIs cover molecular to ecosystem-level sciences, including SmartCow, a leading RI in livestock research, that provides advanced access to diverse cattle types, husbandry systems and cutting-edge animal science technologies to strengthen AgroServ's focus on sustainable animal production. Since 2022, AgroServ has enabled innovation through excellence-based selection of projects combining multiples RIs. SmartCow supports 4 projects, collaborating with other RIs to bridge animal sciences with AgroServ's broader agroecological services, fostering interdisciplinarity solutions. These projects focus on the use of forage legumes, vegetable by-products and feed additives to reduce enteric methane emissions, while maintaining animal performances and quality of animal products. Four Transnational/Virtual Access (TA/VA) calls have been completed (two more planned in 2026), attracting a balanced mix of early-career (57.9%) and established researchers (42.1%). Selected projects (49 to date), represent diverse institutions, including universities (64%), applied research centres (26%), industry (9%) and government (2%). The geographical reach of the proposals was also broad, with global participation, including several low- and mid-income countries. AgroServ's legacy will extend beyond 2027, ensuring continued support for agroecology through enduring networks, open-access services, and cross-border knowledge exchange. By bridging science, policy, and practice, AgroServ empowers resilient, sustainable food systems worldwide.

Exploration of resilience metrics in grazing dairy cows

A. I. Trujillo[1], A. L. Astessiano[1], M. Regueiro[1], E. Jorge-Smeding[1]
[1] UDELAR. Facultad de Agronomia, DPAP, Garzon 780, 11900 Montevideo, Uruguay

Grazing dairy systems require animals with enhanced adaptive capacity to fluctuations in weather and nutrition, making resilient cows highly desirable. Resilience is the ability to be minimally affected by or to rapidly return to the unperturbed state. Time-series data, such as daily milk yield, are required to quantify and rank animals within a herd. Most resilience indicators were developed in confined systems, and their applicability to pasture-based systems remains uncertain. LnVar, calculated from daily milk yield without explicitly identifying macro-perturbation events (MP), may provide a practical resilience metric under grazing. However, due to high daily variability, it is unclear whether LnVar reflects individual resilience to MP. This study evaluated whether lactation-level and stage-specific LnVar reflect individual resilience and cow rankings within the herd, compared to event-based traits rankings during MP in a commercial dairy grazing system in Uruguay. Eighty-three autumn-calving multiparous Holstein cows (mean milk yield: 28.8 ± 5.0 kg/day; mean lactation length: 298 ± 27 DIM), monitored throughout their 2024 lactation, were analyzed. LnVar was calculated as the natural logarithm of the variance of daily milk yield residuals. Predicted milk yield was estimated using a 5th-order polynomial quantile regression (0.5 quantile). LnVar was computed for the entire lactation and for three stages: 21–100, 100–200, and 200–300 DIM. MP were defined as periods of ≥5 consecutive days with a ≥5% decrease in herd milk production relative to potential production. Three MP were identified (MP1–MP3). MP1 (April 22–July 1) was likely associated with rainfall and declining temperatures, while MP2 (October 7–November 18) and MP3 (November 25–December 16) were linked to feeding changes. The herd averaged 45, 213, and 262 DIM at the onset of MP1, MP2, and MP3, respectively. For each MP, the milk loss velocity (Vpert), recovery velocity (Vrecov), and total milk loss (%Loss) were estimated. Cows were ranked within the herd for each trait. Spearman correlations were used to evaluate associations among rankings. Repeatability of each trait was estimated using the intraclass correlation coefficient (ICC) derived from a linear mixed model with individual as a random effect. Concordance of rankings across lactation stages and MP was assessed using Kendall's coefficient of concordance (W). Correlations showed positive associations between overall LnVar and stage-specific LnVar ($r > 0.63$; $p<0.0001$), with the strongest correlation observed for 21–100 DIM ($r = 0.78$; $p<0.0001$). Both overall LnVar and 21–100 DIM LnVar were negatively correlated with %Loss during MP1 ($r = –0.58$ and $–0.49$, respectively; $p<0.0001$). Repeatability was low for all traits (ICC<0.18). However, Kendall's W indicated moderate agreement for LnVar rankings across lactation stages ($W = 0.57$; $p<0.01$), while concordance for Vpert across MP was weaker and non- significant ($W = 0.42$; $p = 0.067$). Vrecov and %Loss showed low and non-significant agreement ($W <0.40$; $p>0.10$). LnVar consistently reflected individual rankings, with early lactation influencing overall LnVar due to higher milk yield and increased susceptibility to perturbations. The association between LnVar and milk loss during MP1 suggests that perturbations occurring in early lactation contribute more strongly to LnVar than events occurring later or with lower impact. Despite moderate consistency in rankings, the low repeatability indicates that within-individual variation exceeded between-individual variation. These findings suggest further research is needed to validate LnVar as a robust resilience indicator for identifying superior animals under challenging conditions.

Resilience indicator and productive performance in a commercial grazing dairy farm

A. I. Trujillo[1], M. Regueiro[1], E. Jorge-Smeding[1], A. L. Astessiano[1]
[1] UDELAR-Facultad de Agronomia, DPAP, Avda. Garzón 780, 12900 Montevideo, Uruguay

Dairy cows under grazing conditions are particularly required to be resilient to environmental challenges. This study explored the relationship between the resilience indicator LnVar across the entire lactation and animal performance in a commercial grazing dairy farm in Uruguay. Eighty-three autumn-calving multiparous Holstein cows (mean milk yield: 28.8 ± 5.0 kg/d; mean lactation length: 298 ± 27 DIM; parity: 3.2 ± 1.2) from a commercial dairy farm located in the main dairy basin of Uruguay (temperate climate) were monitored throughout their 2024 lactation. During the prepartum period, cows were fed a corn silage–based TMR, whereas during lactation they grazed alfalfa and oat pastures and were supplemented with a corn silage–based TMR at a feedpad (5–10 kg DM/d). Milk yield was recorded daily, and body condition score (BCS, 1–5 scale) and body weight were assessed at −30, at parturition, and at 21, 100, and 200 ± 15 DIM. Resilience was quantified as LnVar, calculated as the natural logarithm of the variance of daily individual milk yield residuals. Predicted milk yield was estimated using a fifth-order polynomial quantile regression (0.5 quantile). Higher LnVar values indicate lower resilience. Cows were ranked according to LnVar values, and animals with the highest and lowest resilience were selected (High-Res, n = 8; Low-Res, n = 8). Data were analyzed using mixed models including parity and DIM as covariates. High-Res and Low-Res cows differed significantly in LnVar (2.32 vs 3.34 ± 0.04, mean ± SEM; $P < 0.001$). High-Res cows showed lower mean milk yield (26.5 vs 30.7 ± 1.2 kg/d, $P = 0.0306$), lower peak milk yield (31.9 vs 38.6 ± 1.56 kg/d, $P = 0.032$), and lower accumulated milk yield (7,700 vs 8,973 ± 307 kg, $P = 0.015$). However, body condition score at 21 DIM was greater in High-Res cows compared with Low-Res cows (3.3 vs 2.7 ± 0.12, $P = 0.01$). These results suggest that cows classified as highly resilient tended to have lower milk production but better body condition during early lactation. However, it remains unclear whether this relationship reflects a cause or a consequence of resilience, and further research is needed to clarify this association. The greater body condition may indicate a more favorable nutritional status, which could potentially translate into improved reproductive efficiency.

Effect of incorporating Bromus valdivianus Phil. on the nutritive value of a mixed pasture during the spring–summer season in southern Chile

R. G. Pulido[1], I. Calvache[1,2], B. Barría[2], C. Asenjo[2], J. P. Keim[2], O. A. Balocchi[2]
[1] Universidad Austral de Chile, Ciencia Animal, PO Box 567, 5190000 Valdivia, Chile, [2] Universidad Austral de Chile, Producción Animal, PO Box 567, 5190000 Valdivia, Chile

Nutritive value varies with climatic conditions and plant phenology, making the inclusion of nutritionally stable forage species essential for sustaining milk production. Consequently, Bromus valdivianus Phil., a native species from southern Chile, shows strong summer performance and a high nutritive value. The objective of this study was to evaluate the nutrient concentration of a polyphytic pasture (Pol) composed by Lolium perenne L., Trifolium repens L., and Bromus valdivianus Phil., compared to a mixed pasture (Mx; Lolium perenne L. and Trifolium repens L) during the spring–summer period in southern Chile. Three sectors were used, each divided into two pasture types: one Mx and one Pol. Sampling was conducted weekly using a 0.25 m² quadrat thrown randomly three times, cutting at 5 cm above ground level, with a total of 554 samples collected across both seasons. Regarding climatic conditions during the study, in spring 2024 temperatures ranged between 5–25 °C with constant rainfall of 5–10 mm, while in summer temperatures ranged between 15–35 °C and precipitation was concentrated at the end of the season, reaching 70 mm. Nutritive value was estimated using near-infrared reflectance spectroscopy (NIRS). The results showed that nutritive value concentrations (CP %, ME Mcal kg^{-1} DM, NDF %, ADF %, and NSC Mcal kg^{-1} DM) did not differ between pasture types during spring. In summer, polyphytic pasture showed higher crude protein (CP) concentrations (+0.85 percentage units) than that of MX (18.9 vs. 18.05% for Pol and Mx, respectively). Neutral detergent fiber (NDF) was also higher in Pol (59.48%) than in Mx (57.92%; +1.56 percentage units), while acid detergent fiber (ADF) averaged 30.31% in Pol and 29.10% in Mx (+1.21 percentage units). In contrast, metabolizable energy (ME) did not differ between pasture types, averaging 2.62 and 2.56 Mcal kg^{-1} DM for Mx and Pol, respectively. In terms of accumulated nutrients (kg ha^{-1}), the Pol pasture showed significantly higher values than Mx across both seasons for all variables. Overall, the polyphytic pasture outperformed the mixed pasture during summer in both nutrient concentration and accumulation (CP, NDF, and ADF), supporting its suitability as a forage option for this season in southern Chile.Project financed by FONDECYT 1240451.
Project financed by FONDECYT 1240451.

Polyphenol oxidase activity, phenolic concentration and utilisable crude protein in red clover (Trifolium pratense L.) accessions

G. Baduge[1], M. Vaga[2], S. Krizsan[3]
[1] University of Inland Norway, Department of Agricultural Sciences, 2322 Hamar, Norway, [2] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, SE-75007 Uppsala, Sweden, [3] University of Inland Norway, Department of Agricultural Sciences, 2322 Hamar, Norway

Red clover (RC) is an important forage legume in northern Europe due to its high protein content and ability to fix N from the air through symbiosis with soil bacteria. Further, RC has high polyphenol oxidase (PPO) activity and a high concentration of phenolic substrates. Upon activation, PPO catalyses the oxidation of phenolic compounds, which subsequently interact with plant proteins to form complexes that are less susceptible to ruminal degradation. If effectively utilised, RC has strong potential as a future sustainable protein feed resource. In this study, we made use of a unique RC accession material developed within the Grogrund project "Genomic selection of red clover". The RC accessions represented synthetic cultivars, landraces and commercial varieties from the Nordic countries. We examined whether RC type and ploidy were associated with PPO activity, phenolic compound concentration, and in vitro-determined metabolisable protein (utilisable crude protein, uCP) and whether traits were interrelated. Forty-four accessions were evaluated (20 diploid and 20 tetraploid), including four control varieties (two diploids and two tetraploids). The analysed accessions consisted of synthetic, commercial and landrace varieties. Herbage was harvested at the second cut in 2023, wilted, chopped, and ensiled with formic acid-based additives in plastic bags using a vacuum machine to establish an oxygen-depleted environment. Phenolic concentration and PPO activity were measured in fresh RC leaf material. Utilisable crude protein at 16 h rumen retention time (uCP16) was estimated from the ensiled material using a fully automated gas in vitro system. Silages were also analysed at Dairy One (Ithaca, NY, USA) for Cornell protein fractions. Silages were well preserved as indicated by adequate lactic acid content (81.2 ± 13.77 g/kg DM), a negligible amount of butyric acid (0.5 ± 0.04 g/kg DM) and low ammonia-N (28.1 ± 5.41 g/kg total N). Diploid accessions had higher uCP values than tetraploids (196 ± 1.60 vs 184 ± 1.70 g/kg DM; $P < 0.01$). Compared with commercial types (184 ± 2.22 g/kg DM), landraces (195 ± 3.07 g/kg DM; $P < 0.01$) and synthetic cultivars (192 ± 1.04 g/kg DM; $P < 0.01$) showed higher uCP values. Crude protein also significantly influenced uCP ($R_2 = 0.73$; RMSE = 5.78; $P < 0.01$). Similarly, several Cornell protein fractions were significant predictors of uCP, including soluble protein ($R_2 = 0.32$; RMSE = 8.54; $P < 0.01$), insoluble true protein ($R_2 = 0.29$; RMSE = 8.70; $P < 0.05$), and indigestible protein ($R_2 = 0.30$; RMSE = 8.65; $P < 0.01$). Phenolic concentrations varied among RC types, with higher values in commercial types (28.4 ± 3.64 mg g^{-1} DM) than in landraces (23.8 ± 3.90 mg g^{-1} DM; $P < 0.05$) and synthetic populations (24.4 ± 3.59 mg g^{-1} DM; $P < 0.01$). Similarly, active PPO activity (Δ min^{-1} mg^{-1} FM) differs among RC types ($P < 0.01$), with the highest values observed in landraces (292 ± 78.3), followed by commercial cultivars (180 ± 69.3) and synthetic cultivars (143 ± 67.5). The differences observed among the RC accessions suggest genetic diversity in protein utilisation traits. Variation in RC type and ploidy levels across these traits can be strategically leveraged to enhance breeding programmes aimed at improving protein utilisation efficiency.

Winter grazing or bale haylage fed indoors for pregnant heifers: growth performance and synthesis of welfare and behavioral indicators

V. Brocard[1], D. Fouvez[2], G. Trou[2], S. Schetelat[1], D. Benoit[2], E. Tranvoiz[2], M. Le Guenic[2]
[1] Institut de l'Elevage, Monvoisin, 35650 Le Rheu, France, [2] Chambre d'agriculture de région Bretagne, RP M Le Lannou, 35000 Rennes, France

Climate change is leading to milder winters and a persistence of grass growth later into autumn and even winter in the most oceanic regions. Since 2021, trials have been conducted at the Trévarez experimental station (western France) to provide reference data on the nutritional value of autumn/winter grass and its utilization by dairy heifers in an oceanic climate. The objective of this work was to study the potential use of winter grass by dairy heifers and to compare the performance of these animals with that of heifers kept indoors and fed bale silage. These results are complemented by animal welfare and behavioral data to evaluate the impact of winter grazing on animals under weather conditions considered potentially less favorable than in spring. A trial was therefore carried out over three winters from 2021 to 2023. Each year, twelve pregnant Holstein heifers raised under conventional farming conditions were divided into two homogeneous groups (IND group and GRAZ group) and paired accordingly. The trial began between November 4 and 14 depending on the year and ended between February 6 and 9, for a total duration of 85 to 97 days. Heifers in the IND group spent the winter indoors on a straw-bedded area and were fed wrapped round bales (bale silage) without any concentrate supplementation. Heifers in the GRAZ group spent the winter at pasture, without any supplementary forage or concentrate. Each winter, the grazing heifers used between 9 and 12 paddocks averaging 1.3 ha (0.75 to 2.59 ha), with an average residence time of 9 days per paddock (2 to 17 days) and an instantaneous stocking rate of 3 livestock units per hectare. During the trial, rainfall ranged from 186 mm to 528 mm depending on the winter, with an average temperature of 7 °C and between 7 and 20 days of frost (down to −7 °C). The crude protein content of winter-grazed grass was high (20–22% CP in DM) and higher than that of bale silage. Average daily gains of the two groups were not significantly different and met the target levels over the three winters (826 to 1094 g/day for the IND group and 907 to 1005 g/day for the GRAZ group). The indicators selected to assess animal welfare (body condition score, lameness, and injuries) were derived from the Welfare Quality Protocol (2009) and the Boviwell tool. The welfare evaluation was only performed during one winter (2023/24). The welfare indicators did not differentiate between the two groups. However, a difference was observed regarding cleanliness: animals became dirty indoors from December onwards, whereas they remained clean at pasture throughout the trial. Twice as many social behaviors were observed indoors compared with grazing, mainly agonistic behaviors. At the end of the trial, no marked difference was observed between the two groups regarding the human–animal relationship. The nutritional value of winter grass and its utilization by heifers over the three years indicate that it is a forage of real interest. Grazing carried out under the conditions described did not appear to cause particular difficulties for the pastures. Under the winter conditions of 2023–2024, winter grazing of pregnant heifers did not reduce animal welfare. The quality of social interactions also appeared less negative at pasture, with less competition between animals.

Chemical composition, in vitro digestibility, and methane production of selected fodder trees in late summer

E. Manzocchi[1], J. Botzas-Coluni[2], A. Manoukians[1], M. Probo[2], M. Terranova[3], P. Mariotte[2]
[1] Ruminant Nutrition and Emissions, Agroscope, Tioleyre 4, 1725 Posieux, Switzerland, [2] Grazing systems, Agroscope, Tioleyre 4, 1725 Posieux, Switzerland, [3] AgroVet-Strickhof, ETH Zurich, Eschikon 27, 8315 Lindau, Switzerland

Climate change increasingly exposes livestock systems to recurrent summer droughts, reducing pasture productivity and the availability of high-quality forage. In this context, fodder trees gain renewed interest as resilient resources thanks to their deep roots and ability to supply biomass when herbaceous vegetation declines. This study evaluated the chemical composition, in vitro digestibility, methane (CH_4) production potential, and palatability of leaves from five tree species (Alnus cordata, Fraxinus ornus, Morus alba, Salix caprea, and Tilia cordata). Leaves were collected in August 2024 from forage hedgerows established on grassland plots within the AgroForageTree project in Western Switzerland. A short-term palatability test was conducted on six castrated male sheep (license 2024-14-FR) to assess intake of the leaf species compared with a control hay (grass-rich grassland, 1st cut, full heading). The in vitro organic matter digestibility (IVOMD) and CH_4 production were quantified using the Hohenheim Gas Test. Five diets consisting of 80% control hay and 20% freeze-dried leaves (DM basis), plus a 100% hay control, were incubated in three runs using rumen fluid from two rumen-cannulated dry cows (license ZH113/18), with three analytical replicates per diet. Condensed tannins were analysed by the HCl-butanol method, and diet chemical composition by Weender analysis. After 24h incubation, pH, ammonia, and volatile fatty acids (VFA) were measured in the liquid phase. Total gas production over 24 h was recorded, and CH_4 and CO_2 concentrations were determined by gas chromatography. Data were averaged by replicate and analysed in R using linear mixed-effects models with tree species as fixed and run as random effect. Salix caprea was the most palatable species (palatability index 106%), while Alnus cordata was the least consumed (palatability index 49%). Mixed-diet IVOMD ranged from 57 to 66%, with the highest digestibility ($P < 0.01$) for Morus alba (66±0.9%), similar to the control hay (65±0.9%). The lowest IVOMD ($P < 0.01$) occurred with Alnus cordata (57±0.9%), while the remaining species showed intermediate values. Total VFA were highest for Morus alba (59±2.2 mM) and Tilia cordata (58±2.2 mM), and lowest for Alnus cordata (52±2.2 mM). The Morus alba diet also yielded the highest ammonia concentration (9.9±0.5 mmol/L; $P < 0.01$), consistent with the elevated crude protein content of M. alba leaves (198±8.8 g/kg DM). The lowest CH_4/CO_2 ratio was observed with Salix caprea (143±6.7 ml/l), likely due to its higher condensed tannin content ($P < 0.01$), known to inhibit methanogenesis. In contrast, Fraxinus ornus, Morus alba, and the control hay produced the highest CH_4/CO_2 ratios (151±6.7 ml/l; $P < 0.01$). In summary, Morus alba showed the most promising nutritive characteristics, while Salix caprea displayed the strongest potential for reducing CH_4 emissions in vitro. Further research, including in vivo trials at farm scale, is needed to evaluate biomass production, intake, and the integration of fodder trees into grazing systems.

Agolin and Polygain Supplementation Reduces Methane Production Without Affecting Blood Metabolites in Grazing Sheep Under Commercial Farm Conditions

B. Z. Tunkala[1], K. Anderson[1], M. Flavel[2], I. Sawyer[3], R. Eckard[1], F. Dunshea[1,4], S. S. Chauhan[1]
[1] The University of Melbourne, Faculty of Science, Dookie College, 3647 VIC, Australia, [2] The Product Makers Pty Ltd, Keysborough, 3173 VIC, Australia, [3] Feedworks Pty Ltd, Romsey, 3434 VIC, Australia, [4] The University of Leeds, Faculty of Biological Sciences, Leeds, LS2 9JT Leeds LS2 9JT, United Kingdom

Enteric methane from ruminant livestock contributes substantially to agricultural greenhouse gas emissions and represents an energy loss accounting for up to 12% of dietary intake in sheep. Feed additives such as plant essential oils and polyphenol extracts have shown potential to reduce methane production while maintaining productivity in ruminants. However, most studies have been conducted under controlled conditions, and evidence from commercial production systems remains limited. This study tested the hypothesis that supplementation with Agolin (an essential oil blend) and Polygain (a sugarcane polyphenol extract), individually or combined, would reduce methane emissions in grazing lambs without negatively affecting growth performance or animal health. A total of 200 crossbred lambs (≈3 months old) were allocated to four treatment groups (n = 50 per group): control, Agolin (0.0002% of the body weight per day), Polygain (0.25% of dry matter intake (DMI) per day), and a combination of Agolin and Polygain in half doses each. Animals grazed pasture in separate paddocks on a commercial farm in Northern Victoria and received daily pellets blended with the assigned supplements for 80 days. Methane emissions were measured rotating groups through a GreenFeed emission monitoring unit during multiple measurement periods. Body weight was recorded every three weeks. Blood metabolites were analysed to assess metabolic and health status before and after supplementation. Data were analysed using mixed-model statistical procedures in GenStat 23rd edition with treatment as a fixed effect and individual animal as a random factor. Initial body weights were similar across groups (~37 kg), confirming baseline uniformity. Supplementation did not affect body weight gain or average daily gain throughout the study. Methane production (g/day) was significantly lower in Agolin (35), Polygain (36.9) and combination (34) groups compared to the control group (38.5) ($P < 0.001$). Methane intensity was numerically reduced by 9.78% with the combined additives and by 5.96% with Polygain alone ($P < 0.10$). Most blood biochemical indicators, including urea, albumin, non-esterified fatty acids, liver enzymes, and creatinine, were not affected by the treatments, suggesting no negative impact on animal health and physiology. Overall, Agolin and Polygain supplementation did not compromise growth performance or key metabolic health indicators in lambs. The significant reduction in methane production, particularly when the additives were combined, indicates potential additive effects in sheep under commercial grazing conditions. These findings support the hypothesis that feed additives can reduce methane emissions without reducing productivity. Further study with longer monitoring periods is needed to confirm the magnitude of the mitigation effect and evaluate the economic feasibility of adoption in commercial farms.

Modifying aspects of ruminal fermentation to mitigate enteric methane generation in goats through the use of saponin- and tannin- rich plant sources - A meta-analysis.

E. Malematja[1], K. Daniel[1], M. Mabelebele[1], J. W. Ng'Ambi[1]
[1] University of South Africa, Department of Agriculture and Animal Health, 28 Pioneer Ave, Florida Park, Roodepoort, 1710 Johannesburg, South Africa

The present meta-analysis attempts to integrate data from various studies in order to increase statistical power, identify the research gaps, resolve conflicts, and provide up-to-date, comprehensive information on the use of saponin- and tannin-rich plant sources to improve rumen fermentation products as well as to mitigate enteric methane (CH4) generation in small ruminants, particularly, goats. Thirty-two (32) studies retrieved from Google Scholar, Web of Science, Scopus, and PubMed and extracted data on Dry matter intake (DMI), fermentation efficiency (FE), rumen- pH, -ammonium- nitrogen (NH3-N), total volatile fatty acid (TVFAs), -bacteria population, -protozoa population, and CH4 from these studies were subjected to random-effects model in OpenMEE statistical software for meta-analysis. The results were presented as standardized mean difference (SMD) at a 95% confidence interval (CI). Meta-analysis results revealed a significant increase in propionate (SMD= 0.71; CI= 0.21, 1.21) and a reduction in the ratio of acetate to propionate (SMD= -0.98; CI= -1.57, -0.38). Furthermore, pooled results revealed a significant reduction in NH3-N (SMD= -1.34; CI= -1.86, -0.83), protozoa population (SMD= -1.08; CI= -1.95, -0.22) and CH4 (SMD= -0.84; CI= -1.16, -0.51). Subgroup analysis showed that higher inclusion levels (>30%) had increased acetate, the ratio of acetate to propionate, and bacterial populations. However, NH3-N and protozoa populations were reduced by higher inclusion levels (>30%). Similarly, feeding duration, sex, and phytochemical compounds were predictors for propionate, butyrate, NH3-N, bacteria, and protozoa population in goats supplemented with saponin- and tannin-rich plant sources. Meta-regression analysis using a moderator revealed negative relationships between NH3-N, bacterial population, protozoa population and sex. Similarly, feeding duration was linearly related to bacteria population, while inclusion level was linearly related TVFAs, NH3-N, bacteria population, and enteric CH4. In conclusion, supplementing saponin- and tannin-rich plant sources improved rumen fermentation parameters and successfully reduced protozoa populations and enteric CH4 generation, with no adverse effects on DMI. Key words: phytochemical compounds, fermentation parameters, rumen characteristics, ruminants, rumen microbes

Effects of individual and combined feed additives on ruminal in vitro fermentation characteristics.

B. Hiley[1], Í. R. R. Castro[1], S. Huws[1], K. Theodoridou[1]
[1] Queen's University Belfast, 19 Chlorine Gardens, BT9 5DL Belfast, United Kingdom

To achieve sustainable agricultural and food security, livestock production efficiency needs to improve. Enteric methane (CH4) from ruminants represents both a dietary energy loss and a major greenhouse gas emission. Whilst many feed additives reduce methane in vitro, effects are inconsistent and may disrupt fermentation characteristics. Combining additives with differing modes of action may stabilise results, benefit other fermentation characteristics, and reduce microbial adaption for long-term use. This study assessed seven feed additives individually and in combination at two doses (full and half doses that were tested individually). Additives included seaweeds (Ulva sp. [UV1] and Solieria chordalis [SC1]), essential oils (capsicum [CAP], oregano [ORE] and Cinnagenol [CNG]; cinnamaldehyde:eugenol 3:1) and commercial or near-market additives (Golf [GLF] and Feed Additive 1 [FA1]). Batch fermentations were conducted 3 times in 100 mL serum jars using a grass silage (perennial ryegrass) substrate and filtered rumen fluid collected from abattoir from 5 animals, buffered with Van Soest (1:1 ratio). Additives were analysed in triplicate alongside blank and control incubations for 24h at 39°C. Measurements included pH, gas production, ammonia-N, digestibility, methane production and yield, and volatile fatty acid (VFA) profiles. Data were analysed in RStudio using ANOVA or Welch's ANOVA with Tukey or Dunn post-hoc tests, when significant ($P<0.05$). Individually, FA1 was the only additive to significantly reduce CH4 production and yield (-53.6% and -54.7%, respectively) relative to the control. FA1 also significantly reduced total gas production (-18.3%) and increased pH (3.6%), whilst non-significantly increasing digestibility (5.7%), ammonia-N (13.8%), Acetate:Propionate (A:P) ratio (11.6%) and total VFA (8.1%). No additive significantly altered ammonia-N, digestibility or VFA production. Additive combinations using FA1 as a base maintained significant CH4 reductions. The most consistent responses occurred with FA1+CNG and FA1+ORE. FA1+CNG reduced CH4 production by 53.8% (full dose) and 50.2% (half dose), whilst FA1+ORE reduced CH4 production by 52.2% (full dose) and 52.4% (half dose). Dry matter digestibility increased numerically across all treatments, with the greatest increases observed for FA1+CNG and FA1+ORE full doses (24.9% and 27.8%). Methane yield declined significantly for all combinations; FA1+CNG and FA1+ORE full doses reduced yield from 6.43 mL/g digested organic matter to 2.33 and 2.32 mL/g, equivalent to reductions of 60.7% and 62.2%, respectively. Only these two combinations reduced the A:P ratio at both doses, however not-significantly. Total gas production decreased across treatments, significantly for FA1+ORE at both doses. Total VFA was numerically decreased by all treatments except for the FA1+GLF half dose and FA1+CAP full dose. The pH was significantly increased in all treatments, whereas ammonia-N and individual VFA fractions were unaffected by all treatments. Overall, additive combinations sustained CH4 mitigation without detrimental effects on key fermentation parameters. Although statistical significance was not observed for digestibility, ammonia-N, or A:P ratio, numerical improvements indicated potential interactions were present, particularly for FA1+CNG and FA1+ORE. The stated combinations highlighted improvements beyond that of stacking the results of the additives individually. These findings suggest combining feed additives, with differing modes of action, may enhance methane mitigation strategies whilst supporting rumen fermentation and therefore warrant further in vivo evaluation for application within the livestock sector.

Assessment of some Mediterranean shrubs by in vitro studies: total gas production and CH4, CO2, H2, O2, N2 profiles

A. Cabiddu[1], B. Solinas[2], G. Moniello[2], P. A. Ruiu[1], G. M. Marrosu[1], M. Decandia[1], M. Acciaro[1], V. Giovanetti[1], M. G. Serra[1], M. Niolu[1], S. Rodrigo[4], G. Moreno[4], E. Sales-Baptista[5], A. Oliveira[5], M. I. Ferraz De Oliveira[3,5]

Bonassai, 07100 Sassari, Italy, [2] Università degli Studi di Sassari, Facoltà di Medicina veterinaria, Via Vienna 2, 07100 Sassari, Italy, [3] Evora University, Livestock Department, Largo dos Colegiais, 2, 7000-803 Evora, Portugal, [4] University of Extremadura, Department of Plant Biology, Ecology and Earth Science, Avenida Virgen del Puerto 2, 10600 Plassencia, Spain, [5] MED Mediterranean Institute for Agriculture, Environment and Development & CHANGE Global Change and Sustainability, Polo da Mitra, 7000-083 Evora, Portugal

In Mediterranean countries, shrub species often represent the main available feed resource for grazing ruminants, particularly when grass is scarce or inexistent. Extensive livestock systems, plays a crucial socio-economic role and is frequently one of the few viable economic activities. Woody species are generally characterized by moderate crude protein (CP) content and high concentrations of phenolic compounds; however, these values can vary considerably among species and according to phenological stage. The low nutritional value of shrubs is largely affected by their lignified fraction, phenols and other plant secondary compounds. Although plant secondary metabolites are commonly regarded as antinutritional factors in ruminants, phenolic compounds are known to inhibit ruminal biohydrogenation and may contribute to methane production mitigation. The objective of this work, carried out as part of the LIFE Scrubsnet project, was to evaluate the effect of different shrub species on ruminal fermentation with particular emphasis on methane production. Twig samples (mainly leaves) from shrubs collected in Spain, Portugal and Italy were characterized for their chemical composition and assessed for in vitro total gas production and gas profile (CH4, CO2, H2, O2 and N2). The shrub species evaluated were Arbutus unedo (AU), Quercus ilex (QI) and Morus alba (MA) and they were compared with corn silage (CS) as a control. Two fermentation runs were performed. Samples (440 ± 0.2 mg) were incubated in triplicate with 40 mL of medium and 20 mL of rumen fluid. The average NDF content (% DM) was 20.94, 50.64, 35.11 and 41.79 for MA, QI, AU and CS respectively. Crude protein content (% DM) was 19.00, 8.92, 8.15 and 7.78 while phenols (% DM) were 2.31, 10.14, 9.78 and 0.00 for MA, QI, AU and CS respectively. Total cumulative gas production (GP) as well as CH4, CO2, H2, O2 and N2 were measured at 24 hr of incubation and expressed as mL/g DM incubated. Data were analysed using a GLM model including forage species as a fixed effects. The relationship between gas production and the chemical composition of the studied species was analyzed using linear regression models. The total gas production was significantly higher ($P < 0.001$) in MA and CS compared with AU and QI. A similar trend was observed for methane emission, with MA and CS showing approximately twofold higher CH4 emissions ($P < 0.001$) than AU and QI. The CO2 production was higher ($P < 0.01$) in MA compared with the other treatments. The NDF content affected negatively the total gas production ($r_2 = -0.39$; $P < 0.01$) and CH4 ($r_2 = -0.30$; $P < 0.01$). The phenols content affected negatively the total gas production ($r_2 = -0.50$; $P < 0.01$) and CH4 production ($r_2 = -0.27$; $P < 0.01$). No significant differences were detected among the forage species for N2, H2 and O2 production. These results confirm that Mediterranean shrubs species can significantly modulate ruminal fermentation patterns, potentially contributing to improved environmental sustainability of extensive livestock systems through reduced methane emissions.

Dose-Dependent Modulation of Methane Production, Rumen Fermentation, Digestibility and Rumen Microbial Community by L-Carvone: An in vitro Study

H. Jalal[1], L. Pompei[1], M. Giammarco[1], M. Irfan Malik[2], S. Akram[3], C. Chaves Lopez[3], M. Zeeshan Akram[4], F. Ghiaccio[5], R. Colleluori[5], I. Fusaro[1]

[1] University of Teramo, Department of Veterinary Medicine, Loc. Piano d'Accio, 64100 Teramo, Italy, [2] The University of Tennessee Institute of Agriculture (UTIA), Department of Animal Science, Knoxville, TN 37996 Knoxville, United States, [3] University of Teramo, Department of Bioscience and Technology for Food, Agriculture and Environment, Via R. Balzarini 1, 64100 Teramo, Italy, [4] KU Leuven, Nutrition and Animal-Microbiota Ecosystems Laboratory, Department of Biosystems,, Heverlee,, 3001, Leuven, Belgium, [5] University of Bologna,, Department of Veterinary Medical Sciences,, Ozzano Emilia,, 40064 Bologna, Italy

There is growing interest in natural feed additives to mitigate ruminal methane emissions. This study evaluated L-carvone (LC), a monoterpene compound from essential oils, for its dose-dependent effects on rumen fermentation, in vitro dry matter digestibility (IVDMD), methane production, and microbial composition. Three treatments were tested: a basal diet (total mixed ration; TMR + 0 µL/L LC), LC250 (TMR + 250 µL/L LC), and LC500 (TMR + 500 µL/L LC), using a 59:41 concentrate-to-forage substrate. Fermentation parameters were analysed using the Gas Endeavour system and 16 S rRNA gene sequencing was applied to investigate the ruminal microbiota profile. Data were evaluated via linear mixed models with treatment as a fixed factor and experimental runs as a random factor. Pairwise comparisons were performed using Bonferroni correction, with P value below 0.05 considered significant. Total gas and methane production decreased progressively with increasing LC inclusion, with significant reductions observed only at LC500 ($P < 0.001$). Similarly, LC500 reduced methane production by 28% ($P < 0.001$) and decreased IVDMD by approximately 15%, while LC250 showed a numerical but non-significant reduction in methane production without affecting IVDMD. Total volatile fatty acid (VFA) concentration was reduced in LC500 ($P < 0.01$) as compared to TMR and LC250, mainly due to lower propionate, iso-butyrate, and iso-valerate concentrations, while the proportion of butyrate increased from the TMR to LC250 and was highest at LC500 ($P < 0.05$). Ammonia-N concentration also decreased in LC500 ($P = 0.040$). Alpha diversity was highest in LC250, while beta diversity indicated significant microbiota compositional divergence among treatments ($P < 0.05$). Increasing LC supplementation reduced Bacteroidota abundance such as Prevotella genus, while increased Firmicutes, particularly butyrate-producing genera such as Butyrivibrio, Pseudobutyrivibrio, and Ruminococcus. These results suggest that LC can modulate rumen fermentation by altering VFA production and reducing methane emissions through shifts in the rumen microbiota. Optimizing the inclusion rate is therefore essential to achieve methane mitigation without impairing feed digestion.

In Vitro Assessment of Eucalyptus and Ginger Essential Oils on Methane Production in Rumen Fermentation

F. Ghiaccio[1], A. Federiconi[1], V. Piensi[1], V. Palanca[1], R. Colleluori[1], L. Zambianchi[1], P. Parazza[1], A. Formigoni[1], A. Palmonari[1]

[1] University of Bologna, Department of Veterinary Medical Science, Via Tolora di sopra, 50, 40064 Ozzano dell'Emilia (BO), Italy

The global demand for sustainable livestock farming has intensified research into strategies aimed at reducing the environmental footprint of ruminant production. Methane (CH_4), a by-product of rumen fermentation, can represent an energy loss of up to 12% for the animal and contributes to global warming due to its high greenhouse potential. Essential oils have been proposed as natural feed additives for reducing CH_4 emissions through modulation of rumen fermentation, particularly via their effects on ruminal protozoa and methanogenic bacteria. Ginger essential oil (GEO) contains bioactive secondary metabolites, that alter protozoan membrane permeability and inhibit glycolytic enzyme activity. Previous studies reported that GEO can reduce CH_4 by 16–21%, though effects on total gas, the acetate: propionate ratio and ammonia (NH_3) have been inconsistent across the studies. Eucalyptus essential oil (EEO), rich in cineole and eucalyptol, has shown stronger anti-methanogenic and antiprotozoal activity, with protozoa reductions of up to 64.5% and dose-dependent CH_4 inhibition reported in vitro, although high in vivo dosages may reduce feed palatability. We hypothesized that both oils would reduce in vitro CH_4 production compared to CTR, with EEO showing greater inhibition based on its reported anti-methanogenic and antiprotozoal properties in the literature. Therefore, this study investigates the impact of GEO and EEO on CH_4 emission and NH_3 concentration using the Gas Endeavour System® (GES; Bioprocess Control, Lund, Sweden), an in vitro rumen fermentation system. The experiment was conducted over 3 independent fermentation trials, each performed on a separate day to account for daily variability. Each fermentation included two treatment conditions (GEO, EEO) and control (CTR; TMR without additives). Both oils were tested at a single concentration of 22.5 mg/L of fermentation medium, derived from in vivo recommendations (40–50 mg/head/day) and scaled using a conversion formula accounting for rumen volume (100 L) and reactor capacity (0.5 L), with a 5-fold adjustment factor to account for the inherent differences between in vitro and in vivo conditions. CH_4 production was measured at 8h, 12h and 24h. Fermentation liquid phase samples were collected after 24h and analysed for pH and NH_3. Data were analysed using one-way ANOVA and treatment means were compared with CTR using Dunnett's test. At 24h, both EO significantly reduced CH_4 production compared to CTR (CTR: 313.7 ± 52.4 ml; GEO: 238.0 ± 50.2 ml, −24.1%; EEO: 81.8 ± 6.7 ml, −73.9%, $p<0.05$). At earlier time points, only EEO showed statistically significant CH_4 inhibition ($p<0.05$), while GEO did not differ significantly from CTR at 8h or 12h. NH_3 concentration was not significantly affected by either treatment ($p>0.05$). Overall, EEO demonstrated a stronger and more consistent in vitro anti-methanogenic effect than GEO at the tested inclusion level, with a CH_4 reduction nearly three times greater at 24h. The GEO reduction (−24.1%) is consistent with the 16–21% range previously reported in the literature, while the EEO result (−73.9%) exceeds prior estimates and aligns with its known antiprotozoal and antibacterial mechanisms of action. These findings support the potential use of EEO as a natural CH_4 mitigation strategy. Further research is required to assess its impact on broader rumen fermentation dynamics, including VFA profile and digestibility, and to confirm efficacy under in vivo conditions.

In vitro screening of potential synergistic combinations of garlic, cinnamon and oregano to decrease rumen methanogenesis

A. H. Chekikene[1], J. Muñoz-Grein[1], M. Mireaux[2], A. Belanche[1]
[1] University of Zaragoza, Department of Animal Nutrition and Food Science, Miguel Servet 177, 50013 Zaragoza, Spain, [2] CCPA France, ZA Bois de Teillay, 35150 Janzé, France

Reducing methane (CH4) emissions while maintaining or even increasing rumen fermentation efficiency represent a challenge in ruminant production. This study aimed to evaluated the effects of combining up to three natural feed additives including garlic extract (G), and essential oils from cinnamon (C) and oregano (O) on rumen CH_4 emissions and fermentation patterns. Two in vitro experiments were conducted using batch cultures inoculated with rumen fluid from 4 cows and a 60:40 forage to concentrate diet. Experiment 1 was a dose-response trial in which 4 doses of garlic extract (up to 0.12 g/L), cinnamon EO and oregano EO (up to 2 g/L) were incubated for 24h to determine the optimal dose for the next experiment. Experiment 2 evaluated 11 treatments, including the control, individual additives (100%G, 100%C and 100%O), binary (50G-50C, 50G-50O and 50C-50O) and ternary combinations (33G-33C-33O, 75G-12C-12O, 12G-75C-12O and 12G-12C-75O). Treatments were incubated during 5 days with daily media renewal. Rumen fermentation parameters, gas and CH4 production were measured at 24h and day 5. The effects of additive combinations were further assessed using ANOVA and Bliss independence analysis to compare expected versus observed responses and to identify additive, synergistic or antagonistic effects among feed additives. In Experiment 1, garlic extract demonstrated a strong antimethanogenic potential, reducing CH_4 emissions by up to 83% and ammonia-N levels by up to 24%, without significantly affecting total VFA concentrations. Additionally, it shifted from acetate towards propionate production. High doses of Cinnamon and oregano (100–200 mg/g DM) significantly inhibited CH_4 emissions (up to 98%) but severely impaired GP and VFA concentrations, indicating excessive antimicrobial activity. In contrast, low doses (50 mg/g DM) exerted limited antimethanogenic effects with minimal effects on VFAs. In Experiment 2, garlic alone (G100) showed strong antimethanogenic effects (–70 to –78% CH_4) while preserving overall fermentation and promoting a shift toward propionate and butyrate on day 1. Garlic-based blends (G50–C50 and G75–C12–O12) sustained CH_4 reduction (76% and 86% respectively) while maintaining GP and VFA concentrations. In contrast, cinnamon alone (C100) and oregano alone (O100) strongly suppressed CH_4 (up to –90%) and ammonia-N (up to –40%) but markedly impaired fermentation. Bliss independence analysis confirmed the synergistic interactions among garlic-based combinations for CH_4 reduction and propionate enhancement above the expected values. The incubation during 5 consecutive days amplified the antimethanogenic effects of all additives, likely due to accumulative microbial inhibition, however garlic was the only that maintained fermentation activity overtime. The ternary blend G75–C12–O12 provided the best long-term balance between CH4 mitigation and fermentative stability. Overall, garlic extract demonstrated a robust antimethanogenic potential while preserving fermentative activity in vitro. Nonetheless, potential issues related to palatability and odor transfer to milk may arise under practical conditions. Combining garlic extract with cinnamon and oregano (G50-C50 and G75-C12-O12) enabled to decrease the garlic dose while increasing mitigation efficacy without impairing rumen fermentation. The combined use of ANOVA and Bliss proved to be a valuable approach for investigating interactions among feed additives. These findings warrant further in vivo validation to determine their practical feasibility.

In vitro screening of succinogenic bacteria and dicarboxylic acids as alternative electron sinks during bromoform-mediated methanogenesis inhibition

L. Gonzalez-Chappe[1], A. Daudet[1], P. Alvarez-Hess[2], R. Tognelli[2], A. Pittaluga[1], A. Relling[1]
[1] The Ohio State University, Animal Sciences, 1680 Madison Ave, 44691 Wooster, United States, [2] Rumin8 Pty Ltd, 45 Ventnor Ave,, 6005 West Perth WA, Australia

Combining alternative electron sinks with methanogenesis inhibitors may redirect reducing equivalents toward propionate formation when methane (CH_4) production is suppressed, thereby conserving energy otherwise lost as CH_4. A randomized complete block design was conducted to evaluate the effects of a CH_4 production inhibitor (oil-stabilized bromoform ($CHBr_3$); 4,000 mg $CHBr_3$/kg oil; Rumin8 Pty Ltd, Australia), alone or in combination with either succinogenic bacteria (Native Microbials, Inc., San Diego, CA, USA), fumarate, or malate (Bartek Ingredients Inc., Stoney Creek, ON, Canada) on gas production and composition, digestibility and fermentation parameters in an in vitro batch culture system. Rumen fluid was collected from two cannulated beef heifers fed a diet containing 90% concentrate and 10% forage (dry matter (DM) basis), which also served as the incubation substrate. The experiment was conducted in three independent runs (blocks), with sampling at five time points (3, 6, 12, 24, and 48 h). Within each run, duplicate vessels (n = 2) were allocated to each treatment at each time point, yielding a total of six replicate vessels per treatment per time point. Treatments consisted of: (i) a control without additives (CTL); (iii) oil-stabilized $CHBr_3$ at 2% of dietary DM (BR); and (iii) BR combined with either succinogenic bacteria (BACT), or fumarate at 0.5% (FLOW), 1.5% (FMED), or 2.5% (FHIGH) of substrate's DM, or malate at 0.5% (MLOW), 1.5% (MMED), or 2.5% (MHIGH) of substrate's DM. All additives (except $CHBr_3$) were diluted in anaerobic buffer, and 1 mL of the corresponding solution was added to each incubation vessel at the start of incubation; anaerobic buffer alone was added to CTL and BR. Data were analyzed using linear mixed-effects models (lmer; RStudio), with treatment, time, and their interaction as fixed effects and block as a random effect. Treatments MLOW and MHIGH decreased pH relative to remaining treatments ($P \leq 0.01$). No treatment effects were detected for DM or neutral digestible fiber digestibility ($P \geq 0.12$). Inclusion of $CHBr_3$, for all the treatments, decreased CH_4 production below the limit of detection and increased aqueous hydrogen (H_2) concentration across all $CHBr_3$-containing treatments compared with CTL ($P \leq 0.01$). However, gas phase H_2 concentration was not affected by treatments ($P \geq 0.35$). Addition of CHBr3 decreased acetate and increased ethanol and formate concentrations compared with CTL ($P \leq 0.05$). Propionate, butyrate, succinate, isovalerate, and valerate were not affected by treatment ($P \geq 0.25$). Isobutyrate, 2-methylbutyrate, and lactic acid were below the limit of detection across all treatments. Bromoform supplementation decreased CH_4 production and shifted fermentation away from acetate toward ethanol and formate production, suggesting microbial adaptation to methanogenesis inhibition. However, under the conditions of this experiment, adding BACT, fumarate, or malate did not effectively redirect reducing equivalents toward increased propionate production.

In vitro ruminal digestibility of bay laurel (Laurus nobilis L.) essential oil at different concentrations

A. Maggiolino[1], N. Parabita[1], G. Incampo[1], G. De Mastro[2], G. Basile[2], C. Ruta[2], P. De Palo[1]
[1] University of Bari Aldo Moro, Department of Veterinary Medicine, S.P. per Casamassima km 3, 70010 Valenzano, Italy, [2] University of Bari Aldo Moro, Department of Soil, Plant and Food Science, Via Amendola 165/a, 70126 Bari, Italy

The global rise of antimicrobial resistance, linked to antibiotic use in human medicine and intensive livestock production, has increased interest in sustainable strategies to reduce antibiotic reliance in animal production. In this context, plant-derived bioactive compounds have attracted attention as complementary approaches to conventional antimicrobials. Although essential oils cannot replace therapeutic antibiotics, their use as phytogenic feed additives may help modulate rumen fermentation and improve feed utilization efficiency. However, identifying appropriate supplementation levels remains challenging, as excessive dosages may negatively affect ruminal microbial balance and impair ecosystem functionality. The aim of this study was to evaluate the effects of bay laurel essential oil supplementation at different concentrations on in vitro digestibility. Bay laurel essential oil was extracted from leaves of Laurus nobilis L., mechanically separated from branches, dried in a ventilated oven, and subsequently subjected to steam distillation for 3.5 h using an Inherba Inox Plus extractor. Essential oil yield was expressed as percentage (w/w), corresponding to the amount of essential oil obtained from 100 g of dried plant material. The extracted essential oil was evaluated at four concentrations (0, 25, 50, and 100 mg/L) to assess its effects on in vitro digestibility. Rumen fluid was collected and stored in thermos flasks as inoculum to start in vitro fermentation, which was conducted for 48 h using the Daisy II incubation system (ANKOM Tech., Fairport, NY). In vitro digestibility was calculated as (PB − PA)/PB, where PB represents the percentage of a given parameter before digestion and PA the percentage of the same parameter after digestion, both expressed on an organic matter basis. Lipids and crude protein were determined according to AOAC procedures. Crude fiber was determined using the Weende method. Neutral detergent fiber (NDF), acid detergent fiber (ADF), and acid detergent lignin (ADL) were determined. Gas production was measured using an automated pressure transduction system (ANKOM Technology, Macedon, NY). Data were tested for normal distribution using the Shapiro–Wilk test, and analysis of variance (ANOVA) was performed considering treatment as a fixed effect (SAS, 2018). Post hoc comparisons among means were conducted using Bonferroni test. The analysis showed that essential oil supplementation increased apparent disappearance at 50 mg/L ($P < 0.01$), and reduced it at higher dosage ($P < 0.01$). Also other parameters like gas production and fiber disappearance showed same trend, with higher values at 50 mg/L and reduced values at 100 mg/L ($P < 0.01$). Overall, the results indicate a dose-dependent effect of bay laurel essential oil on in vitro ruminal fermentation. At lower concentrations, supplementation appeared to be associated with improved digestibility parameters, suggesting a favourable modulation of microbial activity and more efficient substrate utilization. Conversely, increasing doses, especially at the highest concentration, were associated with reduced digestibility and lower gas production. These findings suggest the existence of a dosage cut-off beyond which the effect shifts from potentially beneficial to detrimental, in agreement with previous literature. Further research is needed to clarify the long-term effects of essential oil supplementation and to determine the extent to which it may influence metabolism and energy partitioning in ruminants.

How carbonate based buffers and magnesium based buffers affect methane production in a rumen simulated environment

B. Naughton[1,2], O. A . Demehin[1], I. Hodge[1], P. Quille[2], B. Wenner[1], S. O Connell[1]
[1] Celtic sea minerals, Strand Farm, Currabinny, Carrigaline, Co. Cork, , Ireland, P43 NN62 cork, Ireland, [2] Munster technological university, NORTH CAMPUS, DROMTACKER KERRY CO KERRY, V92 HD4V kerry, Ireland

Rumen buffering and methane (CH_4) emissions are key factors influencing both digestive health and environmental sustainability in intensively fed beef and dairy cattle. High-grain diets, commonly used to maximise energy intake, can disrupt rumen pH homeostasis, leading to acidosis and reduced animal performance. Effective rumen buffering strategies including targeted dietary interventions and feed additives help maintain optimal pH and support beneficial rumen microbiota, enhancing nutrient utilisation and overall productivity. However, improved rumen fermentation efficiency can also increase CH_4 output, a potent greenhouse gas responsible for approximately 40% of global anthropogenic emissions from livestock. Balancing rumen health with emission reduction remains a critical challenge for sustainable animal agriculture. This study aims to identify how commercially available carbonate and Mg based rumen buffers affect methane production in an in vitro rumen fermentation model. Three feed grade buffer sources (1 x carbonate and 2 x Mg based) with particle size ranging from 289-339µm (Dx95) were obtained from commercial sources with each buffer being assessed for its total Mg content as well as its Mg solubility. Each Ankom RF rumen simulation vessel contained a buffer treatment (8.66mg) and a 20% starch dairy diet (4g) to which 40 ml of fresh rumen fluid from a Friesian cow was added which was subsequently incubated at 39$_o$C for 12 h. Vessels were analysed after 6 and 12h with solubilised Mg, pH, methane and VFA production measured. Mg based buffers used in this study ranged from 42-52%w/w Mg. Solubility was dependent on fermentation time with higher Mg^{2+} solubilised at 12 hours (44-65%) versus 6 hours (18-52%). However, differences in Mg solubility between samples was only significant ($p>0.05$) at 6 hours. All buffers kept pH above pH 5.5 after 6 hours of fermentation with the 52% soluble Mg buffer having the highest average area above pH 5.8 (2.07 mmol H^+.s) and the 18% soluble Mg buffer having the lowest average area above pH 5.8 (0.7 mmol H^+.s). The carbonate buffer-maintained pH within an optimal average area above 5.8 (1.5 mmol H^+.s). Methane production between buffers was significantly different at 6 hours ($p>0.05$) with high soluble Mg buffer producing significantly more (0.36g CH4) than the carbonate buffer and low solubility Mg buffer (0..24 and 0.23 g, respectively). This study provides greater understanding on how rumen buffers can alter fermentation dynamics leading to differences in CH4 production. The data suggests that highly soluble magnesium buffers may increase methane production due to rumen pH being higher than optimal.

Effect of hydroponic barley fodder-containing diets on methane production and rumen fermentation in dairy cattle: an in vitro assessment

E. Pacifico[1,3], M. Terranova[2], S. Amelchanka[2], M. Senese[1], P. Premarajan[1], M. Niu[3], L. Pinotti[1]
[1] University of Milan, Veterinary Medicine and Animal Science (DIVAS), Via dell'Universita, 26900 Lodi, Italy, [2] ETH Zurich, Agro-Vet Strickof, Eschikon 27, 8315 Lindau, Switzerland, [3] ETH Zurich, Department of Environmental Systems Science, Institute of Agricultural Science, Eschikon 27, 8315 Lindau, Switzerland

Water and arable land limitations, coupled with the urgent need to reduce enteric methane (CH4) emissions from the livestock sector, represent a major challenge to modern animal production systems. Hydroponic barley fodder (HBF) offers a resource-efficient, "landless" feed alternative, though its specific ruminal fermentation kinetics and methane mitigation potential remain largely uncharacterized. The objective of this study was to characterize the nutritional value and evaluate the enteric CH4 mitigation potential of HBF at two distinct harvest maturities when incorporated into cattle diets, validating its use in sustainable, land-independent ruminant production systems. The HBF was collected on two different days of the growth cycle, on day 4 (T4: peak enzymatic activity and energy mobilization) and day 6 (T6: standard harvest maturity and maximum biomass) as critical metabolic inflection points. HBF was tested as a single ingredient (100% HBF) and in combination with hay and concentrate at different inclusion levels (from 0 to 60%). In vitro fermentation was assessed utilising the Hohenheim Gas Test (HGT) technique. Individual rumen fluid from three fistulated cows was mixed with a buffer solution, and 200 mg of total substrate was incubated in glass syringes for 24 hours at 39 °C to measure pH, gas volume, gas composition, ammonia and digestibility. We hypothesized that HBF, being nutrient-dense and lower in fiber than standard hay, would favor propionate production (a hydrogen sink), thereby lowering methanogenesis. To definitively validate this metabolic shift, we evaluated the CH4/CO2 ratio (expressed as mL/L) and sampled the ruminal fluid to analyze Volatile Fatty Acid (VFA) profiles. While VFA analytical results are currently pending, the CH4/CO2 ratio serves as a crucial preliminary indicator: a lower ratio confirms a genuine shift towards hydrogen-consuming pathways, proving that CH4 mitigation is achieved through improved energetic efficiency rather than merely reflecting a decrease in overall feed digestibility. Here, we show preliminary findings that align with our expectations. The pure substrates exhibited notably higher digestibility up to 71.6% and lower CH4/CO2 ratios (reduced by up to 6.8%) compared to the control diet (60% DM hay, 40% DM concentrate), furthermore, we observed a progressive dose-response effect in the hay-substitution diets. The observed difference in CH4 mitigation potential between the harvesting stages suggests that the physiological maturity of T6 optimizes ruminal fermentation characteristics. Hence, our next step is to conduct final verification runs and integrate the pending VFA data to consolidate these promising gas kinetics and digestibility metrics. Preliminary in vitro data indicate that HBF is a highly digestible feed component with the potential to reduce the CH4 emissions. Therefore, replacing fibrous roughage with specific harvest maturities of hydroponic fodder is a promising strategy but needs to be verified in following in vivo studies.

Barrier protective effect of single-malt distillery-derived Lactobacillus postbiotic

O. A. Demehin[1], M. Ryan[1], A. Dowley[1], S. O Connell[1,2]
[1] Celtic sea minerals, Marigot Research Center, Sycamore court, Clash Road, V92N6C8 Tralee, Ireland, [2] Center for Applied Bioscience Research, Munster Technological University, South Campus, Clash Road, V92CX88 Tralee, Ireland

The gut barrier, a multilayered system of cells, mucus, proteins, and microbes, plays a vital role in preventing pathogen infiltration, making it central to global efforts in infectious disease prevention and research. The objective of this study was to evaluate the effects of Lactobacilli postbiotic formulation, developed using a patented process that repurposes distillery by-products, on inflammation and gut barrier integrity. Murine macrophage RAW264.7 cells were treated with the postbiotic and were subsequently primed with lipopolysaccharide (LPS) to induce a pro-inflammatory response. The inflammatory response was assessed by measuring the expression of TNF-α mRNA by rtPCR. Additionally, intestinal epithelial Caco-2 cells cultured as monolayers in transwells were exposed to Escherichia coli to induce barrier disruption. Subsequently the monolayers were treated with the postbiotic. Barrier integrity was evaluated by measuring FITC-Dextran (MW: 3 kDa) permeability across the monolayer and analysing tight junction gene expression. Results demonstrated that postbiotic activated RAW264.7 cells under unprimed conditions, as evidenced by increased TNF-α levels. In contrast, LPS-primed cells treated with postbiotic demonstrated reduced expression of TNF-α suggesting anti-inflammatory activity. In Caco-2 cells, E. coli exposure increased FITC-Dextran permeability. The postbiotic treatment significantly ($P<0.05$) mitigated this effect with >50% reduction in permeability and caused a significant ($P<0.05$) downregulation of CLDN-2 tight junction protein expression with a fold change of 0.15. Overall, the findings suggest that postbiotic possess immunomodulatory properties and contribute to the restoration of epithelial barrier function, highlighting their potential role in reducing tissue damage associated with infection leading to gut health maintenance. This represents a unique advancement in postbiotic development through the sustainable and innovative use of distillery by-products.

Milk oligosaccharides shape the gut mucosal barrier in vitro in suckling rabbits

M. Rumeau[1], M. Beaumont[1], C. Lencina[1], E. Jones[1], L. Cauquil[1], S. Combes[1], C. Knudsen[1]
[1] Université de Toulouse, INRAE, ENVT, GenPhySE, 29 chemin de Borde Rouge, 31320 Castanet Tolosan, France

Milk oligosaccharides (MOs) are non-nutritional complex bioactive carbohydrates that are naturally present in mammalian milk. In rodent and human newborns, they are known to exert multiple beneficial functions in the intestinal tract, namely preventing pathogen adhesion, favoring the growth of beneficial bacteria through prebiotic action, enhancing epithelial barrier function and having immunomodulatory capacities. Given their beneficial effects, MOs could represent promising novel feed additives in livestock nutrition, particularly to facilitate the weaning transition. Our study aimed to investigate in vitro the effects of three structurally different types of MOs: a neutral MO, represented by lacto-N-tetraose (LNT), a fucosylated MO, represented by 2'-fucosyllactose (2'FL) and a sialylated MO, represented by 6'-sialyllactose (6'SL), on the gut mucosal barrier using the rabbit, a livestock species particularly susceptible to digestive disorders around weaning. Two gut mucosal barrier components were studied: the gut epithelium and the immune cells in the underlying lamina propria. Suckling rabbit cecal epithelial cell monolayers were derived from organoids to reproduce the cellular complexity of the intestinal epithelium (n=4). Gut immune cells were studied through the culture of suckling rabbit cecal lamina propria mononuclear cells (LPMCs) that comprise most gut immune cells, mainly macrophages, dendritic cells and lymphocytes (n=18). Cells were cultured in vitro under control conditions or exposed to LNT, 2'FL or 6'SL (20 and 2 mg/ml respectively for epithelial cells and LPMCs). The gene expression of 84 genes implicated in epithelial barrier function, inflammatory and immune response was assessed after 24 h of culture. All MOs induced a marked upregulation of epithelial cell differentiation (KRT20, CA2) but had no impact on epithelial cell proliferation (PCNA, MKI67). Regarding the barrier function, the three MOs induced a marked decrease in the expression of genes coding for transmembrane mucins (MUC1, MUC13). While 2'FL had no impact on tight junctions, and LNT solely reduced the expression of TJP2, 6'SL induced a moderate reduction in the expression of two key tight junction markers (TJP1, CLDN3) in accordance with a reduction in transepithelial resistance. Finally, MOs impacted inflammatory pathways in epithelial cells with a sharp increase in CXCL10 expression with LNT and 6'SL and a 10-fold increase in the expression of CXCL8 solely with 6'SL. In LPMCs, MOs had no impact on proliferation (MKI67) or lymphoid (CD69, FOXP3, JCHAIN) and myeloid (CD14, CD80, CD86, FLT3) cell specific markers, regardless of MO structure. Inflammatory pathways were however modulated by MOs in LPMCs, with a consistent upregulation of inflammatory markers (IL6, CXCL8) with 2'FL and 6'SL and a marked upregulation of regulatory pathways (IL10, IL2RA) and inflammatory marker CCR5 solely with 2'FL, while LNT had no effect on LPMCs in vitro. Our study demonstrates an impact of MOs on the gut barrier function and highlights a structure specificity. However, a greater impact of MOs on epithelial cells compared to LPMCs was evidenced, that could be associated with the greater physiological exposition of these cells to MOs in vivo. Interestingly, in both cell types, 6'SL induced a marked increase in CXCL8 indicating clear immunomodulatory impacts of this MO that should be further studied. Co-culture models would enable to better understand the direct and indirect impacts of MOs on the different components of the gut mucosal barrier. Finally, these results pave the way for future on-farm applications that should be evaluated in in vivo studies.

Curcumin loaded liposomes ameliorates DSS-induced colitis in mice: in vitro and In vivo studies

L. L. La Min[1], K. Adhimoolam[2], T. Min[1]
[1] Jeju National University, Department of Animal Biotechnology, Jeju International Animal Research Center (JIA), Sustainable Agriculture Research Institute (SARI), 1 Arall-dong, 102 Jejudaehak-ro, 63243 Jeju, South Korea, [2] Jeju National University, Jeju International Animal Research Center, 1 Arall-dong, 102 Jejudae-hak-ro, 63243 JeJu, South Korea

Inflammation is a significant health concern in livestock animals. It adversely affects animal health, compromises performance, and reduces final product quality. Curcumin, a polyphenolic compound derived from the rhizomes of the turmeric plant, exhibits anti-inflammatory properties. However, its application is limited by poor bioavailability. Nano-encapsulation enhances its physicochemical stability and biological activity, thereby improving its efficacy compared with free curcumin. In this study, we synthesized curcumin-loaded liposomes (Cur-L) and evaluated their protective effects against inflammation using in vitro and in vivo models. Cur-L showed an average particle size of 172.5 ± 3.0 nm and a zeta potential of −29.42 ± 1.32 mV, along with high encapsulation efficiency (98%) and drug-loading capacity (9.8%). The protective effects of Cur-L against inflammation were confirmed in LPS-induced RAW 264.7 cells and a DSS-induced mouse model of colitis. Cur-L decreased the nitric oxide production in LPS-stimulated RAW 264.7 cells. In vivo, Cur-L administration alleviated DSS-induced clinical symptoms, including body weight loss and disease activity index scores, and improved colon length and histopathological damage. Additionally, Cur-L modulated the gut microbiota by increasing the abundance of beneficial bacteria. Together, these results indicate that Cur-L is a potential therapeutic agent for treating inflammation and warrants further investigation. Keywords; Curcumin, DSS-induced colitis in mice, Inflammation, livestock animals

Ensiled forages modulate rumen fermentation and microbiome in lambs

A. Chaudhry[1]
[1] *Newcastle University, Natural and Environmental Sciences, Agriculture Building, NE17RU Newcastle upon Tyne, United Kingdom*

Ensiled forages are essential to feed ruminant animals during shortage of either fresh or dried forages. Ryegrass (RG) is mostly ensiled to fill the gap of forage shortage especially during cold or dry seasons. Indeed, many other forages such as whole crop cereals and legumes are also ensiled for feeding ruminants. Interestingly, ensiled Brassica (BR) forages are rarely used as a novel alternative when availability of ensiled RG is restricted. Therefore, a series of replicated field, animal and lab-studies evaluated the potential value of ensiled BR against RG for lambs. Nevertheless, this paper presents only their nutrient composition and fermentation plus microbiome before and after in vitro incubation with rumen fluid (RF) from freshly killed lambs. The BR had (g/kg) significantly ($P<0.01$) lower DM (192 vs 660), pH (3.5 vs 6.1) and NDF (384 vs 485) but higher CP (216 vs 135), DUP (53 vs 21) and NH3 (58 vs 46) than RG. Representative samples of RF were collected immediately post-killing from 24 Mule lambs weighing 38kg (+1.6) consuming ensiled BR or RG. The RF samples were pooled to get 4 replicated RF per group of BR and RG consuming lambs. The pooled samples were filtered (unbuffered, RF1) before aliquots of RF1 were buffered (RF2) for in vitro incubation with samples of BR and RG to determine their respective in vitro dry matter degradability (IVDMD). Aliquots of post-incubated RF2 were filtered (RF3) and tested alongside aliquots of RF1 and RF2 for rumen fermentation but only RF1 and RF3 were used to extract DNA to study microbiome. The DNA samples were subjected to the Shotgun Metagenomic analysis with Next Generation Sequencing and Bioinformatics by Novogene Ltd. The results were either numerically or visually illustrated for similarities or variations in RF1 and RF3 for RG and BR. Mean IVDMD (g/kg) of BR at 763 was significantly greater than 525 for RG (SEM 13, $P<0.01$). Mean pH was higher at 7.9 for RF1 than 6.9 for RF3. Moreover, RG showed a numerically higher pH of 7.9 than 7.7 for BR. RF1 had significantly higher NH3 of 361 mg/L than RF3 at 294 mg/L. Total VFA of BR at 39.6 mmol/L were more than RG at 34.6 mmol/L. The main effects of BR on NH3 and total VFA were also higher than RG. Metagenomic results showed comparable total scaftig (>500bp) number (344,455 vs 352,920) and average length (1,013 vs 1,040 bp) in RF1 of RG and BR respectively. Conversely, F3 showed 268,191 and 219,022 scaftigs with mean length of 1,088 and 1,032bp for RG and BR respectively. Overall, the RG and BR varied for identical and unique genes. The ensiled forages compared well for the abundance of bacterial phylum, family, genus and species. The phylum data showed good correlation ($r > 0.6$) and the alpha diversity indices compared well for both forages. However, in vitro incubations with RF3 decreased some phyla (Bacteroidetes), families (Prevotellaceae), genera (Prevotella) and species (Prevotella). Conversely, it increased some phyla (Firmicute), families (Lachnospiraceae), genera (Ruminococcus) and species (Selenomonas ruminantium & bovis). The Bacteroidetes phylum was more common for RG than their BR counterparts. These variations reflected the higher fibre content in Ryegrass than Brassica. The enhanced abundances of Firmicutes, Bacteroidetes and Fibrobacteres phyla indicated perhaps the improved fibrolytic and proteolytic activities in RF with RG. The ACE and Cha1 indices and phylum diversity indicated that the RG based RF1 and RF3 had higher phylum richness than their BR counterparts. Apparently, ensiled Brassicas can be used to not only replace or complement Ryegrass but also modulate rumen fermentation and microbiome in lambs. This strategy may optimise nutrient use efficiency to promote sustainable ruminant production.

Linking in vitro methane yield with rumen fermentation patterns and milk quality traits during the transition period

R. El Hawat[1], D. Giannuzzi[1], S. Massaro[1], S. Schiavon[1], S. Pegolo[1], A. Cecchinato[1], F. Tagliapietra[1]
[1] University of Padova, DAFNAE, Legnaro, 35020 Padova, Italy

Enteric methane (CH_4) mitigation in dairy systems requires scalable indicators capturing biologically meaningful variation among cows under farm conditions. While in vitro CH_4 yield is widely used to characterize feed and additives for ruminants, the potential of in vitro systems to assess the methanogenic potential of rumen fluid, and the extent to which these measurements reflect milk quality traits and rumen metabolism across the transition period, remains unclear. We hypothesized that variation in in vitro CH_4 yield could reflect rumen metabolic phenotypes associated with milk fatty acid (FA) profiles and fermentation dynamics during the transition period. Sixty Holstein–Friesian cows were sampled at the beginning of the dry period (T0, 60 d prepartum) and early lactation (T1, 30 d postpartum). Individual rumen fluid samples were collected using an oro-ruminal probe. A subsample was analyzed for volatile fatty acids (VFA) and ammonia (NH_3), while the remaining fluid was used as inoculum for in vitro fermentation assays to evaluate gas production kinetics and CH_4 yield per gram of total mixed ration (TMR). Milk samples were analyzed for FA composition by gas chromatography. Cows were equipped with rumen boluses to monitor rumen pH and rumination activity. CH_4 yield was also predicted from milk FA using published equations. Within each sampling point, cows were classified into low, medium, and high in vitro CH_4 yield tertiles (T0: <24.1, 24.1–26.8, >26.8; T1: <21.2, 21.2–24.6, >24.6 mL/g DM). Data were analyzed separately for T0 and T1 using linear models including CH_4 class, parity order, and parity season as fixed effects. Response variables included rumen fermentative parameters (pH, VFA, NH_3), milk yield, milk FA profile and FA-based CH4 predictions. Variation in in vitro CH_4 yield was associated with rumen parameters measured in vivo. At T1, cows in the low CH_4-yield tertile showed lower rumen pH measured in vivo ($P < 0.05$), higher propionate concentrations, and a lower (acetate + butyrate)/propionate ratio ($P < 0.05$), consistent with a more acidic rumen environment and fermentation patterns typically associated with reduced methanogenic activity during early lactation. This pattern was not observed during the prepartum stage (T0). Late-phase in vitro gas production increased across CH_4-yield tertiles at both stages, although overall volumes were lower at T1, suggesting stage-dependent differences in fermentative activity across the transition period. Clearer differentiation of milk FA emerged at T1. In early lactation, cows in the low CH_4-yield tertile showed higher total milk and n-6 PUFA contents ($P <0.05$), whereas high CH_4-yield cows showed relatively higher C4:0 and C16:0 contents. In contrast, prepartum patterns were less pronounced, although odd-chain FA (OCFA) increased with CH_4 yield at T0 ($P <0.10$). This relationship reversed at T1, where OCFA decreased progressively from low to high CH_4-yield cows ($P <0.05$). FA-based CH4 predictions were consistent with measured in vitro CH_4 classes but only at T1. These stage-dependent shifts indicate that associations between CH_4 phenotype and rumen-derived milk lipid markers vary across the transition period. Overall, in vitro CH_4 yield captured biologically meaningful between-cow variation in rumen fermentation patterns and milk lipid composition, supporting further investigation into its potential for scalable identification of low-emission phenotypes in commercial dairy systems.

Extracellular vesicles from low- and high-virulence Streptococcus uberis strains differentially regulate bovine neutrophil viability and inflammasome activation in vitro

M. Penati[1], O. Balbi[1], Y. Dadi[1], G. Salvi[1], R. I. Lazar[1], N. C. Cirone Silva[2], C. Lecchi[1,3], F. Ceciliani[1], L. G. De Matos[2]
[1] University of Milan, Department of Veterinary Medicine and Animal Science, Via dell'università 6, 26900 Lodi, Italy, [2] Universidade Estadual de Campinas (UNICAMP), Department of Food Science and Nutrition, School of Food Engineering (FEA), Rua Monteiro Lobato, 80, SP, CEP 13083-862 Campinas, Brazil, [3] MOOVET DXC S.r.l., Precision Diagnostics LAB for Animal Health – Spin-off of the University of Milan, Department of Veterinary Medicine and Animal Science, Via dell'università 6, 26900 Lodi, Italy

Streptococcus uberis is a major causative agent of bovine mastitis; however, the role of bacterial extracellular vesicles (BEVs) in strain-specific modulation of host innate immunity remains poorly understood. Using a previously optimized and MISEV 2023-compliant workflow for BEV isolation, this study evaluated whether BEVs derived from two S. uberis strains with low or high virulence exert differential effects on bovine polymorphonuclear cells (PMNs). BEVs were isolated from bacterial culture supernatants by sequential centrifugation, 0.22 µm filtration, and ultracentrifugation. Vesicle preparations were characterized by nanoparticle tracking analysis, cryo-electron microscopy, Western blotting, and flow cytometry to confirm particle size distribution, morphology, and Gram-positive membrane origin. For functional assays, BEVs were normalized based on total protein content, and three protein concentrations for each preparation were tested. PMNs were isolated from bovine peripheral blood and exposed to increasing BEV doses to generate dose-response curves and determine median lethal dose (LD50) values using the WST-1 assay. Cell viability and proliferative capacity were assessed by measuring metabolic activity, while inflammatory activation was evaluated by measuring inflammasome-associated caspase-1 activity as a marker of pyroptotic signaling. BEV exposure induced concentration-dependent effects on PMN viability and inflammasome activation. BEVs derived from the high-virulence strain caused a more pronounced reduction in neutrophil viability and stronger caspase-1 activation at lower protein-normalized concentrations compared with vesicles from the low-virulence strain, indicating strain-dependent immunomodulatory properties. These findings integrate standardized BEV isolation procedures with functional immune assays to quantify vesicle bioactivity on bovine neutrophils. The data support the hypothesis that differences in S. uberis virulence may be partially mediated by BEV-driven modulation of neutrophil survival and inflammatory cell death pathways, providing mechanistic insight into host-pathogen interactions during bovine mastitis. Keywords: bovine mastitis, bacterial extracellular vesicles, inflammation, cell death, Streptococcus uberis.

A botanical and organic acid blend protects intestinal cell viability and reduces heat stress-induced oxidative stress across human, porcine, and avian in vitro models

F. Ghiselli[1], A. Toschi[1], B. Tugnoli[1], E. Grilli[1]
[1] Vetagro S.p.A., Via Ignazio Porro 2, 42124 Reggio Emilia, Italy

Heat stress (HS) is a major challenge in animal production, with rising global temperatures increasing its economic and welfare impact. At the intestinal level, HS disrupts epithelial barrier integrity, increases reactive oxygen species (ROS) production, and promotes cell death, ultimately impairing nutrient absorption and immune function. Dietary strategies capable of protecting intestinal cells from HS-induced damage are therefore of practical relevance for both swine and poultry production. The aim of this study was to evaluate the protective effect of a blend of botanicals and organic acids (AviPlus®, AP), against HS-induced viability loss and oxidative stress, using three intestinal cell lines: human Caco-2, porcine IPEC-J2, and avian cIEC-H2. Cell viability was assessed under two experimental designs. In the concurrent treatment design, AP was added at HS onset (42°C, 24h) and maintained for 6 days, to evaluate both protection during and recovery after the challenge. In the pre-treatment design, cells received AP for 6 days before HS exposure (42°C, 24h), with viability recorded at day 8. AP was used at a final concentration of 1000 ppm. Viability was measured with PrestoBlue® (Thermo Fisher Scientific). For ROS assessment, cells were pre-treated for 6 days and then exposed to HS for 4h at 42°C. ROS were quantified with CellROX® (Thermo Fisher Scientific). Viability data were analyzed by two-way ANOVA (time × treatment) and ROS by one-way ANOVA with Tukey's post-hoc test. In the concurrent treatment design, HS reduced viability to 49% (cIEC-H2) and 45% (IPEC-J2) of thermoneutral control by day 6. AP significantly limited this drop (cIEC-H2 76%, IPEC-J2 90%; $p<0.05$ vs HS control). In Caco-2, HS reduced viability to 83% at 24h, while AP-treated cells maintained 89% and subsequently recovered beyond thermoneutral levels (>110%) by day 6. In the pre-treatment design, AP improved post-challenge viability across all three cell lines: IPEC-J2 102% vs 81% (HS control), cIEC-H2 90% vs 80%, Caco-2 88% vs 81% (all $p<0.05$). HS significantly increased ROS levels compared to thermoneutral control across all three cell models: +28% in Caco-2 and cIEC-H2, +82% in IPEC-J2. AP reduced HS-induced ROS by approximately 13% in Caco-2, 15% in cIEC-H2, and 22% in IPEC-J2 (all $p<0.05$ vs HS control). In Caco-2 and cIEC-H2 this corresponded to a full restoration of thermoneutral levels, while in IPEC-J2 the reduction was significant but partial. AP consistently reduced HS-induced viability loss and oxidative stress across all three intestinal cell models. The protective effect was observed under both concurrent and preventive administration, suggesting that the blend may exert its action through multiple mechanisms. The consistent response across species supports its potential as a nutritional strategy to maintain intestinal health and animal performance under heat stress conditions in swine and poultry production.

Exploring the combined effects of plant extracts, tannins, and saponins on cecal fermentation in weaned piglets using consecutive batch culture incubations

J. Muñoz-Grein[1], A. H. Checkikene[1], M. A. Latorre[1], A. Belanche[1]
[1] Univeristy of Zaragoza, Department of Animal Production and Food Science, Miguel Servet 177, 50013 Zaragoza, Spain

The post-weaning period in piglets is characterized by abrupt dietary changes, reduced nutrient digestibility, and instability of the gut microbiota, frequently leading to digestive disorders. Therefore, nutritional strategies aimed at enhancing hindgut fermentation are a priority during this critical period. Plant extracts such as essential oils, tannins, and saponins have attracted increasing attention due to their antimicrobial and immunomodulatory properties. Although these compounds have shown promising effects when supplemented alone, their potential synergistic effects of their combinations in weaned piglets remain largely unexplored. The objective of this in vitro study was to evaluate the individual and combined effects of dietary supplementation with: a plant extract blend containing turmeric, green tea and Scutellaria baicalensis (P); tannins from chestnut and quebracho (T); and saponins from yucca, quillaja, and oats (S), on cecal fermentation in weaned piglets. The experimental diet was subjected to enzymatic digestion with HCl, pepsin, and pancreatin to simulate gastric and small intestinal digestion. The undigested residues were then incubated in batch culture system using four pooled cecal inoculum from 40 weaned piglets. A total of 11 treatments were evaluated: a control (CTL); individual additives at 5% inclusion rate (P100, T100, S100); binary combinations (P50–T50, P50–S50, T50–S50); and ternary combinations (P33–T33–S33, P75–T12–S12, P12–T75–S12, P12–T12–S75). Fermentation bottles were incubated anaerobically at 37 °C. Incubations lasted five days, with daily renewal of the incubation medium. Gas production (GP), methane and fermentation products were measured on days 1 and 5. On day 1, cecal pH and total volatile fatty acid (VFA) concentration were not affected by additive supplementation, indicating no inhibition of overall hindgut fermentation. However, all additives reduced ammonia-N concentration (up to 5%, $P < 0.001$) and the molar proportion of branched-chain fatty acids (−7%, $P = 0.008$), suggesting reduced proteolysis compared with CTL. This effect was particularly evident in treatments containing tannins (T100, P12–T75–S12, P50–T50, and T50–S50). Treatment P100 tended to increase gas production (+7.9%, $P = 0.087$) and significantly increased the molar proportion of butyrate (+4.8%, $P = 0.029$) compared with CTL. These effects were consistent when fermentation products were expressed per unit of substrate. Additionally, treatment P75–T12–S12 showed a tendency to increase propionate production. By day 5, most previously observed effects were maintained and, in some cases, intensified, likely reflecting the antimicrobial properties of the additives. Treatment T100 reduced total VFA concentration compared with CTL (−25%, $P < 0.001$), although this negative effect was attenuated when tannins were combined with other additives. The inclusion of low doses of tannins in ternary combinations (P33–T33–S33, P75–T12–S12, and P12–T12–S75) reduced proteolysis without compromising overall fermentation activity and increased the molar proportion of butyrate ($P < 0.001$). In conclusion, this in vitro study demonstrates that combining plant extracts, tannins, and saponins may represent a promising nutritional strategy to optimize hindgut fermentation in weaned piglets. Low-dose tannin inclusion in combination with plant extracts and saponins reduced proteolysis while enhancing the production of beneficial VFA. Further in vivo studies are required to confirm these findings.

Dose-Response Effects of Isoacids Supplementation in Dry Cow Diets: Impacts on Microbial Nitrogen and Fiber Fermentation

R. Bevilacqua[1], D. H. Kleinschmit[1], A. Gomez[1], M. T. Socha[1]
[1] Zinpro Corporation, R&D, 7500 Flying Cloud Drive, Suite 800, 55344 Eden Prairie, MN, United States

Recent research has demonstrated the benefits of isoacids supplementation in enhancing rumen efficiency, notably increasing microbial protein synthesis and fiber fermentation in lactating dairy cows (Firkins et al., 2024; Redoy et al., 2025). However, the dose-response relationship of isoacids when supplemented in dry cow diets, particularly in relation to requirements defined by the CNCPS model, remains unexplored. This study investigated the effects of incremental isoacid supplementation on microbial growth and fiber fermentation in dry cow diets, including dosages exceeding established model requirements. Four dual-flow continuous fermenters were assigned to an experiment with a 4×4 Latin Square design, each fed a dry dairy cow diet formulated using the CNCPS model within NDS software. The diet (% DM) was comprised of corn silage (34.4), wheat straw (29.3), grass silage (14.0), soybean meal (11.7), fine-ground corn grain (10.4), and mineral mix (0.2), with an initial isoacid deficit of 0.5 g/kg DM. Treatments included: control (CON), low (LIA, 0.8 g/kg DM), medium (MIA, 1.2 g/kg DM), and high (HIA, 1.6 g/kg DM) isoacids dosages. Each period involved a 7-day adaptation and 5-day sampling phase. Liquid and solid dilution rates were set at 10%/h and 5%/h, respectively. Samples were collected at 9 and 24 hours post-feeding for microbial nitrogen (Kjeldahl method), neutral detergent fiber (NDF), and acid detergent fiber (ADF) analyses. Data were analyzed using the lme4 package in R, with treatment and period as fixed effects and fermenter nested within period as a random effect; linear, exponential, and quadratic models were assessed. At 9 hours post-feeding, microbial nitrogen concentrations did not differ significantly among treatments. NDF digestibility (NDFd) exhibited a quadratic trend ($p < 0.1$), and ADF digestibility (ADFd) followed a linear pattern ($p < 0.1$), but these were not mirrored by nitrogen efficiency measures. At 24 hours, microbial nitrogen concentration increased linearly with isoacids dosage, with each unit increase yielding 37 mg N/L more microbial nitrogen ($p < 0.01$). No significant trends were observed in fiber fermentation parameters at this time point, but nitrogen efficiency improved linearly with increased isoacid supplementation ($p < 0.05$). The delayed response between fiber digestibility and microbial nitrogen enhancement is hypothesized to result from the lower digestibility of fiber sources like wheat straw in dry cow diets compared to lactating cow diets. The findings indicate that isoacid supplementation of dry cow diets promotes a linear increase in microbial nitrogen production, even at dosages exceeding CNCPS model requirements. While fiber fermentation is enhanced, NDF digestibility appears to plateau at higher supplementation levels. These results suggest that isoacid supplementation may improve metabolic efficiency in prepartum dairy cows, offering potential benefits for preparation for calving and transition into lactation.

The effects of supplementation with the natural additive Fator P on feeding of Rhipicephalus microplus parasite larvae.

L. Fernandes[1], L. Ferreira[1], R. Bin[2], I. Santos[2], R. Paranhos[3]
[1] Premix Nutrição Animal, Research, development and innovation, Milton José Robusti Street, 75, 14021-613 Ribeirão Preto, Brazil, [2] University of São Paulo, Ribeirão Preto Medical School, Bandeirantes Avenue, 3900, 14040-906 Ribeirão Preto, Brazil, [3] University of Franca, Dr. Armando de Sáles Oliveira Avenue, 201, 14404-600 Franca, Brazil

Infestations by the hematophagous ectoparasite R. microplus are one of the main challenges to health of beef and dairy cattle. Fator P is a natural zootechnical feed additive that has been shown to improve several production features in beef and dairy cattle. Due to its composition and to the mechanisms by which ticks infest and feed on their hosts, we hypothesised that when cattle receive Fator P in the diet, can have a negative impact on the rate of engorgement by larvae of R. microplus. In order to test this hypothesis, we employed an artificial feeding system (AFS) with unfed infesting larvae to engorge them on fresh blood supplied from bovines fed, or not, with the Factor P additive for different periods of time. Purebred, castrated Holstein steers, aged 18 to 20 months were randomized into two groups based on weight, body condition score, paternity and innate tick loads. The study was blinded and both groups were confined in individual pens in a feed lot with an empty pen separating each animal; the test group received Fator P (dosed at 6,0 gr / animal / day) and both groups received 2,2% of body on a dry matter (DM) in diet. Blood samples were collected in CaCl2 on days 28, 56, 63, 70, 87, and 119 after the start of treatment with the additive; blood and larvae were distributed in triplicate in the AFS for 48 hours . The statistical method used was the Mann-Whitney test, with p-values <0.05. Of the initial total of unfed larvae released in the AFS, the percentage of engorged larvae recovered after 48 hours varied between 21.3% to 24.1% on blood from animals treated with Fator P plus feed, and 39.8% to 39.9% on blood from animals treated with feed alone from days 56 and 119 ab initio treatment. We conclude that when animals feed on natural additive Fator P supplemented meal, it was observed reduction of 40.65% relative to the negative control (p<0.0001) and also the number of engorged females recovered on the animals in the same experiment (data not shown). In the field, the results showed that the inclusion of the additive in the animals' diet was able to reduce tick counts by up to 34.0% (p=0.2429) in animals after 42 days of treatment, and by 74.4% (p=0.0024) in animals after 98 days of treatment. These findings corroborate our field observations and suggest that the additive interferes with the physiology of the tick. Others has shown that guinea pigs fed on fish oil contain high levels of eicosapentaenoic acid, which impairs accumulation of arachidonic acid in salivary glands and subsequent production and secretion of dienoic prostaglandins in tick saliva. These salivary mediators are essential for feeding performance because they increase the amount of blood present in the feeding lesion. Fator P can be an important strategic tool in the control of R. microplus, especially when used in an integrated manner with other control practices.

Effect of fermentation of field pea grains with Companilactobacillus kimchii on the microbiome in pigs using metagenomics and metaproteomics

F. Quinger[1], N. Klein[1], A. Camarinha-Silva[1], M. Rodehutscord[1], J. Seifert[1]
[1] University of Hohenheim, Institute of Animal Science, Emil-Wolff-Str., 70599 Stuttgart, Germany

Feed fermentation is a processing technique able to increase nutrient digestibility and reduce antinutritional factors in feedstuffs. Additionally, by supplying the gut with prebiotics and probiotics, fermented feed may influence the composition of the gut microbiota. By applying different meta-omics approaches, not only can the composition of the microbiota be determined, but also, by using metaproteomics, the functionally contributing part of the microbiota. We therefore investigated the influence of the fermentation of pea grains on the ileal and faecal microbiome in pigs by using metagenomics and metaproteomics. Four diets based on wheat (20%), barley (13%), rapeseed meal (10%), and 50% pea grains were formulated. The peas were either unfermented (control), unfermented with added lactic and acetic acid, fermented, or fermented with added carbohydrases. The fermented peas were produced by inoculating a mixture of ground pea grains and water (1:1.5, w/w) with 1 ml/kg of an overnight culture of Companilactobacillus kimchii and incubating it at 37 °C for 24 h. Eight barrows (27.6 ± 2.0 kg initial body weight) were fitted with a T-cannula at the distal ileum and assigned to the four dietary treatments in a 4 × 4 double Latin-square design. Daily feed allowance was 4% of the mean body weight. The experiment included 4 experimental periods of 11 days each. Samples of ileal digesta and faeces were collected on the last day of each period for microbiome analyses. For shotgun metagenomics, DNA was extracted using the FastDNA SPIN Kit for Soil (MP Biomedicals LLC, Santa Ana, CA) and sequenced (PE150) on an Illumina NovaSeq 6000 platform (Illumina Inc., San Diego, CA). For protein extraction, bacterial cells were lysed by ultrasonication, and in-gel digestion was performed with trypsin. Metaproteomic analysis of peptides was conducted using an Exploris 480 mass spectrometer with an Ultimate 3000 RSLCnano system (Thermo Fisher Scientific, Darmstadt, Germany). Identification and quantification of protein groups were performed using MetaLab MAG. Statistical analysis was conducted in R. For metagenomics, the median number of reads per sample, which was obtained after quality control and used for downstream analysis, was $34.98 \times 10_6$. Metaproteomic analysis identified ~22,000 protein groups, of which ~17,500 were retained for analysis. In the ileum, β-diversity for both, taxonomic read annotations and microbial proteins, was affected by the dietary treatment ($P < 0.05$), with the fermented diets clustering separately from the other diets. Differential abundance analysis showed an increased abundance for reads and proteins of the genera Companilactobacillus, Weissella, and Enterococcus_B in the ileal digesta for the fermented diets. The ratio of proteins to DNA, calculated from the relative abundances of genera in metaproteomics and metagenomics, respectively, was <1 for Companilactobacillus and Weissella in ileal digesta for the fermented diets, and lower than in the other diets ($P < 0.05$). No effect on β-diversity was detected in the faeces. The results demonstrate that feeding fermented pea grains primarily affected the composition of the ileal microbiota, whereas the effect on the faecal microbiota was less pronounced. However, the discrepancies in relative abundances between metagenomics and metaproteomics point to a lower functional contribution of taxa originating from the fermented pea grains than the taxonomic composition based on metagenomics suggests.

Metabolomic responses of porcine gut organoids to Escherichia coli

M. Du Teil Espina[1], H. Fijten[1], B. Han[1], M. Vrieling[1], S. Van Hemert[1]
[1] Wageningen Bioveterinary Research, Houtribweg 39, 8221RA Lelystad, Netherlands

Weaning diarrhea is a common and economically significant disease in young pigs, typically occurring within the first 1–2 weeks after weaning due to stress, dietary changes, and an immature immune system. A primary cause is infection with enterotoxigenic Escherichia coli (ETEC), which adheres to the small intestinal lining via fimbrial adhesins and secretes enterotoxins such as heat-labile (LT) and heat-stable (STb) toxins that disrupt epithelial ion transport, resulting in fluid hypersecretion, diarrhea, dehydration, and impaired growth performance. A deeper understanding of the molecular interactions between ETEC and the intestinal epithelium is essential for the development of improved preventive and diagnostic strategies. In vitro intestinal organoid models provide a physiologically relevant platform to study host–pathogen interactions under controlled conditions. To identify novel metabolic markers associated with early-stage ETEC infection, we investigated metabolite production in porcine gut organoids following bacterial challenge. Organoids were cultured and seeded onto transwell inserts to allow apical infection and basolateral sampling. The response to the ETEC strain CVI-1000 (E. coli O149:K91, F4/K88ac+, LT+, STb+) was compared with strain CVI-1084 (LT+, STb+), which is genetically identical to CVI-1000 except for the absence of the F4 fimbrial adhesin. Cell lysates and basolateral supernatants were collected 2 hours post-infection for metabolomic analysis. Preliminary results demonstrated a significantly higher proportion of adherent bacteria in organoids exposed to CVI-1000 compared to CVI-1084, underscoring the critical role of F4-mediated attachment in early host–pathogen interactions. Ongoing metabolomic analyses aim to elucidate infection-induced alterations in epithelial metabolic pathways and to identify candidate biomarkers for early detection of ETEC-associated weaning diarrhea.

A transcriptomic approach to study the effects of reducing the dietary balanced protein level on small intestine metabolism of slow-growing broilers

A. E. P. Mary[1], J. Gulmann Madsen[2], A. R. Williams[2], T. A. Woyengo[1]
[1] Aarhus University, ANIVET - Monogastric Nutrition, Blichers Allé, 20, 8830 Tjele, Denmark, [2] Copenhagen University, Veterinary and Animal Sciences, Grønnegårdsgade, 8, 1870 Frederiksberg, Denmark

Production of slow-growing broilers has gained interest due to increasing demand for higher welfare standards. However, compared with fast-growing breeds, slow-growing broilers have a greater environmental impact because of poorer feed efficiency. This study investigated the combined effects of reducing dietary metabolizable energy (ME) and balanced protein (BP) on performance, carcass traits, nitrogen balance, carbon footprint and small-intestinal gene expression. A total of 1,008 male Rustic Gold chicks were allocated to 48 pens, balanced for body weight, and randomly assigned to eight dietary treatments (21 chicks/pen; 6 pens/treatment). In a 2×4 factorial design, diets contained either 100% or 98% ME and 100%, 95%, 90% or 85% BP relative to Ross 308 recommendations. Birds received starter (day 0–10), grower 1 (day 10–21), grower 2 (day 21–29) and finisher diets (day 29–42). At day 42, jejunal tissue from two birds per pen was collected for RNA-seq analysis. Gene expression was analysed using DESeq2, with adjusted p-values (Padj) < 0.10 considered significant. Among 13,984 expressed genes, differentially expressed genes (DEG) were identified between birds fed 85% and 100% BP at 100% and 98% ME level (100ME-85BP vs. 100ME-100BP, and 98ME-85BP vs. 98ME-100BP). At 100% ME, only SLC30A2, encoding the zinc transporter ZnT2, was upregulated in 100ME-85 BP compared to 100ME-100BP fed broilers ($\log_2$FC = 6.11, Padj < 0.0001). All other genes showed nominal, non-significant expression differences. A few genes approached significance (Padj = 0.11), including IFT57 and NT5C1B, which were also upregulated in 100ME-85BP compared to 100ME-100BP fed broilers ($\log_2$FC = 1.09 and 0.51, respectively). Considering non-significant DEG with $|\log_2 FC| > 2.0$, expression of 41 genes was downregulated and 73 upregulated between 100ME-85BP and 100ME-100BP fed broilers. At 98% ME, 125 DEG were identified between 98ME-100BP and 98ME-85BP (Padj < 0.10). Six genes related to transcription and translation (ID2, RPS20, RPL23, RPL32, RPL35, RPL39L) and two involved in oxidative phosphorylation (CST3, ND3) were upregulated in 98ME-85BP compared to 98ME-100BP fed birds (Padj < 0.10). Balanced protein reduction also downregulated 51 genes involved in lipid/energy metabolism and 59 genes related to amino-acid/protein metabolism between broilers fed 98ME-85BP and 98ME-100BP (Padj < 0.10). Ongoing pathway analyses will further clarify the metabolic processes affected by graded dietary BP reduction. The present results point to a dietary energy-protein interaction, whereby reducing BP level slightly but significantly remodels small-intestinal gene expression only when ME is simultaneously reduced. None of the previously reported performance and carcass trait outcomes from this study showed such an interaction. Together, these findings may indicate that most of the jejunal metabolic pathways are preserved, but a modest adaptive intestinal response may occur to maintain alignment between nutrient absorption and metabolic demands under reduced dietary inputs. This may impact slow-growing broilers' nutrient excretions. Therefore, such insights are relevant when evaluating new nutritional strategies aiming to lower the environmental impact of slow-growing broiler production.

Untargeted metabolomics in urine and milk reveals coordinated nitrogen related metabolic responses to dietary protein degradability in dairy cows

M. Errico[1], A. Catellani[1], F. Froldi[1], M. Moschini[1], G. Rocchetti[1], A. Gallo[1]
[1] Università cattolica del sacro cuore, Department of Animal science Food and nutrition, Via Emilia Parmense 84, 29122 Piacenza, Italy

Untargeted metabolomics in urine and milk reveals coordinated nitrogen-related metabolic responses to dietary protein degradability in dairy cows Michela Errico1, Alessandro Catellani1, Federico Froldi1, Maurizio Moschini1, Antonio Gallo1, Gabriele Rocchetti1 1 Department of Animal Science, Food, and Nutrition (DIANA), Università Cattolica del Sacro Cuore, Via Emilia Parmense 84, 29122 Piacenza, Italy.Corresponding author: michela.errico@unicatt.it Optimizing nitrogen utilization in dairy cows requires identifying systemic metabolic responses to dietary protein degradability. We hypothesized that differences in rumen protein fractions would induce coordinated metabolic changes detectable within the low molecular weight range (50–250 m/z) in milk and urine. Nine dairy cows were assigned to a 3 × 3 Latin square design and fed three diets differing in protein composition: high soluble protein (SOL), high rumen-undegradable protein (BY), and a balanced control (CTR). After 21-day experimental periods, milk and urine samples were analyzed by UHPLC–HRMS Orbitrap. The UHPLC system consisted of a degassing system, a quaternary UHPLC pump, an autosampler device, and a thermostatically controlled Waters BEH C18 column (2.2 x 100 mm, 1.7 µm) held at 35°C. The mobile phase consisted of (A) water with 0.1% formic acid and (D) acetonitrile with 0.1% formic acid. The duration of the method was 11 min, the injection volume was 10 µL, and the flow rate 0.2 mL/min. The mass range in the full scan experiments was set at 50–250 m/z. Multiblock data integration (mixOmics) was applied to investigate shared metabolic signatures between biofluids. A strong correlation (69%) on the first predictive component (PC1) indicated coordinated systemic regulation between milk and urine. Urea emerged as a discriminant metabolite in milk under the SOL diet, reflecting enhanced nitrogen turnover associated with high soluble protein feeding. The first predictive component (PC1) was driven by metabolites related to nitrogen and intermediary metabolism, including urea, uracil, 6-hydroxynicotinate, N-acetyl-leucine, 5-methyl-cytosine, and organic acids such as malic and sebacic acid, indicating coordinated modulation of urea cycle activity, nucleotide metabolism, amino acid turnover, and tricarboxylic acid (TCA) cycle intermediates. Correlation network analysis further highlighted xanthurenic acid as a central hub linking tryptophan degradation to systemic nitrogen and energy metabolism. As a product of tryptophan degradation through the kynurenine pathway, it was strongly associated with urea, L-tryptophan, N-acetyl-leucine, and purine-related compounds, indicating tight coupling between aromatic amino acid catabolism and systemic nitrogen handling. Connections with citric acid and isocitrate further support integration between nitrogen disposal and energy metabolism. The involvement of ethanolamine and O-phosphoethanolamine suggests additional effects on membrane turnover and cellular remodeling. Overall, low-mass untargeted metabolomics effectively captured diet-specific metabolic signatures and revealed coordinated regulation of tryptophan degradation, urea cycle activity, and energy metabolism, providing mechanistic insight into nitrogen utilization dynamics in dairy cows.

Dietary vitamin D_3 dose-dependently modulates gene expression in peripheral blood mononuclear cells of dairy cows following an intramammary immune challenge

G. Costa Monteiro Moreira[1,2], G. De Aguiar[3], Y. Martel-Kennes[4], C. Silvestri[5], D. E. Rico[6]
[1] Université Paris Saclay, UVSQ, INRAE, BREED, 78350 Jouy-en-Josas, France, [2] Ecole Nationale Vétérinaire d'Alfort, BREED, 94700 Maisons-Alfort, France, [3] Department of Animal Science, Universidade Federal do Paraná, 80035-050 Curitiba, Brazil, [4] Sollio Agriculture, Bureau 200, H4N 3H7 Montreal, Canada, [5] Centre de Recherche de l'Institut Universitaire de Cardiologie et de Pneumologie de Québec (CRIUCPQ), Département de médecine, Faculté de Médecine, Université Laval, G1V 4G5 Québec, Canada, [6] Centre de recherche en sciences animales de Deschambault (CRSAD), Deschambault, G0A 1S0 Québec, Canada

While extensive research in dairy cow nutrition has allowed for a better characterization of dietary vitamin D3 (VitD) needs, especially in the context of calcium homeostasis, it is still unknown how these needs vary during periods of immune challenge (e.g., infections or the peripartum period). We evaluated transcriptional responses of peripheral blood mononuclear cells (PBMCs) in dairy cows following an intramammary lipopolysaccharide (IM-LPS) infusion under four VitD dietary supplementation levels (1X–4X baseline dose based on NRC requirements). Eight multiparous Holstein cows (90 JEL) from the CRSAD dairy herd were used in a duplicated 4 x 4 Latin Square design with 4 periods of 14 d each and 7 d washouts. Treatments were:1) 1X NRC requirements (Control; 1040 IU/kg DM); 2) 2X NRC requirements (2X; 2,080 IU/kg DM); 3) 3X NRC requirements (3X; 3,120 IU/kg DM) and 4) 4X NRC requirements (4,160 IU/kg DM).The IM-LPS challenge (25 µg of E. coli 0111:B4 LPS; EB Vaccigrade; InvivoGen) was performed at 8h00 on d12 of each period and blood samples collected immediately before and 4h after the challenge for PBMCs preparations. Total RNA was extracted from PBMCs (TRIzol) and quality assessed using an Agilent Bioanalyzer (median RIN = 4.7). To account for partially degraded samples, rRNA-depleted libraries were prepared and sequenced (PE 100 bp, Illumina NovaSeq). Libraries yielded between 49 and 72 million reads per sample. Reads were aligned to the bovine reference genome (NCBI ARS-UCD2.0) and differential expression analysis were performed using DESeq2 package (padj < 0.05, $|\log_2 FC| > 1.5$) and identified 90, 401, 350, and 267 significantly regulated genes in the 1X–4X comparisons (0h vs. 4h), respectively. Fifteen genes exhibited consistent differential expression status, which was also consistent with dose-dependent regulation across all treatments. Among these, PTX3 and CXCR6, key modulators of innate and adaptive immunity, were upregulated with increasing VitD, while DOK2, a negative regulator of T/NK signaling, decreased. These patterns suggest that VitD supplementation enhances immune responsiveness by promoting early inflammatory mediators and modulating inhibitory checkpoints. Our findings provide novel insights into the transcriptional mechanisms by which VitD modulates immune function, with potential implications for mastitis treatment and general immunomodulation during periods of stress in dairy cattle. Keywords: Vitamin D3, bovine mammary gland, RNA-seq, LPS, immune regulation, differential gene expression

Functional diversity of cannabinoid receptors in the Czech Red Pied and Czech Red cattle

K. Novák[1], T. Paulová[2,3], E. Pěchoučková[2,3]
[1] Institute of Animal Science, Department of Genetics and Breeding of Farm Animals, Přátelství 815, 104 00 Prague, Czech Republic, [2] Czech University of Life Sciences, Faculty of Agrobiology, Food and Natural Resources, Kamýcká 129, 165 06 Prague, Czech Republic, [3] Institute of Animal Science, Department of Nutritional Physiology and Animal Product Quality, Přátelství 815, 104 00 Prague, Czech Republic

Although hemp (Cannabis sativa L.) plants were used as an effective fodder crop across Asia and Europe, their current use is restricted. The effect on the animals is considered potentially harmful in view of the psychoactive compounds present in a variety-specific manner. In cattle, the admitted addition to the fodder mixtures is not significant, according to a recently updated EFSA report from 2011. On the other hand, the susceptibility to the psychoactive cannabinoids is determined not only by the substance concentration, but also by the functional forms of cannabinoid receptors. Therefore, the diversity in the genes encoding cannabinoid receptors, CNR1 and CNR2), was investigated and the results were interpreted for local cattle breeds of the Czech Republic. The panel of breeds included Czech Red Pied cattle (CRP, Simmental type), the conserved nucleus herd of this breed, and the conserved Czech Red cattle (CR), which is considered an indigenous mountain breed. The pooled genomic DNA samples from 150 bulls of the CRP production population, 35 animals from the historical nucleus herd, and 80 animals of CR were sequenced using Illumina HiSeq technology. The obtained 60× coverage was sufficient to detect polymorphisms above the 0.05 frequency with 95% efficiency. The diversity as revealed against the UMD3.1.1 reference sequence was evaluated for each population. The gene CNR1 (located on chromosome 9, 29,042 bp) demonstrated 300 polymorphisms in commercial CRP, where 8 were located in mRNA (5616 nt) and 4 SNPs in the protein coding sequence (1419 nt). Nevertheless, only one SNP was associated with an amino-acid substitution (A>G at position 62659162, encoding the Met23Val). The variability in the nucleus herd of CRP was comparable, comprising 262 polymorphisms, 9 of which were located in mRNA and 5 in the coding sequence. In the CR population, 236 polymorphisms were found in the CNR1 gene, among them 9 in mRNA and 4 in CDS. The presence of an additional polymorphism (C>T at 62660127) in the coding sequence in the conserved nucleus herd of CRP confirms the previously suggested background of the historical cattle population. This picture was supported by the variability observed in the CNR2 gene (chromosome 2, 37,925 bp) that harboured 505 polymorphisms in the CRP population. Eight SNPs were in mRNA (3796 nt), and 3 SNPs in CDS of 1086 nt, where all SNPs were synonymous. A characteristic diversity can be assumed for the nucleus herd of CRP as based on the SNP 129632443A>G in CDS, which is absent in other populations. Statistical reconstruction of haplotypes suggests non-arbitrary grouping of SNPs, which might be ascribed to the historical origin or alternating selection pressure. A considerable number of polymorphisms found in coding and adjacent regions suggested variation in susceptibility to undesirable psychoactive compounds. The question arises as to what extent the variability in the cannabinoid receptor genes is caused by the selection pressure exerted by the use of hemp as feed in the pre-historical and medieval times. At the same time, a genetic estimate of cattle predisposition to the hemp feed might contribute to the use of the limits set by EFSA. At least a partial transition to hemp as a feed crop is supported by the presence of antimicrobial components and common reasons related to organic farming such as higher green matter productivity and soil recultivation.

Effect of dietary Lactobacillus Plantarum TWK10 on growth performance, nutrient digestibility, blood profile and gut microbiome in beagles

S. Y. Jang[1,2], K. Lee[1,2], K. Das[1,2], L. Pu[1,2], I. H. Kim[1,2]
[1] Dankook University, Department of Animal Biotechnology, 119, Dandae -ro, 31116 Cheonan, South Korea, [2] Smart Animal Bio Institute, 119, Dandae -ro, 31116 Cheonan, South Korea

Dogs have cohabited with humans for thousands of years and serve major companions. The health and well-being of dogs, like that of their owners, are closely linked to the composition and function of gut microbiota. Providing appropriate care and a nutritionally balanced diet is therefore essential for maintaining companion animal health. Therefore, this study aims to evaluate the effects of dietary supplementation with Lactobacillus plantarum TWK10 on the overall health of beagles. Eight healthy beagles with an initial body weight of 12.50 ± 1.28 kg were enrolled in a 10-week crossover study consisting of two experimental phases: Phase 1 (weeks 0–4) and Phase 2 (weeks 6–10), separated by a 2-week washout period. Dogs were assigned to receive either a control (CON) commercial diet or the CON diet supplemented with L. plantarum TWK10 at a dose of 1×10^{10} CFU/day. Growth performance, blood profiles, nutrient digestibility, fecal moisture and pH, and fecal microbiota and microbiome composition were assessed at the end of each phase. Data was analyzed using linear mixed models for growth performance, nutrient digestibility, fecal pH, and hematological parameters, with dietary treatment and experimental period as fixed effects and individual dogs as a random effect using SPSS version 22.0 (SPSS Inc., Chicago, IL, USA). Alpha-diversity indices were analyzed using the Kruskal-Wallis test, and beta-diversity was assessed by principal coordinate analysis using Bray–Curtis's dissimilarity and PERMANOVA. Our results showed that beagles fed Probiotic supplementation had no significant effects on growth performance, nutrient digestibility, or overall fecal microbiota composition; however, it resulted in reduced fecal pH and significantly increased serum calcium, insulin-like growth factor-1, creatinine, and immunoglobulin G concentrations compared with the CON group. While no differences were observed in alpha- or beta-diversity indices between groups. At the taxonomic level, the relative abundance of the phyla Firmicutes and Bacteroidota and the genus Prevotella was higher in the probiotic-treated group. Collectively, these findings suggest that dietary L. plantarum TWK10 (1×10^{10} CFU/day) may confer beneficial effects on gut health in beagles without altering production traits.

Integrative Genomic and Molecular Modeling Analyses Elucidate the Structural and Functional Impact of the GCKR P446L Variant in Type 2 Diabetes

M. J. Jang[1], R. K. Pathak[2], T. H. Min[1], Y. J. Seo[1], C. Lim[1], J. M. Kim[1]
[1] Chung-Ang University, Department of Animal Science and Technology, 4726 Seodong-daero, Daedeok-myeon, 17546 Anseong-si, South Korea, [2] University of Rovira i Virgili, Department of Chemical Engineering, Carrer de l'Escorxador, 43003 Tarragona, Spain

Type 2 diabetes mellitus (T2DM) is a complex metabolic disorder influenced by genetic and environmental factors. To identify functionally relevant variants associated with T2DM, we conducted a genome-wide association study (GWAS) in 35,120 individuals from the Korean Genome and Epidemiology Study (KoGES) meta-cohort, analyzing 465,971 genotyped single-nucleotide polymorphisms (SNPs). Among variants exceeding the genome-wide significance threshold ($P < 5 \times 10^{-8}$), the missense SNP rs1260326 (P446L) in the GCKR gene emerged as a genome-wide significant non-synonymous variant associated with T2DM. GCKR encodes glucokinase regulatory protein (GKRP), which modulates glucokinase (GCK) activity in hepatic glucose metabolism. To assess the functional consequences of the P446L substitution, structural modeling and protein–protein docking analyses were performed to compare interactions between GCK and GKRP in wild-type and mutant forms. The mutant protein exhibited enhanced binding affinity but altered interaction patterns within the GCK–GKRP complex, suggesting perturbation of normal regulatory dynamics. Molecular dynamics simulations further revealed reduced structural stability and altered conformational behavior in the mutant GKRP relative to the wild type. These structural alterations indicate that the P446L substitution may compromise GKRP-mediated regulation of GCK, potentially contributing to dysregulated glucose metabolism and increased T2DM susceptibility. By integrating large-scale population genomics with molecular structural analysis, this study provides functional evidence supporting the biological relevance of the GCKR P446L variant in T2DM.

Ensemble Stacking Model Based Integration of Omics Data Uncovers Dynamic Biological Mechanism Landscape and Prognostic Factors of Sleeve Gastrectomy in Morbid Obese

Y. J. Seo[1], M. J. Jang[1], C. Lim[1], J. M. Kim[1]
[1] Chung-Ang University, Department of Animal Science and Technology, 4726 Seodong-dearo, Daedeok-myeon, 17546 Anseong-si, South Korea

Bariatric metabolic surgery achieves durable weight loss in morbid obesity, yet postoperative responses vary widely across individuals. Most prediction models rely primarily on clinical variables, limiting insight into molecular determinants of heterogeneous outcomes. We developed and internally validated a multi-omics stacking ensemble to predict 12-month percent excess BMI loss (%EBMIL) after vertical sleeve gastrectomy (VSG) using preoperative transcriptomic, metabolomic, and lipidomic profiles derived from subcutaneous adipose tissue (SAT), visceral adipose tissue (VAT), and blood. To improve learning stability in a limited-cohort setting, we performed data amplification (35×5) via smoothed bootstrapping. Base learners—including linear regression, ridge, lasso, elastic net, XGBoost, and random forest—were trained within each omics layer, and their predictions were integrated using an elastic net meta-model. We exhaustively evaluated tissue- and omics-layer combinations to identify the optimal predictive configuration. The best-performing ensemble combined blood lipidomics with SAT RNA-seq, SAT lipidomics, and VAT RNA-seq, achieving strong internal-validation performance (R^2=0.927521, MAE=2.604036, RMSE=3.274321). Pathway-based functional analysis of key predictive features highlighted features enriched in glycerophospholipid metabolism, implicating circulating glycerophospholipids as molecular signals associated with post-VSG lipid metabolic remodeling across interconnected organs and tissues, including liver, intestine, adipose tissue, and skeletal muscle. Collectively, this stacking-based multi-omics framework provides an accurate and biologically informed approach for predicting 12-month %EBMIL and prioritizing candidate biomarkers underlying inter-individual variability in surgical weight-loss outcomes.

The effect of reduced protein diet on epigenetic changes in muscles of Krškopolje pigs

K. Poklukar[1], M. Škrlep[1], M. Čandek-Potokar[1], M. Englund[2], C. Guerrero-Bosagna[2], F. Pértille[2]
[1] Agricultural Institute of Slovenia, Animal Science department, Hacquetova ulica 17, 1000 Ljubljana, Slovenia, [2] Uppsala University, Physiology and Environmental Toxicology, Department of Organismal Biology, Norbyvägen 18 A, 752 36 Uppsala, Sweden

Krškopolje pig is a local breed with lower protein requirements compared to modern breeds. Biological mechanisms underlying this adaptation are poorly understood. It is hypothesized that diets with low protein (LP) content could lead to epigenetic modifications, influencing gene regulation in the muscle. It is assumed that such effects might differ in different production systems. The aim of the present study was to identify DNA methylation differences in the longissimus dorsi (LD) muscle of pigs fed a LP diet compared with animals receiving a standard high protein (HP) diet. Study was conducted in two production systems, organic outdoor and conventional indoor. In both systems, two experimental groups (LP, HP) were formed with 10 pigs per treatment (HP vs. LP). Pigs were slaughtered at 330 days of age and samples of LD muscle collected. DNA was extracted and analysed using GBS-MeDIP method. In organic outdoor production system, comparing LP and HP diet identified 16 differentially methylated regions (DMRs, $P<0.05$, FDR=0.439) located mainly in promotor and intronic regions. Twelve related-genes were associated with DMRs (e.g., MTOR, FGF9 and ZIC3), being significantly enriched in gene ontology terms such as muscle tissue development and tissue morphogenesis (Q-value < 0.05), as well as PIP3-activates-AKT signalling pathway (Q-value<0.01). In indoor conventional system, 12 DMRs were identified between HP and LP treatment ($P<0.05$; FDR=0.384) being mainly located in intergenic regions (75%). One DMR was located close to TKFC gene, which is involved in glycerol and carbohydrate metabolic process, and regulation of immune response. Since the effect of LP diet on epigenetic profile was small in both production system, we additionally assessed the effect of rearing system. We identified 55 DMRs ($P<0.05$; FDR=0.361), with related-genes enriched in endoplasmic reticulum subcompartment (OSBPL8, PEDS1, BCAP31), adherens junction (TRPV4, JUP), and apical plasma membrane (SLC5A10, TRPV4) cellular component terms (Q-value<0.05). Additionally, the RHO GTPase cycle pathway was significantly enriched (Q-value<0.05). In conclusion, the LP diet had a minor effect on DNA methylation consistent with lower protein requirements, while rearing system induced differences were more important. Maintaining agrobiodiversity: Holistic sensory and consumer testing of local chicken breeds and crossbreds thereof with commercial lines

D. Mörlein[1], C. Siebenmorgen[1], J. Mörlein[1], M. Strack[2], A. Risius[3]
[1] University of Göttingen, Kellnerweg 6, 37077 Göttingen, Germany, [2] isi GmbH, Ascherberg 2, 37124 Rosdorf, Germany, [3] Fulda University of Applied Sciences, Leipziger Straße 123, 36037 Fulda, Germany

Crossbreeding with commercial lines presents an opportunity to improve the production performance of local chicken breeds and thus their economic viability while preserving agrobiodiversity through parental stocks. It remains to be shown whether sensory claims and information provision to consumers could support marketing efforts. Herein, a mixed method approach was applied to generate consumer insights and for objective sensory evaluation of three local breeds (Altsteirer, Ramelsloher, Bielefelder) and crossbreds thereof with commercial lines (White Rock, Ranger). Therefore, diverse culinary use cases as well as different marketing channels were considered for deriving implications for marketing strategies. For objective sensory assessment, chicken broths, sous-vide cooked breast meat, steamed meatballs, and fricassee, were evaluated under controlled conditions by trained sensory panelists via Quantitative Descriptive Analysis (QDA) and Napping. Various chefs were provided chickens and commented on their usage for higher level gastronomy. Additionally, a real-life consumer acceptance study (n = 642) was conducted in a local cafeteria whereby considering various dishes using breast and thigh meat; also an information intervention regarding the loss of agrobiodiversity was tested. Finally, through an in-home test (n = 108) consumers' willingness to use whole chickens for home cooking was tested. Overall, no or rather small sensory differences between local breeds and their crosses were found by trained assessors, with the differences being product- and preparation-specific. Broths showed strong variation in salty taste and fatty aftertaste ($p = .001$), favouring purebreds. In meatballs, differences were most apparent between breast and leg meat ($p < .048$) and sous-vide cooked breast samples showed textural differences ($p = .003$). The real-life cafeteria experiment revealed that overall liking was higher for commercial breeds. However, consumers preferred local crossbreed thighs over commercial breed thighs, namely with local breed thighs being more tender and less dry. Providing information about agrobiodiversity loss showed a significant increase of the overall liking of local breed dishes and improved consumer attitudes towards agrobiodiversity preservation. The home-use test revealed both opportunities and barriers for whole-animal utilization as the study revealed distinct segments varying in their attitudes. Importantly, the preparation of whole chickens is perceived too time-consuming (and demanding) by a relevant share of consumers, and also feelings of disgust were identified. As household income, family structure, cooking skills were found to influence both acceptance and willingness to pay, targeted approaches appear promising for marketing whole chickens. In conclusion, no clear sensory advantages of local breeds or their crossbreeds could be identified. In turn, their sensory properties don't hinder marketing, and the choice of crossbreeding partners had no substantial impact on the sensory qualities. The study highlights the potential of information dissemination to support local breeds' preservation. Future research should aim at validating consumer attitudes regarding the use of whole chickens as this is considered key for the marketing of local breeds (and crossbreds thereof). Finally, the sensory protocols developed herein add to the existing set of methods for a more holistic sensory analysis of poultry as well as for generating consumer insights with high external validity.

Assessment of post-thaw semen quality in two conserved Norwegian rooster lines

A. Kettunen[1], E. L. F. White[1], M. Honkatukia[1], N. Svartedal[2], A. K. Krogenæs[3], J. Peippo[4], A. Sayyari[3]
[1] Nordic Genetic Resource Center - NordGen, FarmAnimals, C/o Norwegian University of Life Sciences, Faculty of Biosciences, P.O. Box 5003 NMBU, NO-1432 Ås, Norway, [2] Norwegian Genetic Resource Centre, NIBIO, P.O. Box 115, N-1431 Ås, Norway, [3] Norwegian University of Life Sciences, Faculty of Veterinary Medicine, P.O. Box 5003, NO-1432 Ås, Norway, [4] Natural Research Institute Finland, Tietotie 4, FI-31600 Jokioinen, Finland

The Norwegian gene bank for laying hens, established in 1974, maintains 12 heritage breeding lines at Hvam Upper Secondary School. Previous studies have shown that these lines are only distantly related to commercial layer populations. The gene bank is unique in its kind, and there is currently no backup of genetic material, neither as live animals nor as frozen germplasm. This highlights the need for a complementary ex situ cryopreservation strategy. To support this, the Norwegian Genetic Resource Centre conducted semen collection and cryopreservation trials in 2016 and 2018, resulting in 540 frozen semen doses. Despite subjectively assessed post-thaw motility appearing relatively high (≤ 40%), an insemination trial in 2018 resulted in extremely low fertilization rates (< 4%), prompting further investigation into post-thaw sperm quality. In this pilot study, we applied computer-assisted sperm analysis (CASA) to frozen-thawed semen from two conserved breeding lines, Jærhøns (JH) and NorBrid8 (NB8), to assess sperm motility impairment not detected by manual microscopy. Sperm motility was assessed from 24 individual doses (12 JH, 12 NB8), each representing one rooster and evaluated under two post-thaw storage methods, T1 and T2. In T1, motility was assessed immediately after thawing the straws in a 37 °C water bath for 30 seconds, whereas in T2 the remaining sample was held at 4 °C for up to 5 minutes before analysis to evaluate sensitivity to short-term cold exposure. Recorded traits included total motility (MOT), progressive motility (PROG), curvilinear velocity (VCL), average path velocity (VAP), straight-line velocity (VSL), straightness (STR), and linearity (LIN). To evaluate breed and storage method effects on sperm motility, we fitted linear mixed models with breed and storage method as fixed effects and rooster as a random effect to account for repeated measurements. MOT and PROG averaged 36.5% (SD 8.9%) and 19.9% (SD 5.9%), and both breed and storage method clearly influenced several CASA traits, with substantial variation attributable to individual males. NB8 exhibited lower MOT and PROG but higher VCL, VAP, and VSL than JH, while T2 reduced motility, all velocity traits, and lowered LIN without affecting STR. Principal Component Analysis (PCA) supported these patterns: PC1 (59% variance; velocity and linearity) and PC3 (12%; secondary kinematics) were influenced only by storage method, whereas breed differences were confined to PC2 (25%; motility). Correlation analyses further distinguished the breeds, with NB8 showing strong, coherent associations between motility and kinematic traits and JH displaying weaker or inconsistent covariance, indicating that NB8's motile sperm form a more integrated functional group despite lower MOT. This study represents our first step toward objectively characterizing sperm motility in frozen–thawed rooster semen, and future work combining similar analyses with controlled insemination trials will be essential to determine which sperm motility parameters—or composite indices—best predict fertilization success in Norwegian laying hen breeding lines.

Quo vadis Leicoma pig?

R. Schafberg[1], F. Rosner[1], B. Kröck[1], H. Reyer[2], M. Wensch-Dorendorf[1]
[1] Institute of Agricultural and Nutritional Science/Martin-Luther University Halle-Wittenberg, Animal Breeding, Th.-Lieser-Strasse 11, 06120 Halle, Germany, [2] Research Institute for Farm Animal Biology, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

The pig breed Leicoma was developed in the 1970s in the former German Democratic Republic as a synthetic maternal line and officially recognized in 1986. Its genetic foundation comprises German Landrace, Dutch Landrace, and Duroc, with minor contributions from Estonian Bacon and German Sattelschwein. Following German reunification and the structural transformation of the pig industry, the population declined drastically, and the breed has been classified as endangered since 2010. A severe genetic bottleneck in 2013–2014 reduced the effective breeding population to one boar and 19 sows. To counteract the loss of genetic variability, five historical sire lines were reactivated in 2016 using cryopreserved semen from the national in vitro gene bank. The objective of this study was to evaluate the effectiveness of these conservation measures by jointly examining reproductive performance and population genetic parameters under practical breeding conditions. The dataset comprised 1,158 litters from 317 herdbook sows recorded between 2019 and 2025 on a conservation-oriented farm in Saxony-Anhalt. The data was provided by the supervising pig Breeding Association Baden-Württemberg, known as German Genetics. The traits analyzed were number of piglets born alive (NBA) and number of piglets weaned (NW). Further traits can be found in the abstract by Frenkel et al. (2026, abstract # 1252314348).To account for physiological differences between parities, first parity (n = 317) and later parities (n = 841) were analyzed separately. Models were develeoped based on univariate linear models in SAS. The statistical models finally included year-season and breed of the mating partner as fixed effects. For later parities, parity number was fitted as an additional fixed effect. Age at first farrowing (first parity) or farrowing interval (later parities) was included as covariate. Random additive genetic effects were modeled using the numerator relationship matrix derived from the complete pedigree (N=647) in BLUPF90 under an animal model. Variance components were estimated by restricted maximum likelihood (REML), and heritabilities were calculated as the ratio of additive genetic variance to total phenotypic variance. Individual inbreeding coefficients were computed from pedigree information. In the pure line, mean NBA was 10.3 in first parity and 10.5 in later parities, while mean NW was 8.4 and 9.1, respectively. Heritability estimates for NW and NBA were between 0.09 and 0.25. Despite the small sample size, these values for fertility traits are within the expected range. The results correspond to the breeding goals from the 1990s, when NBA was to be achieved at 11.5 and NW at 10.3 piglets per sow and year. The moderate heritabilities indicate that additive genetic variation has been maintained despite the recent bottleneck, allowing continued genetic improvement within a conservation framework. Comparison with historical data (1973–1996) demonstrated stable fertility performance and no indication of inbreeding depression. The maximum inbreeding coefficient observed was 0.30, whereas the mean coefficient amounted to 0.06 among inbred animals and 0.04 across the total population. Given the bottleneck experienced a decade earlier, these values suggest effective management of relatedness and successful reintroduction of genetic diversity through cryoconserved material. Molecular genetic analyses of piglets born in 2025 were additionally conducted by bloodline as given by the pedigree to verify the effective contribution of the reactivated sire lines and to further characterize current genetic variability.

Genomic relationships among four Northwestern European dual-purpose cattle breeds: Implications for strategic exchange and preservation of unique and shared genetic diversity.

J. Huisman[1,2], J. Hoorneman[1,2], J. Ten Napel[1,2], G. Brockmann [3], P. Korkuc [3,4], D. Todd [5], A. Blom[6], M. Schoon[1,2]
[1] Wageningen University & Research, Animal Breeding and Genomics, Droevendaalsesteeg 1, 6708 BP Wageningen, Netherlands, [2] Centre for Genetic Resources The Netherlands (CGN), Wageningen University & Research, Droevendaalsesteeg 1, 6708 BP Wageningen, Netherlands, [3] Humboldt-Universität zu Berlin, Albrecht Daniel Thaer-Institut für Agrar- und Gartenbauwissenschaften, Unter den Linden 6, 10099 Berlin, Germany, [4] Leibniz-Institut für Zoo- und Wildtierforschung, Alfred-Kowalke-Straße 17, 10315 Berlin, Germany, [5] The National Bovine Data Centre, Scope House, Hortonwood 33, TF1 7EX Telford, United Kingdom, [6] The Irish Cattle Breeding Federation, Link Rd, Ballincollig, P31 D452 Cork, Ireland

Dual-purpose black and white cattle were the most common type of cattle in Northwestern European countries until the late 19th century, valued for their high milk production and decent slaughter value. Nowadays, they are largely replaced by Holstein Friesian cattle, a specialized dairy breed selected for high-input farming systems. However, increasing interest in agroecological and organic farming systems provides new opportunities for the original dual-purpose breeds. These cattle are well-suited for extensive low input systems which require robust, self-sufficient, healthy cows with high fertility. Even though interest in local dual-purpose cattle breeds has increased, their economic gain in conventional agriculture is limited, and consequently most of these breeds are rare. Because of common origin and overlapping breeding goals, these local dual-purpose cattle breeds might benefit from strategic exchange of breeding animals. More specifically, exchange of genetic material of breeding bulls between (commercial) artificial insemination (AI) centres or national gene banks may be promising. Here, we examine genomic diversity within and between four dual-purpose cattle breeds from the Netherlands (Dutch Friesian), Ireland (Irish Pure Friesian), United Kingdom (British Friesian) and Germany (Deutsches Schwarzbunte Niederungsrind), and compare to Dutch Holstein. We combined SNP datasets with 100-300 individuals per breed, generated with different genotyping methods, and filtered down to 20K SNPs with <10% missingness in the combined dataset. We find considerable overlap between the dual-purpose breeds in PCA and STRUCTURE plots, reflecting the common ancestry and continued exchange of individuals. But each local breed also harbours unique variation, in line with slight differences in breeding goal, adaptation to local circumstances, and random genetic drift. Holstein show as completely differentiated from all four dual-purpose breeds and not suitable for (regular) exchange of breeding animals. Exchange between the dual-purpose breeds requires a balance between bringing in genetically dissimilar breeding stock, and staying true to the individual breed characteristics. Simulations show that (limited) exchange of available breeding material via AI centres and national gene banks can contribute to overall conservation of genetic diversity for all four breeds while preserving unique variation. Furthermore, collections in gene banks are built up over time, aiming to include as much of the genetic variation present in the in situ population as possible. This long-term collection presents a wide variety of genetics available for exchange between breeds, allowing for a more strategic approach using a combination of earlier and modern genetics of each breed. We show an approach of exchanging frozen semen with a limited number of matings per bull between all breeds to be cost-effective and most successful conserving genetic diversity overall and within breeds.

Genomic analysis of genetic diversity and population stratification in Swabian-Hall pigs

L. Vollmer[1], J. Geibel[1,2], L. Kistner[3], A. Weigend[1], C. Worat[1], R. Weishaar[4], M. Petig[4], D. Hinrichs[3], S. Weigend[1,2], C. Reimer[1,2]

[1] Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Höltystraße 10, 31535 Neustadt, Germany, [2] University of Goettingen, Center for Integrated Breeding Research, Wilhelmsplatz 1, 37075 Göttingen, Germany, [3] University of Kassel-Witzenhausen, Faculty of Organic Agriculture, Nordbahnhofstr. 1a, 37213 Witzenhausen, Germany, [4] 4Züchtervereinigung Schwäbisch Hällisches Schwein e.V., Haller Straße 20, 74549 Wolpertshausen, Germany

Understanding genetic structure and levels of inbreeding within and between farms is essential for sustainable breeding management, especially in small endangered local breeds. Subdivision among populations contributes to genetic differentiation, with within-farm mating practices influencing the distribution of heterozygosity and inbreeding. Therefore, genomic selection has become standard practice to monitor breeds and guide breeding programs. In this study, SNP array genotype data were analyzed to assess the genetic structure, differentiation, and inbreeding of Swabian-Hall pigs from three farms P, E and W. To ensure data quality, SNPs with MAF < 0.05, markers with >5% missing genotypes, and individuals with >5% missing data were removed. LD pruning was then applied to marker independence. Principal component analysis (PCA) was performed to visualize population structure, and Wright's F statistics were calculated to quantify genetic differentiation and inbreeding. ADMIXTURE analysis was conducted for K = 2–4 to examine the genetic composition of individuals. The PCA reveals that individuals from the farms W and E were relatively close to each other, indicating a high degree of genetic similarity, whereas farm P shows a slight shift along the first principal component, suggesting moderate differentiation. The pairwise FST values support this pattern as differentiation between W and E is lowest (0.0259), while the comparisons between P and W (0.0588) and P and E (0.0548) show higher differentiation. This confirms that W and E are genetically more closely related to each other than to P. The total FST value of 0.0479 indicates low to moderate genetic differentiation overall. Negative FIS values in all farms indicate a slight excess of observed heterozygosity compared to the Hardy-Weinberg expectation. The following ADMIXTURE analysis shows similar genetic makeup. Individuals from W and E exhibited comparable cluster proportions, while individuals from P showed partially different proportions. Together, PCA, FST, and ADMIXTURE consistently indicate that farm P is genetically more distinct, whereas W and E are more similar. The genomic analyses provide important insights for improving conservation strategies within the breed. By integrating PCA, FST, and ADMIXTURE results, subtle population structure and potential inbreeding risks can be identified. This information allows informed mating and animal exchange decisions that maintain genetic diversity while supporting performance traits. In this study, the observed stratification between farms could partially result from differences in blood refreshments and crossbreeding history, leading to varying allele frequencies. To reduce stratification, greater animal exchange between farms, particularly between P and W/E, is recommended. However, in order to improve conservation and breeding strategies within the breed, it is sometimes essential to carefully weigh performance characteristics against the preservation of genetic diversity. Further research is needed to refine these strategies and provide more information on optimizing the breeding program for Swabian-Hall pigs.

Genetic Insights into the Diversity and Structure of European Draft Horse Breeds

L. Vostry[1], H. Vostra-Vydrova[1], A. Halvonik[2], N. Moravcikova[2], K. Palesova[2], R. Kasarda[2], B. Hofmanova[1], G. Mészáros[3], V. Cubric-Curik[4], I. Nagy[5], A. Bokor[5], I. Curik[4,5]

[1] Czech University of Life Sciences Prague, Kamýcká 129, 165 00 Prague, Czech Republic, [2] Slovak University of Agriculture in Nitra, Tr. A. Hlinku 2, 949 76 Nitra, Slovakia, [3] BOKU University, Gregor-Mendel-Straße 33, 1180 Vienna, Austria, [4] University of Zagreb, Faculty of Agriculture, Svetošimunska cesta 25, 10000 Zagreb, Croatia, [5] Hungarian University of Agriculture & Life Sciences (MATE), Guba Sándor 40, 7400 Kaposvár, Hungary

For centuries, draft horses have been an essential component of agriculture, forestry, and transportation, contributing substantially to the economic development of European regions while also shaping the cultural landscape and traditional farming systems. The aim of this study was to evaluate genetic diversity, population structure among European draft horse breeds. We analysed 1,042 individuals from twelve breeds – Belgian, Clydesdale, Czech Moravian Belgian, Franches-Montagnes, Muraközi/Međimurje horse, Noriker (Austria), Noriker (Czechia), Noric of Muran, North Swedish Horse, Percheron, Shire, and Silesian Noriker – using a dataset containing a minimum of 50,042 SNPs per individual. Observed heterozygosity was comparable across breeds (approximately 0.26), with the exception of Noriker (Austria) (Ho=0.34). Genomic inbreeding coefficients estimated using runs of homozygosity (FROH) and homozygosity-by-descent segments (FHBD) were generally moderate, ranging from approximately 0.03 to 0.14 (FROH>2Mb) and from approximately 0.05 to 0.14 (FHBD), whereas Clydesdale showed higher values compared to others (FROH>2Mb=0.26; FHBD=0.22). In contrast, most FIS values were negative, indicating preferential mating among unrelated individuals. Estimates of contemporary effective population size ranged from approximately 66 to 236 individuals across breeds. Estimated historical effective population size detected a demographic decline in most breeds between 25 and 8 generations ago. These results provide important insights into the current levels of genetic diversity and demographic history of European draft horse breeds and may support future conservation and breeding strategies. This work was supported by projects GACR 24-14325L, QL25020022, APVV-20-0161, VEGA 1/0316/25 ,IP-2022-10-8926, and the Flagship Research Groups Programme of the Hungarian University of Agriculture and Life Sciences.

Pedigree analysis and genomic characterization of two local German cattle breeds

V. Fenske[1], N. Krattenmacher[2], G. Thaller[2], D. Hinrichs[1]
[1] University of Kassel, Faculty of Organic Agriculture, Section of animal breeding, Nordbahnhofstr. 1a, 37213 Witzenhausen, Germany, [2] Kiel University, Institute of animal breeding and husbandry, Olshausenstr. 40, 24118 Kiel, Germany

Local dairy cattle breeds represent a unique genetic and cultural heritage and should be conserved for future generations. In addition, these breeds are well suited to a wide range of different environments and may play an important role in adapting breeding programs to future production challenges. The aim of the present study was to estimate pedigree- and genome-based inbreeding measures, the number of effective founders, and marginal genetic contributions of key ancestors in two Northern German cattle breeds (Angler dairy cattle (ADC) and Red and White dual purpose cattle (RDN)). Pedigree and SNP-chip data were provided by Vereinigte Informationssysteme Tierhaltung w.V. The pedigree file for the ADC breed contains information on 132,611 animals born between 1906 and 2025, while the RDN pedigree includes 155,813 animals born in the same period. SNP data were available for 7,570 ADC and 5,318 RDN animals, respectively. In the ADC pedigree, 72,887 animals were inbred with an average inbreeding coefficient (F) of 0.024 and a maximum F of 0.380. In the RDN pedigree, 45,822 animals were inbred with an average F of 0.026 and a maximum F of 0.315. To estimate the effective number of founders and marginal genetic contributions by breed and sex, three reference populations were defined. Reference population 1 (Ref1) included animals born between 2010 and 2014, Ref2 included animals born between 2015 and 2019, and Ref3 comprised animals born between 2020 and 2025. The number of bulls in Ref1, Ref2, and Ref3 for ADC was 1,720, 1,237, and 1,507, respectively, whereas in the RDN population the numbers were 894, 571, and 1,361. For cows, the corresponding numbers were 7,610, 9,471, and 14,539 in ADC and 5,746, 5,096, and 7,168 in RDN. For ADC bulls, the number of effective founders decreased from 424.2 in Ref1 to 344.5 in Ref3. In the RDN breed, the number of effective founders for bulls declined from 250.9 in Ref1 to 154.7 in Ref3. For ADC cows, the effective number of founders ranged between 302.5 (Ref2) and 312.6 (Ref3), whereas in the RDN breed it ranged between 154.4 (Ref3) and 173.3 (Ref2). In the RDN breed, the highest marginal contribution of a single animal to the reference population was 0.07, 0.06, and 0.07 for Ref1, Ref2, and Ref3, respectively, which was higher compared to ADC (0.04, 0.04, and 0.05). In ADC, the marginal genetic contributions of the 20 most influential animals ranged from 0.36 (cows in Ref1) to 0.58 (cows in Ref3). In the RDN breed, the corresponding values ranged from 0.48 (cows in Ref1 and bulls in Ref1) to 0.55 (cows in Ref3). Genomic characterization was performed using a subset of 1,901 ADC animals. After filtering the genotype data for minor allele frequency < 0.01 and SNP call rate < 0.99, 40,405 autosomal SNPs remained for estimating genome-based inbreeding coefficients using the software Plink. Inbreeding coefficients based on runs of homozygosity (ROH) were calculated using two different parameter settings. The first parameter set detected 24,560 ROH and the estimated FROH varied between 0.002 and 0.288 with a mean of 0.043. In the second parameter set, FROH varied between 0.001 and 0.284 and the number of detected ROHs was 21,519. Genomic characterization will be extended to all ADC and RDN animals. Additional genomic inbreeding coefficients will be estimated from the diagonal elements of the genomic relationship matrix, and ROH islands will be identified in both breeds.

Historical expansion and severe recent demographic contraction in the South African Beef Shorthorn population

S. Lashmar[1], E. Cason[2]
[1] Agricultural Research Council, Animal Production, Old Olifantsfontein Road, 0062 Pretoria, South Africa, [2] University of Free State, Department of Animal Science, Agricultural Building, D205 Nelson Mandela Drive, Park West, 9301 Bloemfontein, South Africa

The South African (SA) Shorthorn is one of the country's oldest beef breeds and has historically contributed genetically to several composite beef breeds, globally and locally, including the SA Bonsmara and SA Beefmaster. However, despite its historical importance, the breed has undergone a substantial demographic decline, now represented by only ~13 active breeders, coinciding with the expansion of composite breeds developed using Shorthorn genetics. This study aimed to characterise the demographic trajectory and genetic diversity of the SA Shorthorn population using pedigree records. Pedigree data comprising 35 444 animals born between 1925 and 2024 were analysed. Pedigree depth was moderate, with a mean of 2.71 complete generation equivalents (CGE) and a maximum of 9.18 generations, while the mean generation interval was estimated at 5.16 years. A total of 4 389 founders were identified, representing 12.4% of animals in the pedigree, although unequal founder contributions resulted in an effective number of founders (f_e) of 232.7. The effective population size (N_e), estimated from the rate of inbreeding, was 103.97. Demographic analysis revealed a pronounced contraction in census size, with registrations peaking at 1 919 animals in 1989, followed by an 86.9% decline in the contemporary population. A reference population of animals born ≥2015 (n = 2 510) was defined to represent the modern cohort. Within this population, 127 sires contributed progeny with a mean of 19 offspring per sire, and a Gini coefficient of 0.53 indicated moderate reproductive inequality among males. These results demonstrate that although the SA Shorthorn originated from a relatively broad founder base, the contemporary population has undergone substantial demographic contraction. Monitoring demographic trends and genetic diversity will therefore be important to support the sustainable management and conservation of this historically important breed.

Genomic Structure of Local Sheep Breeds in Tunisia Using SNP Markers

I. Bensouf[1], I. Hayaha[2], N. Mhamdi[1], S. B. S. Gaouar[3]
[1] National Agronomic Institute of Tunis, Laboratory of Animal, Genetic and Feed Resources (LRGAA), National Agronomic Institute of Tunisia, University of Carthage, 43 Avenue Charles Nicolle, Tunis, 1082, Tunisia, 43 Avenue Charles Nicolle, Tunis, 1082, Tunisia, 2000 Tunis, Tunisia, [2] University Mohammed VI Polytechnic (UM6P), African Genome Center (AGC), University Mohammed VI Polytechnic (UM6P), Ben Guerir, Lot 660, Hay Moulay Rachid, 43150 Ben Guerir, Morocco, [3] University of Tlemcen, Applied genetics in agriculture, ecology and public health laboratory, 22, Rue Abi Ayad Abdelkrim, Fg Pasteur BP 119, Tlemcen, Algérie, 13000 Tlemcen, Algeria

Tunisian sheep breeds represent important genetic resources adapted to diverse environmental conditions, yet their genomic structure and diversity patterns remain insufficiently characterized. In this study, genome-wide SNP data from 180 individuals belonging to four Tunisian breeds (Barbarine, Noir de Thibar, Queue Fine de l'Ouest, and Sicilo-Sarde) were analyzed to investigate genetic diversity, population structure, differentiation, and demographic history. Following stringent quality control filtering, genetic diversity indices (observed and expected heterozygosity and FIS) indicated moderate within-breed variation and low levels of inbreeding across populations. Pairwise FST estimates revealed low to moderate genetic differentiation (0.004-0.029), with Sicilo-Sarde emerging as the most distinct breed. Multivariate analysis (DAPC) and model-based clustering (LEA) consistently identified clear genetic separation of Sicilo-Sarde, while Noir de Thibar exhibited higher admixture signals, suggesting historical gene flow among Tunisian breeds. Linkage disequilibrium decay patterns differed among breeds, with slower LD decay observed in Noir de Thibar, indicating potential differences in effective population size or demographic history. Runs of homozygosity analyses revealed generally low genomic inbreeding (FROH), although increased variability was detected in Queue Fine de l'Ouest. Phylogenetic reconstruction based on Nei's genetic distance supported the differentiation patterns observed in structure analyses. Overall, these results demonstrate moderate population structure among Tunisian sheep breeds, highlight the genetic distinctiveness of Sicilo Sarde, and provide valuable insights for the conservation and sustainable management of local ovine genetic resources.

Genomic effective population size in two lines of mice divergently selected for homogeneity of birth weight

C. Ojeda-Marín[1], M. Saura[3], J. P. Gutiérrez[1], N. Formoso-Rafferty[2], I. Cervantes[1]
[1] Facultad de Veterinaria, UCM, Dpto Producción Animal, Avda Puerta del Hierro s/n, 28040 Madrid, Spain, [2] E.T.S.I.A.A.B, UPM, Dpto Producción Agraria, C/Senda del Rey 18, 28040 Madrid, Spain, [3] Instituto de Investigaciones Marinas, Rúa Eduardo Cabello 6, 36208 Vigo, Spain

Effective population size (Ne) is a key indicator of genetic diversity and a fundamental parameter for monitoring extinction risk in populations. Traditionally, Ne has been estimated using pedigree information; however, decreasing genotyping costs have greatly expanded the availability of genome-wide data, enabling more detailed and temporally resolved inference. As part of a divergent selection experiment for environmental variability of birth weight, two mouse lines were developed: a high variability line (HL) and a low variability line (LL). Previous results indicated that LL outperformed HL in terms of production, animal welfare, and robustness. The aim of this study was to estimate Ne using genomic-based methods in order to evaluate the impact of sustained selection and to compare both lines. A total of 1,824 individuals from 26 generations were genotyped using the Affymetrix Mouse Diversity Genotyping Array (616,137 SNPs). For the present analysis, 35 HL and 41 LL individuals from generation 26 were considered. After quality control, 217,770 SNPs were retained. Effective population size was estimated using the linkage disequilibrium (LD) method, across the full spectrum of recombination distances between SNPs, allowing inference of both contemporary and historical Ne. Contemporary Ne was estimated using NeEstimator and currentNe, whereas historical Ne trajectories were inferred using GONE2. The results revealed a pronounced decline in Ne approximately 80-100 generations ago, consistent with the origin of the experimental population. Around 150 generations in the past, Ne exceeded 1,000 individuals in both lines, with consistently larger values in LL. This divergence likely reflects the long-term effects of the divergent selection regime, suggesting higher genetic variability compared to HL despite similar selection intensity and mating systems. Contemporary Ne estimates were below 50 in both lines, with only minor differences between them. Estimates obtained with NeEstimator (18.6 for LL and 20.2 for HL) were lower than those from currentNe (37.79 for LL and 41.80 for HL), likely due to methodological differences in the treatment of linkage disequilibrium. While NeEstimator assumes independent loci and relies on unlinked SNPs, currentNe accounts for recombination and physical linkage, enabling the use of all markers and generally producing higher estimates. Overall, genomic-based approaches provided results consistent with the known demographic history and selection design of the population, while offering improved temporal resolution compared to pedigree-based estimates. These findings highlight the value of genomic methods for disentangling recent and historical changes in effective population size under long-term selection.

Preliminary analysis of ancestral genomic effective population size in a SRC Iberian pig population selected for homogeneity of birth weight

C. Ojeda-Marín[1], M. Muñoz[2], F. Sánchez-Esquiliche[3], J. M. García-Casco[2], F. Goyache[4], J. P. Gutiérrez[1], N. Formoso-Rafferty[5], I. Cervantes[1]

[1] Facultad de Veterinaria, UCM, Dpto de Producción Animal, Avda Puerta del Hierro s/n, 28040 Madird, Spain, [2] INA-CSIC, Dpto Mejora Genética, Ctra de la Coruña, km 7, 28040 Madrid, Spain, [3] Sánchez Romero Carvajal, Dpto Agropecuaria, Jabugo, 21290 Huelva, Spain, [4] SERIDA, Camino de Rioseco, 21290 Gijón, Spain, [5] ETSIAAB, UPM, Dpto Producción Agraria, C/Senda del Rey 18, 28040 Madrid, Spain

In recent decades, interest has increased in promoting homogeneity by reducing variability in traits. This trend is largely driven by economic incentives, as farmers receive higher inputs when defined production standards are achieved. In addition, selection for uniformity has been associated with improved robustness and resilience in several species. Since 2022, a selection experiment aimed at increasing birth weight homogeneity has been conducted in an Iberian pig population from Sánchez Romero Carvajal (SRC) fitting discrete generations. The study aimed to estimate genomic effective population size (Ne) in two generations of the selected SRC Iberian pig population. A total of 95 individuals corresponding to 38 trios from the first two generations were genotyped using the Axiom PorcineHD v1 array (Affymetrix). After quality control, unmapped SNPs, SNPs located on sex chromosomes, and SNPs showing Mendelian errors were removed. A total of 550,896 SNPs were retained for the analysis. The pedigree included 1609 individuals with a mean of 4.61 equivalent generations. Ancestral Ne was estimated using the linkage disequilibrium method, assuming population structure (Ne_{ax}) and not assuming structure (Ne_a). Moreover, Ne was calculated from pedigree information using the individual increase in inbreeding (Nei). GoNe2 was used to estimate Ne_a and Neax and ENDOG v4.9 to calculate Nei. The Nei was 47.54. This was consistent with the mating strategy implemented, in which 14 males from the best 14 dams were mated to 154 females from the best 52 dams per replicate performing two replicates per generation, and the mating avoiding the sharing of grandparents. Ne_{ax} was 26.98 one generation ago and gradually increased to 109.41 approximately 150 generations in the past. Ne_a ranged from 25.45 one generation ago to 45.43 thirteen generations ago and then increased from 131.40 fourteen generations ago to 790 approximately 150 generations ago. Ne_a may reflect formation of the SRC main herd in the 1980s (approximately seven generations ago), showing a sharp decline in Ne around thirteen generations ago. In contrast, Ne_{ax} showed a more gradual decrease in Ne over time. However, a small decline observed five generations ago (Ne_{ax} = 21.7) could also be associated with the formation of the SRC herd. Ne_{ax} detected two subpopulations within the analyzed population. The identified structure could be explained by the fact that this is a selected population, which could carry a family-based structure despite only two generations of selection are analyzed here. In addition, these animals were selected from a population based on the number of live piglets born and the total weight of the litter at 21 days, as well as for carcass quality traits. Nevertheless, Ne was also consistent with the historically demographic changes that occurred in this population. This preliminary study suggests that Nei captures current genetic diversity and mating structure in the SRC population selected for birth weight homogeneity. Furthermore, the present analysis also suggested that approaches that infer ancestral effective population size from genomic data successfully detect historical demographic changes in selected animal populations. Grant: PID2023-149012OB-I00 (RoPig).

Preserving genetic diversity in the local Belgian Piétrain pig populations.

K. Wijnrocx[1], H. Wilmot[2], A. Markey[1], D. Duarte[1,3], P. Mayeres[3], N. Gengler[1]
[1] University of Liège, Gembloux Agro-Bio Tech, TERRA Teaching and Research Center, Passage des Déportés, 2, 5030 Gembloux, Belgium, [2] University of Georgia, Department of Animal and Dairy Science, 425 River Road, GA 30602 Athens, United States, [3] Walloon Breeders Association (AWE Groupe), Rue des Champs Elysées, 4, 5590 Ciney, Belgium

The local Belgian Piétrain pig breed originated in the village of Piétrain in Wallonia (South of Belgium) in the early 20th century, through targeted selection and probable historical introgression with Berkshire into the local white pig population present at that time. The breed is typically characterized by its extreme muscularity, lean carcass composition, and characteristic white coat with black spots. Since then, it has been widely used as terminal sire in crossbreeding programs worldwide to improve carcass quality of the offspring. The Belgian Piétrain therefore demonstrates how the unique genetic and phenotypic traits of a local breed can generate significant value nowadays for regional and international livestock systems. Preserving genetic diversity of this local population inside the global Piétrain gene pool is essential for long-term resilience, prevention of inbreeding depression, and future breeding innovation, and therefore requires close monitoring. So far, the conservation of the original populations of the Piétrain in Belgium has relied on a network of independent breeders rather than large breeding companies, which means each breeder preserves a part of the breed's global genetic diversity, as shown in a recent pedigree- and phenotype-based study. However, in recent years, the Belgian Piétrain population has been declining, and has even been characterized since 2024 as an endangered breed. This threatens the continuity of these local populations and their genetic diversity, which has shown its importance on a much larger scale. Therefore, the goal of this study is to provide insights into the genetic diversity of the Walloon Piétrain population by analyzing SNP genotypes obtained from the routine genetic evaluation. We will use 185 purebred progeny-tested Piétrain boars, genotyped between 2019 and 2024 for genomic characterization of the population. Genomic relationships stratified among breeders will be determined to identify intrinsic particularities of the Walloon Piétrain population. We will estimate the average level of inbreeding based on runs of homozygosity (ROH), and the effective population size. Furthermore, breed-substructure will be analyzed using principal component analysis (PCA). This genomic characterization will complement the previous pedigree- and phenotype-based study, supporting the valorization and sustainable management of the local Piétrain breed. This will benefit the regional breeding context while also positioning the population as a gene reserve for the global pig industry.

Leicoma Pigs – a Traditonal Breed Revived

L. Frenkel[1], B. Kröck[1], M. Wensch-Dorendorf[1], H. Reyer[2], F. Rosner[1], R. Schafberg[1]
[1] Institute of Agricultural and Nutritional Sciences/Martin-Luther University Halle-Wittenberg, Animal breeding, Th.-Lieser-Strasse 11, 06120 Halle, Germany, [2] Research Institute for Farm Animal Biology, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany

The Leicoma pig breed was developed in the 1970s in the former German Democratic Republic (GDR) as a synthetic breed functioning as the maternal line within a hybrid breeding program. In the creation of this synthetic line, genetic material was drawn from the following breeds: German Saddleback, Dutch Landrace, Estonian Bacon Breed, German Landrace, and Duroc. In 1985, the Leicoma accounted for approximately 25 % of the pig population in the GDR. Following German reunification, the breed experienced a severe decline in numbers. Although the use of cryopreserved semen from original Leicoma boars temporarily stabilized the population and even increased its genetic variability, the breed since the end of the Nineties has been classified as an endangered conservation population and is listed on the Red List of endangered livestock breeds. In light of this development, the present study aimed to evaluate the performance of the current Leicoma population. Firstly, performance traits were examine in relation to the breeding objectives defined in 1986 . Secondly, these results were compared with historical performance data from original Leicoma populations collected between 1973 and 1996. This approach allowed conclusions to be drawn regarding the current status of the breed following the population bottleneck observed with one boar in 2013 and 19 sows in 2014, while in 2024, 11 boars and 370 sows resulted in an effective population size of 42.7.The analysis was based on two datasets from one farm provided by the Pig Breeders´ Association Baden-Württemberg, known as German Genetics. Data contained information on reproductive traits (based on 1,158 litters from 317 sows, Schafberg et al. (2026, abstract # 1252314341)), fattening, and slaughter performance of the present Leicoma population (29 castrated test animals, performance testing in Ruhlsdorf during individual periods from 11/2022 to 8/2023). Although the breeding goals defined in the 1980s have not yet been fully achieved, the results indicate that performance in all three performance areas of the current population has remained almost unchanged from its best times. The following means (standard deviations/breeding goal) were observed: average daily gain 896 g (77.7/950), lean meat percentage in percentage 49.4 (3.1/53), carcass length 107.5 cm (2.4/100), pH45 of the loin 6.3 (0.2/6.4). An inbreeding depression resulting from a potential increase of homozygous genotypes could neither be confirmed nor ruled out. The particularly small effective population size and the associated increase in the average inbreeding rate per generation suggest a deviation from optimal breeding conditions. Likewise, the results do not provide evidence of shift toward any of the founder breeds. Further clarification would require at least a SNP genotyping of the current population which is actually in progress. Considering the observed positive performance trends and recent successful examples of marketing Leicoma as a niche product, the Leicoma pig can be regarded as being on a promising path toward revitalization. Nevertheless, the low effective population size continues to indicate an endangered status. In accordance with the Convention on Biological Diversity (1993), the Leicoma breed represents an important animal genetic resource contributing to biodiversity and should be strengthened with respect to both population size and genetic diversity while preserving breed-specific characteristics.

From genes to practice: breeding for intestinal health and resilience

M. Fredholm[1]
[1] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 3, 1870 Frederiksberg C, Denmark

Abstract: Post-weaning diarrhea (PWD) remains one of the most prevalent and economically significant health challenges in pig production, leading to increased morbidity, reduced growth performance, higher antimicrobial usage, and considerable financial losses. The continued rise in litter sizes has resulted in more piglets with reduced robustness, further exacerbating the incidence and impacts of PWD. To uncover the intrinsic mechanisms that shape early-life robustness in piglets and to identify key factors influencing PWD and subsequent antibiotic use, we conducted an extensive clinical characterization of 2,500 pigs with a strong emphasis on gut health—a central determinant of overall resilience. Through genome-wide association analyses, we identified genomic regions and variants linked to health and robustness indicators. These insights provide a foundation for integrating health- and resilience-related traits into future breeding strategies, supporting more sustainable pig production and improved porcine health management.

A dual-challenge model simulating subclinical post weaning enteric dysfunction in piglets: Impacts on gut integrity and markers of inflammation

D. Vodolazska[1], H. Nygaard Lærke[1], C. Lauridsen[1]
[1] Aarhus University, Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark

There is an urgent need for robust experimental animal models that reliably mimic post-weaning enteric disturbances to support development of effective nutritional and management strategies for early-life pig health. A novel dual-challenge model was developed to induce a subclinical enteric disturbance by combining chemical stimulation with dextran sodium sulfate (DSS), which provokes mucosal disruption and compromises epithelial integrity, and bacterial stimulation using Escherichia coli, a common post-weaning enteric pathogen. It was hypothesized that such approach can provide a physiologically relevant simulation of early post-weaning intestinal dysfunction, offering a valuable tool for investigating how nutritional interventions influence resilience, gut function, growth performance, and the potential to reduce antibiotic use, while also allowing assessment of the role of pre-existing intestinal inflammation in shaping subsequent pathogenic infection. A total of 24 piglets (26 days old; 6.5 ± 1.7 kg BW; mixed sex; Landrace × Yorkshire × Duroc) were included in the study. The piglets originated from six sows that were homozygous positive for ETEC F4 susceptibility. The study included four treatments, n=6 piglets assigned to each: DSS, E. coli, a combined DSS + E. coli challenge, and a negative control. After a 7-day adaptation period, piglets assigned to the DSS treatments received 0.32 g DSS/kg BW dissolved in sterile saline with apple juice, while the remaining groups received a sham solution. On day 3, piglets in the E. coli groups were orally inoculated with E. coli O149:F4 (strain 9910045-1 ETEC), followed by once-daily reinoculation for two additional days. In vivo blood plasma samples were collected for sodium and haptoglobin analyses and fecal samples to assess pH and dry matter content, while intestinal tissues were collected post-mortem for tight junction gene expression and mucus cytokine analysis. RNA was extracted (NucleoSpin Tissue RNA Plus), reverse-transcribed, and analyzed by qPCR using TaqMan chemistry. Cytokines were quantified via a Porcine Multiplex Kit (R&D Systems) on the MAGPIX® platform. Data were analyzed by linear mixed models. Both DSS ($P = 0.005$) and E. coli ($P=0.02$) challenges, decreased faecal dry matter and, in the case of DSS, faecal pH ($P=0.01$), confirming that the model effectively induced gastrointestinal disturbances. Plasma sodium concentration increased with progression of DSS administration followed by E. coli challenge ($P=0.003$), implying potentially compromised intestinal absorption. Additionally, haptoglobin, a marker of systemic inflammation, showed markedly elevated concentrations following the E. coli challenge ($P=0.0004$), indicating a pronounced acute-phase response in the challenged piglets. Challenged groups showed a significant increase in MUC2 expression ($P<0.001$), reflecting promotion of mucus-mediated protective mechanisms. Importantly, the typical DSS-induced histological lesions, such as ulceration and substantial epithelial ruptures, were absent, suggesting mild-grade mucosal disturbances without severe tissue damage. Hence, the model successfully induced a mild-grade enteric inflammation characterized by subtle physiological and mucosal alterations without causing severe tissue damage or clinical disease. These results provide a reliable mechanistic platform for future studies aiming at evaluating nutritional, and non-antibiotic strategies to enhance post-weaning gut resilience and reduce antimicrobial use during the weaning transition. The study was conducted in the PIG-PARADIGM project funded by the Novo Nordisk Foundation under the grant number NNFSA210073688.

Blood Transcriptomic Determinants of Post-Weaning Diarrhea in Commercial Pigs

M. Luigi-Sierra[1], J. Sun[1], E. Ibragimov[1], M. Kjelin Morsing[1], M. P. Rydal[1], J. P. Nielsen[1], P. Karlskov-Mortensen[1], S. Cirera[1], M. Fredholm[1]

[1] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 3, Frederiksberg C, 1870 Frederiksberg, Denmark

In pig production systems, post-weaning diarrhea (PWD) is a significant challenge, resulting in impaired growth, increased morbidity, diminished animal welfare, and substantial economic losses. Because PWD is a major driver of antimicrobial use, it contributes significantly to the development of antimicrobial resistance. Identifying early-life molecular signatures that predispose pigs to PWD could enable biomarker-based risk prediction and support targeted antibiotic-free treatment strategies. In this study, we worked with pigs kept in a conventional production system. The pigs were treated individually, and no batch medication was allowed. We performed whole-blood mRNA sequencing from samples obtained the day before weaning (day 25) to identify transcriptomic differences between pigs that remained healthy or experienced self-resolving diarrhea, and those that developed clinically relevant PWD requiring antimicrobial treatment during the 10 days following sampling. From 243 pigs, we identified 16 that required PWD treatment in this period and randomly selected 16 healthy controls. Differential expression analysis (PWD-treated vs. Healthy), controlling for sex and pen, revealed 101 differentially expressed genes ($|FC| > 1.5$, q-value < 0.05). Healthy pigs showed upregulation of genes involved in amino acid homeostasis and growth efficiency, i.e., RRAGD and SH3BP4, suggesting more efficient nutrient sensing and regulatory control of mTOR-related pathways, mechanisms that may help immune cells adapt to dietary change and weaning-associated stress. The healthy group also showed upregulation of immune-modulatory genes, including CCR4, CD163L1, and TNFSF11, consistent with an active but non-inflamed immune state. In contrast, PWD-treated pigs showed a strong activation of cytotoxic and natural killer-associated pathways, including KLRK1, an activating receptor that responds to stress-induced ligands to drive NK- and T-cell cytotoxicity. Upregulation of Th1-related genes (TBX21, IL12RB2, IL2RB, and CD244) indicated a shift toward a cell-mediated, inflammatory immune response in the PWD-treated group. This was accompanied by elevated chemotactic and trafficking signals (CCL5, S1PR5, CX3CR1), suggesting active mobilization of immune cells to tissues. Finally, upregulation of genes involved in cell death and compensatory anti-inflammatory mechanisms, such as FASLG and IL10, are consistent with an immune system already responding to stress in these pigs before weaning. Together, these results suggest that PWD-treated pigs enter the post-weaning period already displaying increased cytotoxic and inflammatory immune activation, whereas resilient pigs exhibit metabolic robustness and a well-regulated immune status. Future work includes: 1) examining the blood transcriptome of these pigs at later stages of life and 2) integrating additional -omic layers (e.g., gut microbiome, genomic data) to better characterize how the pig immune system response evolves under different pathogen or management stressors. Such an integrative approach may clarify which biological pathways are consistently associated with resilience or susceptibility to PWD and support the identification of molecular signatures that could contribute to the development of practical weaning-risk assessment tools in pigs. The research was conducted in the PIG-PARADIGM project, funded by the Novo Nordisk Foundation under the grant number NNFSA210073688.

Digestibility and fibre degradation of wheat bran and Palmaria palmata in post-weaning piglets

C. Meyhoff Crone[1], K. E. Bach Knudsen[1], É. Chassé[1]
[1] Aarhus University, Animal and Veterinary Sciences, Blichers allee 20, 8830 Tjele, Denmark

Seaweeds have attracted significant attention in recent years as potential feeds or feed additives, since their cultivation is not associated with use of arable land suitable for human food production. Most seaweed species have a low digestibility due to the unique and complex carbohydrate (CHO) structure of cell walls and storage polysaccharides. However, Palmaria palmata was found to be quite different from other red seaweed species because its fibres are resembling arabinoxylans from terrestrial plants. The objective of this study was to evaluate the potential of the red seaweed P. palmata as a functional feed ingredient for post-weaning piglets, with emphasis on fibre digestibility and degradation. We hypothesised that the higher content of soluble fibre, primarily mixed β(1→4, 1→3) xylans from P. palmata, would increase digesta viscosity but enhance fibre fermentation. A total of 32 piglets (initial body weight 6.21 ± 1.15 kg) were weaned at 28 days of age and assigned to two dietary treatments for 21 days in two blocks of 16 piglets. Piglets were housed in pairs from the same sow per pen. Diets were based on brown rice and fish meal to ensure that dietary fibre originated predominantly from added P. palmata (PP) or wheat bran (WB). Feed and water were provided ad libitum. All piglets were euthanized and necropsied for sample collection at the end of each block. The PP diet contained 6.6% total non-starch polysaccharides (NSP), of which 2.5% were soluble NSP, whereas the WB diet contained 6.0% total NSP with 0.9% soluble NSP. Diet viscosity was higher for PP than WB (2.61 vs. 1.02 mPa·s). Statistical analysis was performed using a linear mixed model with diet as a fixed effect and pen and litter as random effects. No differences were observed in apparent ileal digestibility (AID) of dry matter between diets. AID of crude protein tended to be higher ($P = 0.078$) for WB (58.5%) compared with PP (53.3%). In contrast, AID of NSP was markedly higher for PP than WB (16.7 vs. 0.1%; $P < 0.001$). Ileal digesta viscosity was also higher for PP than WB (3.27 vs. 1.50 mPa·s; $P < 0.001$). In conclusion, P. palmata showed increased ileal NSP digestibility, likely due to its higher soluble fibre content, but also increased digesta viscosity, which may have limited crude protein digestibility. These results indicate a trade-off between fibre degradation and nutrient utilisation when using soluble fibre-rich seaweed in diets for post-weaning piglets. The research was conducted in the PIG-PARADIGM project, funded by the Novo Nordisk Foundation under the grant number NNFSA210073688.

Early-Life Robustness: Hematological and Immune Pathways Linking Pre-Weaning Growth to Post-Weaning Diarrhea Treatment

J. Sun[1], M. Luigi-Sierra[1], E. Ibragimov[1], M. Kjelin Morsing[2], M. Peter Rydal[2], J. P. Nielsen[2], P. Karlskov-Mortensen[1], M. Fredholm[1]

Abstract Piglets with weaker constitutions are prone to severe post-weaning diarrhea (PWD), often requiring antibiotic intervention. This study aimed to elucidate the intrinsic mechanisms underlying early-life robustness in piglets and to identify key factors influencing PWD and subsequent antibiotic use. A total of 2.073 Danish crossbred Landrace Yorkshire Duroc (LYD) commercial piglets were included in the study. After data quality control, the final sample size for individual analyses ranged from 1.931 to 2.073 animals per phenotype. Complete blood cell count was collected at 25 days of age (one day before weaning). A comprehensive analysis integrating causal mediation analysis, genome-wide association studies (GWAS) and CatBoost classification modeling was conducted. The results revealed a significant negative correlation between pre-weaning relative weight (RW) and the need for antibiotic treatment after weaning (correlation coefficient = –0.344). Building on this observation, we applied causal mediation analysis to dissect physiological mechanisms mediating the relationship between RW and PWD treatment. Sex, batch, pre-weaning diarrhea indicator, and genetic principal components PC1 – PC5 were used as covariates in the causal mediation analysis. Hematological parameters, including hematocrit (HCT), measured hemoglobin (meas_HGB), and calculated hemoglobin (calc_HGB), mediated 6–9% of the total effect ($P < 2.2 \times 10^{-16}$). Immune parameters, including neutrophil percentage (per_Neut), lymphocyte percentage (per_Lym), and the neutrophil-to-lymphocyte ratio (NLR), mediated 2.5–4% of the association ($P < 2.2 \times 10^{-16}$). These mediating effects were stronger in slow-growing piglets than in fast-growing piglets. In the GWAS analysis, sex and batch were fitted as fixed effects for HCT, measHGB, calcHGB, and RW, whereas sex, pen, and pre-weaning diarrhea treatment were fitted as fixed effects for PWD treatment and NLR. In all GWAS models, the genomic relationship matrix was included to account for genetic relatedness. Genome-wide significant quantitative trait loci (QTLs) were identified for RW and several significant mediators. Finally, we evaluated the predictive performance of single nucleotide polymorphisms (SNPs) markers associated with significant mediators. A prediction model built using the relevant SNPs achieved an area under the precision-recall curve (PR-AUC) of 0.204, representing a 1.57-fold improvement over the baseline prevalence (0.129). Despite this improvement, the overall predictive ability remained moderate, indicating that additional informative genetic markers are still needed to improve prediction accuracy. These findings suggest that genetic variation, reflected in early-life hematological robustness, contributes to variation in susceptibility to PWD and may serve as biomarkers for growth performance and disease resilience. The research was conducted in the PIG-PARADIGM project, funded by the Novo Nordisk Foundation under the grant number NNFSA210073688.

Deciphering the intestinal pig microbiome and its function in early life

H. Smidt[1,3], M. Gujare[2], B. Ozdinc[1], J. Boekhorst[2], M. Kleerebezem[2]
[1] Wageningen University & Research, Laboratory of Microbiology, Stippeneng 4, 6708 WE Wageningen, Netherlands, [2] Wageningen University & Research, Host Microbe Interactomics Group, De Elst 1, 6708 WD Wageningen, Netherlands, [3] UNLOCK, Wageningen University & Research and Technical University Delft, PO box 8129, 6700 EV Wageningen, Netherlands

The gut microbiome plays a central role in piglet development, resilience, and intestinal health, and is tightly interconnected with the developing host as well as its nutrition. The PIG-PARADIGM project funded by the Novo Nordisk Foundation in 2021 aims to improve the intestinal robustness and resilience in developing piglets by advancing fundamental knowledge of the pig gut microbiome and its interaction with nutrition and the host. These insights are expected to translate to strategies to reduce the dependence on antibiotics, thereby contributing to the global effort to mitigate antimicrobial resistance. Based on a large cohort study performed in Denmark with >2000 piglets, integrated efforts of the PIG-PARADIGM consortium are fully aligned and integrate host-microbiome multi-omics data to obtain a better understanding of the host-microbiome holobiont in the developing pig. To this end, microbiome-targeted activities set out to provide in-depth characterization of microbiome composition and function throughout the early life development of piglets from birth until 2 months of age. This aimed to establish the biogeography, i.e. the spatial and temporal dynamics, of the intestinal microbiome of the developing animals. While bacterial communities have been studied extensively, our analyses explicitly include all members of the intestinal microbiome, including bacteria and archaea, fungi and protozoa as well as viruses/phages. We use high-resolution metagenomics together with amplicon sequencing of taxonomic marker sequences (16S and 18S rRNA genes and ITS sequences) to map microbial biogeography across gut regions and developmental stages, map bacteria-host, and bacteria-microeukaryote correlations paired with dedicated virome analyses to uncover bacteriophage–bacteria correlations, providing the basis for the generation of hypotheses regarding possible causative interactions between different players within the gut microbiome – host holobiont. Furthermore, we aimed to identify pre-weaning prognostic microbiome biomarkers that allow prediction of antibiotic-treatment-requiring postweaning diarrhea (PWD) disease in piglets. To this end, animals were stratified based on phenotypic characteristics into those that are i) robust (no PWD) (ii) resilient (self-resolving PWD) and (iii) antibiotic-treated (antibiotic-treatment-requiring PWD). Results will be presented that were obtained by multivariate statistics and machine learning techniques used on three types of datasets (a) microbiota composition using 16S rRNA gene profiling; (b) weight dynamics; (c) blood parameters, to generate combinatorial predictive models to identify prognostic biomarkers. Beyond its relevance for swine health, this work will advance fundamental understanding of microbial succession, cross-kingdom interactions, and microbiome functional maturation. The findings could inform microbiome-based interventions, such as targeted bacteriophage applications or early-life microbial modulation, contributing to more robust livestock, reduced antibiotic use, and improved food system sustainability.
The research was conducted in the PIG-PARADIGM project, funded by the Novo Nordisk Foundation under the grant number NNFSA210073688.

Species-level faecal microbiota development from suckling to 25 days postweaning in piglets: response to pre-weaning nutritional supplementation assessed by shotgun metagenomics

K. Jerez-Bogota[1], C. Lauridsen[1], D. Vodolazska[1], F. Asnicar[2], N. Canibe[1], O. Hojberg[1]
[1] Aarhus University, AU-Viborg, Animal & Veterinary Sciences, Bliches alle 20, 8830 Tjele, Denmark, [2] University of Trento, Department of Cellular, Computational and Integrative Biology, via Sommarive 9, 38123 Trento, Italy

Early life gut microbiota influences postweaning resilience in pigs. Nutritional supplementation during lactation is increasingly adopted, yet its impact on microbiome development remains understudied. We hypothesized that pre-weaning supplementation promotes a more resilient gut microbiota. Piglets from 12 hyperprolific sow litters (standardized to 15 piglets) were allocated by litter to Control (n=6 litters; no supplementation) or Supplemented (n=6 litters; milk replacer on d 3–11, liquid creep feed from d 12 to weaning at d 24). Fecal samples from two piglets per litter were collected longitudinally before (11, 18, and 24 d of age), and after weaning (3, 7, 14, and 25 d postweaning). Shotgun metagenomes (Illumina NovaSeq X Plus; 2×150 bp; ~20M reads) were profiled using Sylph against GTDB-R220-C200. Species-level relative abundance and prevalence were modelled with MaAsLin3 (pre-weaning supplementation [treatment], sampling day [time], and their interaction as fixed effects; sow/pig as random effects). Shannon alpha diversity increased with age ($p<0.001$), with a trend for higher diversity in supplemented piglets ($p=0.052$) and no treatment × time interaction. Time was the dominant driver of community structure (Bray–Curtis; $R^2=0.34$, $p=0.001$), with a minor but significant treatment effect ($R^2=0.008$, $p=0.001$) and no treatment × time interaction. For species abundance, 22 species showed treatment × time interactions ($q<0.1$), notably two methanogens (Methanobrevibacter A sp900769095, Methanomethylophilus alvus) and a few uncharacterized Bacteroidota (Prevotellaceae, Muribaculaceae) had higher abundance in supplemented piglets on day 11 of age. For prevalence, 14 species showed earlier pre-weaning colonization in supplemented piglets, notably for five Prevotella species, Anaerovibrio slackiae, and two Vescimonas species. One hundred forty-three species showed a significant main effect of time ($q < 0.1$) on relative abundance, and 133 species on prevalence. Hierarchical clustering of abundance resolved at least 3 clusters, which we describe as steady colonizers (44 species), neonatal decliners (43 species), and weaning bloomers (31 species). Clustering based on prevalence showed that species were either progressively acquired over time (65 species) or were initially widespread but declined by day 14 postweaning (40 species). Cross-referencing clusters showed that decreases in abundance generally preceded losses in prevalence, consistent with progressive displacement during microbiome succession. Supplementation increased (treatment main effect: $q<0.1$) the relative abundance of Prevotella sp002251365, four Cryptobacteroides species, Romboutsia timonensis, and Methanobrevibacter A sp022775905, while Lactobacillus amylovorus, Limosilactobacillus mucosae, and Vescimonas sp900313295 were reduced. For prevalence, L. mucosae was reduced, whereas two uncharacterized species (UBA4334 [Bacteroidaceae] and CAG-103 [Oscillospiraceae]) were more prevalent in supplemented piglets. Pre-weaning supplementation preserved successional dynamics while influencing specific taxa in abundance and prevalence, with an overall trend towards higher alpha diversity, suggesting earlier establishment of a mature-like gut microbiota. Strain-level and functional characterization will further clarify these shifts and their potential relation to postweaning gut health. This work is part of the PIG-PARADIGM project funded by the Novo Nordisk Foundation (NNFSA210073688).

Non Digestible Carbohydrate Structure Differentially Modulates Responses to ETEC F18 in Weaned Pigs

N. Razmgah[1], K. E. Bach Knudsen[1], M. Skou Hedemann[1], N. Canibe[1]
[1] Aarhus University, Animal and Veterinary Science, Blichers Allé 20, 8830 Viborg, Denmark

Post-weaning diarrhoea (PWD) caused by enterotoxigenic Escherichia coli (ETEC) F18 remains a major challenge in pig production, particularly following restrictions on zinc oxide and antibiotic use. Modulation of the non-digestible carbohydrate (NDC) fraction is a promising dietary strategy to enhance gut resilience. This study evaluated arabinoxylan (AX), xylo-oligosaccharide (XOS), and chito-oligosaccharide (COS) ingredients in an ETEC F18 pig challenge model. We hypothesised that AX, XOS, and COS would enhance resistance to ETEC F18 infection and reduce disease severity compared with the Control-ETEC diet. Eighty piglets were allocated to five groups: a non-challenged Control group and four ETEC-challenged groups (Control-ETEC, AX-ETEC, XOS-ETEC, COS-ETEC). The Control diet was based on rice with added oat hull meal and sugar beet fibre as complex NDC sources. In the supplemented diets, 4 % of oat hull and sugar beet fibre were replaced by AX, XOS, or COS. Piglets were orally inoculated with ETEC F18 on days 3 and 4 post-weaning (PW). Growth performance, faecal consistency, faecal dry matter (DM), ETEC shedding, and plasma acute-phase proteins (haptoglobin and PIG-MAP) were monitored over 21 days PW. Data were analysed in R (v4.3.3) using ANOVA and mixed-effects models, with diet and sampling day as fixed effects and block, pen, and piglet as random effects. Differences were considered significant at $P < 0.05$. Of the challenged groups with added NDCs, COS-ETEC showed the closest profile to the non-challenged Control group, regarding faeces consistency and DM%. During the acute post-infection phase (days 2 – 6 post-challenge), the estimated mean probability of diarrhoea based on faecal score remained below ~ 50 % in COS-ETEC, whereas it reached ~ 50 – 100 % in the other challenged groups. In general, due to high variation, significant differences between the COS-ETEC and the two groups receiving AX and XOS were only seen in a few cases. Despite these results, the dietary addition of COS did not reduce ETEC F18 shedding ($P > 0.05$) as compared to the Control-ETEC group, indicating that its anti-diarrhoeal effect was not mediated by direct pathogen suppression. In contrast, the AX-ETEC group displayed a profile closest to the Control-ETEC regarding faecal score, DM%, and estimated probability of diarrhoea based on both parameters. Moreover, the faecal ETEC F18 shedding was numerically highest compared to the other groups during most of the study period. For the acute-phase proteins, the haptoglobin levels on days 2 and 4 post-challenge were lowest in the XOS-group ($P < 0.05$), intermediate in the AX-ETEC and COS-ETEC groups, and highest in the Control and Control-ETEC groups, and with PIG-MAP unaffected across treatments ($P > 0.05$). Daily body weight gain for the whole period was highest for the non-challenge Control group, lowest ($P < 0.05$) for the three ETEC challenge groups with added NDC ingredients, and intermediate in the Control-ETEC. The same trend was observed for daily feed intake at the pen level. These results indicate that NDC ingredients with different structural characteristics differentially modulate host responses to ETEC F18. Although COS-ETEC did not reduce E. coli shedding, it improved faecal consistency and dry matter, suggesting that its effects are driven by strengthened gut resilience rather than bactericidal action. Accordingly, NDC structure and composition represent a key determinant in developing nutritional strategies to control PWD. Keywords: prebiotic, ETEC F18, post-weaning diarrhoea, non-digestible carbohydrates, gut health The research conducted in PIG-PARADIGM project, funded by the Novo Nordisk Foundation, grant number NNFSA210073688

Effects of Dietary L-glutamate, L-aspartate, and Their Combination on Growth Performance, Diarrhea Severity, and Amino Acid Digestibility of Weaned Piglets Challenged with Enterotoxigenic Escherichia coli

S. Wongchanla[1], Y. Park[1], S. Park[1], S. Sun[1], Y. Zhao[1], Y. Liu[1]
[1] University of California, Davis, Animal Science, One Shields Avenue, Davis, CA 95616, 95616 Davis, United States

L-glutamate and L-aspartate are functional amino acids (AA) essential for intestinal epithelial functions and physiological metabolism. This study aimed to investigate the effects of L-glutamate, L-aspartate, and their combination on growth performance, severity of diarrhea, and AA digestibility of weaned piglets challenged with enterotoxigenic Escherichia coli (ETEC). Sixty-five weaned pigs (7.59 ± 1.11 kg BW) were randomly assigned to one of five treatments (n=13). The dietary treatments included a control (CON), CON with 1% glutamate (GLU), CON with 1% aspartate (ASP), CON with 1% glutamate and 1% aspartate combination (GAC), and CON with 50 mg/kg carbadox (ABX) supplementation. All pigs were orally challenged with F18 ETEC for three consecutive days at the dose of 10^{10} CFU/dose/day. The study period lasted for four weeks, with a 7-day adaptation period and 21 days post-inoculation (PI). Body weights, feed consumption, and daily diarrhea scores were recorded throughout the experiment. Fecal samples were collected on d -7 and d 0 before ETEC inoculation, and on d 2, d 5, d 7, d 10, d 14, d 18, and d 21 PI to confirm the presence and dynamics of fecal β-hemolytic coliforms. Ileal digesta samples were collected on d 21 PI for AA digestibility analysis. All data were analyzed using ANOVA, except that diarrhea frequency was analyzed by the Chi-square test, with the individual pig as the experimental unit. The research was conducted in the PIG-PARADIGM project, funded by the Novo Nordisk Foundation under the grant number NNFSA210073688. The results revealed notable benefits associated with GLU, ASP, or GAC supplementation. Compared with CON, pigs fed ASP or ABX had increased ($P < 0.05$) body weight on d 14 PI, and pigs fed ASP, GAC, or ABX had increased ($P < 0.05$) final body weight on d 21 PI. Pigs fed ASP or ABX also enhanced ($P < 0.05$) average daily gain from d -7 to d 14 PI, compared with CON. GLU, ASP, GAC, or ABX supplementation increased ($P < 0.05$) average daily gain from d 0 to 21 PI, compared with CON. Additionally, GLU, ASP, GAC, or ABX supplementation improved ($P < 0.05$) average daily gain from d -7 to d 21 PI, compared with CON. ASP or ABX supplementation also increased ($P < 0.05$) average daily feed intake from d 0 to d 14 PI, compared with CON. Furthermore, supplementing with GLU, ASP, GAC, or ABX enhanced ($P < 0.05$) gain:feed ratio from d -7 to d 21 PI and from d 0 to d 21 PI, compared with CON. Moreover, pigs fed GLU, ASP, or ABX had reduced ($P < 0.05$) diarrhea frequency compared with CON (15.24 to 20% vs. 29.65%). In addition, pigs fed ASP, GAC, or ABX had reduced ($P < 0.05$) fecal β-hemolytic shedding on d 7 PI compared with CON. Apparent ileal digestibility (AID) of dry matter differed among treatments on d 21 PI, with pigs fed ASP showing the greatest ($P < 0.05$) digestibility value compared with the other groups. Additionally, pigs fed GAC had greater ($P < 0.05$) AID of lysine, aspartate, and glutamate than CON. Pigs fed GAC also showed greater ($P < 0.05$) SID of lysine, aspartate, and glutamate compared with CON. Moreover, pigs fed ASP had higher ($P < 0.05$) SID of aspartate compared with CON and ABX. In conclusion, dietary supplementation of L-glutamate, L-aspartate, or their combination enhanced growth performance, reduced diarrhea, and improved amino acid digestibility in ETEC-challenged piglets, supporting improved disease resistance during the post-weaning period.

Dietary protein and amino acid levels affect the gut metabolome and intestinal epithelial function in weaned piglets

L. H. Chen[1], M. S. Hedemann[1], S. Purup[1], K. Jerez-Bogotá[1], N. Canibe[1]
[1] Aarhus University, Animal and Veterinary Sciences, Blichers Alle 20, 8830 Tjele, Denmark

High dietary crude protein (CP) can enhance growth performance in weaned piglets but concurrently increases the risk of post-weaning diarrhea (PWD) by altering microbiota composition and increasing the metabolites from protein fermentation. A pig production trial recently demonstrated that supplementing a high-CP diet (22%) with surplus essential amino acids (EAA), including 35% extra crystalline lysine-HCl, with corresponding increases in methionine (32%), threonine (62%), tryptophan (22%), and valine (67%), reduced diarrhea treatment days by 50%, achieving an efficacy comparable to medicinal zinc oxide. Building on these findings, the aim of this study was to advance mechanistic understanding of how high-CP diets supplemented with surplus EAA influence gut health in weaned piglets. We hypothesized that excessive protein fermentation compromises gut health, while surplus EAA can modulate gut metabolome and mitigate these negative effects. This study included an in vivo animal experiment and in vitro cell assays. A total of 120 piglets were assigned to three dietary treatments: low-protein (15% CP; LP), high-protein (25% CP; HP), and high-protein with extra EAA (25% CP + surplus EAA; HP+EAA). The experiment was conducted in five blocks, each with 24 piglets allocated to six pens (four per pen; two pens per treatment). One piglet per pen was slaughtered on days 7 and 28 post-weaning (PW) for digesta collection from the distal small intestine and colon. Freeze-dried digesta was analyzed by untargeted metabolomics. Cell-based assays using porcine jejunal (IPEC-J2) and colonic (PoCo83-3) cell lines, as well as intestinal ileal and colonic organoids evaluated the effect of digesta and selected protein fermentation-derived compounds on cell viability and barrier function. Linear mixed-effects models were applied with treatment as a fixed effect and block as a random effect. Piglets fed the HP and HP+EAA diets, with significantly lower level of metabolites related to purine, fatty acid, and bile acid metabolism ($p<0.05$), exhibited distinct digesta metabolome profiles in the colon compared with piglets fed the LP diet. The purine nucleotide adenosine monophosphate (AMP) was present at higher levels in the HP+EAA group than in the HP group, indicating that surplus EAA supplementation modulates purine metabolism with enhanced purine salvage pathways that may increase nucleotides availability, thereby supporting colonocyte energy metabolism and anti-inflammatory responses. Lactobacillus genus was more abundant in the HP+EAA group, suggesting enhanced utilization of purine nucleosides and derivatives by these bacteria. In vitro cell line assays demonstrated that digesta from piglets fed the LP diet caused significantly less damage, measured as viability, to intestinal epithelial cells than digesta from piglets fed the HP and HP+EAA diets. Among several tested metabolites, p-cresol, ammonia, and hydrogen sulfide showed the most potent detrimental effects at physiologically relevant concentrations, whereas inosine and AMP stimulated epithelial proliferation. Organoid experiments showed that digesta from the HP group reduced viability more than that from the LP group, while surplus EAA partially alleviated this reduction. In conclusion, although metabolomics did not fully explain the reduction in PWD observed in vivo, the data suggested that purine metabolism-derived metabolites could partially contribute to this beneficial effect. Further, the organoid model more closely reflected in vivo responses than the cell lines. Funded by the Novo Nordisk Foundation (PIG-PARADIGM, NNFSA210073688).

Genetic Determinants of Gut Microbial Genera Abundance and Presence in Growing Pigs

E. Ibragimov[2], M. Luigi-Sierra[2], J. Sun[2], M. K. Morsing[1], M. P. Rydal[1], J. P. Nielsen[1], M. Fredholm[2], P. Karlskov-Mortensen[2]

[1] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 2, 1870 Frederiksberg C, Denmark, [2] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 3, 1870 Frederiksberg C, Denmark

Gut bacterial communities play a crucial role in host physiology and are strongly associated with disease resilience, immune competence, and feed efficiency in pigs. Variation in microbial composition has been linked to economically important production traits as well as resilience to infectious and environmental challenges. Understanding the host genetic architecture underlying microbial community structure may therefore provide novel targets for improving animal health and performance. In this study, we investigated the genetic determinants of gut bacterial genera abundance and presence in a crossbred (Landrace x Yorkshire) x Duroc pig population (n=564). Microbial profiles were generated using 16S rRNA amplicon sequencing, and genotypes were derived using the Neogen 50k SNP panel. We performed genome-wide association analyses using a local-ancestry-aware framework conceptually similar to Tractor (https://github.com/Atkinson-Lab/Tractor), allowing estimation of ancestry-specific genetic effects and enhancing QTL detection in admixed populations. We identified 38 genome-wide significant QTLs associated with abundance/presence of 11 bacterial genera. Genes located near the lead SNPs were significantly enriched for the Gene Ontology terms "cell–cell junction" and "plasma membrane region," suggesting that the identified QTLs may influence bacterial composition through the modulation host–microbe adhesion. Notably, we observed distinct ancestry-specific effects at several loci, highlighting the importance of modeling local genomic background in crossbred populations. These findings demonstrate that host genetic variation contributes substantially to gut microbial composition in pigs. Due to standardized diets and controlled environmental conditions in livestock systems, pig populations offer a powerful model for detecting microbiome-associated QTLs with reduced environmental noise. Insights gained from such systems may facilitate the identification of conserved host–microbiome genetic interactions and inform similar studies in humans, where dietary and environmental heterogeneity often complicate discovery. Overall, our results provide new insight into the host's genetic architecture of gut microbial communities and establish a foundation for microbiome-targeted breeding strategies aimed at improving disease robustness and feed efficiency.

Stakeholder and consumer perspectives on animal welfare improvements in meat production

A. Kyriakidis[1,2], A. N. Louvrou[2], C. Hauschildt[2], M. Ntovas[2], I. Kostopoulos[2], E. Altsitsiadis[1], A. Stamos[1]
[1] Copenhagen Business School, Department of Management, Society and Communication, Have 15, 2000 Frederiksberg, Copenhagen, Denmark, [2] White Research SRL, Research Department, Avenue de la Toison d'Or 67, 1060 Brussels, Belgium

Understanding stakeholder and consumer perceptions across the farm-to-fork value chain is essential for implementing effective animal welfare strategies. This study employed advanced analytical methods to identify barriers and motivators influencing adoption of welfare-friendly practices. This research investigated value chain actors' motivators and constraints using Topic Modelling and assessed EU consumer purchase intentions and willingness to pay using Structural Equation Modelling. Fifty stakeholder interviews conducted between September 2023 and January 2024 were analysed using Latent Dirichlet Allocation (LDA) Topic Modelling integrated with Large Language Model (LLM; Falcon-180B). The LDA algorithm identified latent themes through text preprocessing, treating documents as topic mixtures. Optimal topic numbers were determined through coherence score maximization. The LLM enabled objective categorization, identifying 26 key motivators and barriers across three domains. A consumer survey (n=5,064) tested two theoretical frameworks using Partial Least Squares Structural Equation Modelling (PLS-SEM). The Theory of Planned Behaviour (TPB) and Value-Belief-Norm (VBN) theory were evaluated for reliability, validity, and model fit. Comparative predictive performance was assessed using Cross-Validated Predictive Ability Test (CV-PAT) and Bayesian Information Criterion (BIC). Modelling of the interviews' data identified enhanced public awareness, financial incentives, regulatory frameworks, and certification schemes as primary motivators, while financial constraints, insufficient awareness, inconsistent regulations, and operational difficulties emerged as significant barriers. Survey analysis demonstrated positive attitudes with mean purchase intention of 3.58 (SD=1.06) and mean willingness to pay of 2.89 (SD=1.18). Trust in certification schemes ranged from 3.64 to 3.70. The TPB model explained 40.3% of purchase intention variance and 18.0% of willingness to pay variance, with attitude (β=0.366, $p<0.001$), subjective norm (β=0.276, $p<0.001$), and perceived behavioural control (β=0.197, $p<0.001$) as significant predictors. The VBN model explained 39.1% of intention variance and 23.7% of willingness to pay variance, with personal norms showing strongest influence (β=0.625 for purchase intention; β=0.487 for willingness to pay, both $p<0.001$), preceded by ascription of responsibility (β=0.561, $p<0.001$) and general awareness of consequences (β=0.502, $p<0.001$). Both models demonstrated excellent fit (TPB: GoF=0.461, SRMR=0.078; VBN: GoF=0.467, SRMR=0.055). Cross-validation confirmed TPB superiority for purchase intention prediction (average loss 0.790 versus 1.145, t=23.977, $p<0.001$), while VBN demonstrated superiority for willingness to pay prediction (BIC: -1353.456 versus -971.562). The integration of Topic Modelling with Large Language Model capabilities identified barriers and drivers influencing welfare-friendly practice adoption. Structural equation modelling revealed distinct psychological pathways, with attitude-based mechanisms dominating purchase intention formation while moral-value systems primarily drive willingness to pay premium prices. These findings indicate that effective market development requires targeted interventions addressing identified barriers and leveraging moral-ethical motivations in communication strategies.

Animal welfare and biosecurity on farm: are there conflicts?

C. Correia-Gomes[1], O. Soriano[2], L. M. Tamminen[3], G. Olmos Antillón[3], A. Burrell[1], E. Biebaut[4], T. B. Rodenburg[5], N. Van Noten[6], T. Tobias[5,7]
[1] AHI, 2–5 The Archways, N41 WN27 Carrick on Shannon, Ireland, [2] ADA, c/ Dámaso Alonso, 14, 40006 Segovia, Spain, [3] SLU, Almas allé 8, 756 51 Uppsala, Sweden, [4] University of Ghent, Salisburylaan 133, 9820 Merelbeke, Belgium, [5] Universiteit Utrecht, Heidelberglaan 11, 3584 CS Utrecht, Netherlands, [6] ILVO, Burgemeester van Gansberghelaan 119, 9090 Merelbeke-Melle, Belgium, [7] Royal GD, Arnsbergstraat 7, 7418 EZ Deventer, Netherlands

While biosecurity and animal welfare are widely understood to be essential for sustainable livestock production, tensions can arise when measures to reduce risks for pathogen transmission limit welfare opportunities, or when welfare-enhancing practices increase the likelihood of pathogen dissemination. As part of the Horizon Europe BIOSECURE project, we have explored farm decision-makers, welfare and biosecurity experts' perspectives on the relationship between biosecurity and animal welfare, with a particular focus on situations where the two may come into conflict and eliciting potential solutions for those conflicts. The study was divided in two steps. First, semi-structured interviews with the main farm-level decision-makers were done between May and December 2025. Nine poultry farmers in Ireland, 9 dairy farmers in Sweden and 10 pig veterinarians in Spain were interviewed. Participants were selected to reflect a range of herd sizes and management systems across each sector. Vignettes, developed based on previous input from livestock experts, were used to prompt the discussion. One vignette was common between all sectors (access to outdoor rearing) while the others were sector specific (e.g. barn systems for layers, slow growing breeds for broilers, enrichment material for pigs, and group pens for dairy calves). Secondly, online workshops (done in collaboration with the Horizon Europe aWISH project and the Swedish Center for Animal Welfare) targeting European biosecurity and welfare experts were organised for each species to present the results of the interviews and elicit their perspective in terms of potential conflicts and what solutions should be implemented. Attendance per workshop ranged from 23 to 38 with a near even split between biosecurity and welfare experts. During the workshop they were split into smaller groups and each group dealt with a potential conflict as per interviews' results. Interviews and workshops were recorded and analysed using thematic analysis to identify key themes. From the analysis there were common themes between sectors and farm decision-makers and experts: animal welfare and biosecurity were frequently described as dependent on and essential to each other. Outdoor access was considered "essential" for welfare but poses challenges for biosecurity. Risk mitigation options, such as fencing, were suggested to minimise exposure to wildlife. While solutions were found for many of the conflicts identified, it was acknowledged that some are not easy to implement on farm as they are resource intensive (e.g. extra labour, access to materials and more land, and new/adaptation of buildings) and vary with the different context, productions systems and sectors within countries and across Europe. Farm-specific supports, including knowledge transfer and flexible policies, were identified as key as a strategy of "one-size-fits-all" is not feasible. This study has identified both intuitive as well as non-intuitive conflicts between biosecurity and animal welfare by decision-makers at farm level, and biosecurity and welfare experts and local context appeared differently relevant for each sector and country. For some conflicts ready to use solutions could be identified whereas others may require policy changes or price compensation to accommodate extra costs.

Two frameworks for expert-based livestock welfare scoring: A comparative analysis

Livestock welfare assessments typically incorporate a large number of welfare measures. Although multiple individual measures may be relevant to specific stakeholders (e.g. farmer or slaughterhouse), many applications, such as certification schemes, require a single aggregate welfare index. Consequently, the aggregation method not only affects how welfare is calculated for each stakeholder, but also determines the relative importance assigned to the different measures. This study compares two welfare elicitation and aggregation strategies, evaluating the resulting welfare indices and identifying the strengths and weaknesses of each approach. The first strategy, the indicator-based approach, corresponds to weighting each indicator explicitly, whereas the situation-based approach derives implicit weights from expert preferences between pairs of welfare situations (i.e., sets of indicators presented with different severity levels) using a discrete choice experiment framework. As part of the aWISH project, both approaches were evaluated via two case studies, focusing on broiler and pig welfare assessment at the slaughterhouse. For each species and approach, expert input was collected through online surveys. The broiler surveys included 11 welfare indicators (26/27 expert responses across rounds), whereas the pig surveys included 14 indicators (21/28 responses). The indicator-based survey elicited the perceived welfare severity and relevance of each indicator, whereas the situation-based survey included 30 comparisons, requiring experts to indicate the better welfare and quantify the difference in welfare. While data analysis is ongoing, preliminary results indicate poor to moderate inter-assessor agreement for the indicator-based approach (ICC: 0.40-0.52), with a greater disagreement for the low-severity levels of welfare indicators compared to the high-severity levels of indicators. The situation-based approach shows slight to moderate agreement when experts express a preference between two situations (Fleiss' κ: 0.19-0.46), and poor to good agreement when quantifying the magnitude of differences between welfare situations (ICC: 0.31-0.79). Notably, agreement between experts is not consistently higher or lower across species when comparing both approaches. Despite restricting participation to welfare experts, preliminary findings suggest limited consensus among experts under both approaches. Further comparative analysis will determine how these methodological differences translate into aggregate welfare scores and whether the limited agreement is due to true disagreement or the methodology of surveying. This research was performed within the framework of the Horizon Europe project aWISH (Grant agreement ID: 101060818).

Economic impact of enhanced pig welfare systems on Austrian finishing farms using information from automated monitoring

P. Thobe[1], M. Boimah[1], C. Pfeiffer[2]
[1] Thuenen Institute, Institute of Farm Economics, Bundesallee 63, 38116 Braunschweig, Germany, [2] University of Veterinary Medicine, Animal Welfare Science Unit, Veterinaerplatz 1, 1210 Vienna, Austria

Improving farm animal welfare has become a central objective of European agricultural policy, yet its economic implication at farm level remains insufficiently quantified. The EU project aWish focuses on automated monitoring of animal-based indicators at slaughterhouses to improve the welfare of broiler chickens and fattening pigs during each phase of production. During an aWish stakeholder workshop in Germany, participants discussed the feasibility and economic viability of keeping pigs with intact tails. Financial incentives were a recurring theme. Within aWish, the economic impact of farm-level management changes (enrichment, stocking density, barn design), using tail length, carcass classification and veterinary data from PigInspector (sensor installed at the slaughterhouse), has been explored at an Austrian pilot company. In Austria, voluntary welfare management systems such as 'Mehr Tierwohl – Gut' – (TW60) and 'Mehr Tierwohl – Sehr Gut' (TW100) require substantially more space per pig and additional measures (e.g., bedded resting area, and in TW100 GMO-free feed, intact tails, outdoor access and castration under anesthesia and analgesia), going beyond EU Directive 2008/120/EC and national minimum standards. However, evidence on how these management systems affect production costs and profitability across different farm sizes is still limited. The objective of this study is to quantify the economic impact of farm-level management changes on Austrian pilot farms implementing TW100, using information by automated monitoring data, compared with Austrian legal minimum requirements and EU Directive 2008/120/EC (Stevenson, 2012) in small, medium and large commercial finishing-pig farms. Baseline data were collected in 2024 from six pig farms in Upper Austria using semi-structured questionnaires developed within the TIPI-CAL (Technology Impact and Policy Impact Calculations) framework and validated with project partners and experts. Based on these data, three representative average farms were constructed to protect commercial confidentiality. Information on TW100 was obtained through an online interview with a farmer already implementing this system. Percentage changes in key indicators were applied to the representative farms. A TW60 scenario was modelled to capture intermediate animal-welfare requirements. The TIPI-CAL model (Chibanda et al., 2020) was used to assess the impact of the alternative welfare systems on production costs and farm profitability. Preliminary results indicate that TW60 and TW100 increase fixed and variable production costs per pig place, mainly due to lower stocking densities, higher labour inputs and additional investments in housing and enrichment. These welfare systems can improve technical performance, provided that returns compensate for the additional expenses. The net income effect varies by farm size: larger farms benefit more from economies of scale, while smaller farms face proportionally higher cost increases. In conclusion, feedbacks from automated monitoring at the slaughterhouse enables continuous improvements of animal welfare practices at the farm level. Enhanced welfare management systems such as TW60 and TW100 can substantially improve animal-welfare conditions but tend to raise production costs, especially in smaller farms, unless compensated by price premiums or targeted policy support. These findings are relevant for policy makers, supply-chain actors and farmers when designing incentives and labelling schemes for higher-welfare pig production.

How to evaluate animal welfare improving initiatives on regional and national level?

M. F. Giersberg[1], N. Van Staaveren[1,2], K. Van Langeveld[3,4], N. Van Noten[3], F. A. M. Tuyttens[3,4], T. B. Rodenburg[1]
[1] Utrecht University, Yalelaan 2, 3584 CM Utrecht, Netherlands, [2] University of Guelph, 553 Gordon St, N1G 2W1 Guelph, Canada, [3] Flanders Research Institute for Agriculture, Fisheries and Food (ILVO, Burgemeester van Gansberghelaan 92, 9820 Merelbeke-Melle, Belgium, [4] Ghent University, Heidestraat 19, 9820 Merelbeke-Melle, Belgium

Animal welfare improving initiatives (AWII) can be implemented by different private or public operators and at different levels (regional, national, supranational). To draw conclusions about the effects of AWII on actual animal welfare, sufficient monitoring data need to be available and accessible for analysis. Ideally, such data would be obtained from automated, cost-efficient, and reliable monitoring systems at the slaughterhouse and would correctly reflect the animals' welfare at different production stages. One of the aims of the aWISH project is to identify AWII for pigs and broilers on regional and national level and to evaluate their effects on animal welfare based on the data collected in the aWISH pilot slaughterhouses before and after implementation of the AWII, by comparing different groups of operators, or in comparison with historical records from national data repositories or other data sources. First, we developed four scenarios for these evaluations: a) the AWII has been implemented before the start of the aWISH project, data have been collected before its implementation and are available for an evaluative comparison from private-, national- or research repositories; b) the AWII has been implemented before the start of the aWISH project, suitable data before its implementation are not available, but data collected from different groups of operators during the aWISH project can be used for an evaluative comparison; c) the AWII is implemented during the aWISH project and data have been collected in the aWISH project before and after the implementation; and d) the AWII is implemented after the completion of the aWISH project, data have been collected during the project, are stored in the aWISH data platform, and can serve as 'before data' for future evaluations of the AWII. Second, we conducted an inventory to select suitable AWII for an evaluation within scenario a)-c). This consisted of a literature search and of an interactive multi-actor session. We identified three major challenges based on this inventory: the large volume and variety of AWII, data availability, quality, and accessibility. In our presentation, we will use examples of promising AWII to illustrate scenario a)-c). We found that in many cases, data that would allow for an evaluation of AWII are not yet (routinely) collected and recorded. In cases where such data are available, challenges arise with regard to data quality and access. For initially promising datasets, it turned out that at present the quality of data in terms of accuracy, reliability, and level of detail is insufficient to draw potential conclusions about the effect of an AWII on actual animal welfare. In addition, researchers need to overcome serious barriers (e.g., approval of legal data sharing agreements) to get access to data from external parties. These findings highlight the importance of the aWISH project for scenario d). The automatic collection of high-quality data in the pilot slaughterhouses and their recording in the aWISH data platform are a promising starting point. The structures established within the aWISH project will enable a more feasible evaluation of future AWII. Therefore, these structures need to remain operational after completion of the project and need to be expanded to include additional operators, production chains, and countries.

From animal-based welfare indicators to EU policy integration: lessons from the aWISH project

H. Lambert[1,2]
[1] Eurogroup for Animals, Rue Ducale, 1190 Brussels, Belgium, [2] Animal Welfare Consultancy, Kingsteignton, TQ123BW Devon, United Kingdom

The increasing recognition of animals as sentient beings has strengthened the scientific and policy interest in animal-based welfare indicators (AWIs). While substantial scientific knowledge exists on the development and validation of AWIs for pigs and broilers, less attention has been paid to their operationalisation within EU regulatory frameworks. This gap between scientific development and policy integration presents a critical challenge for the ongoing revision of EU animal welfare legislation. This contribution presents policy-oriented findings from the Horizon Europe project aWISH (Animal Welfare Indicators at the Slaughterhouse), focusing on the applicability and integration of AWIs into EU-level governance. The aim is to analyse how validated animal-based indicators can be embedded within legislative, inspection, and assurance systems in a manner that is scientifically robust, harmonised, and practically feasible across Member States. Drawing on project outputs and a high-level multi-stakeholder policy workshops involving representatives from the European Commission (DG SANTE and DG AGRI), Member State authorities, academia, civil society, and the livestock sector, we identify three core implementation challenges: (1) defining implementation-ready indicators that are measurable, cost-efficient, and scalable; (2) ensuring harmonised measurement, calibration, and reporting across Member States; and (3) embedding AWIs within coherent policy channels rather than parallel voluntary systems. Findings indicate that slaughterhouse-based data collection offers particular potential for centralisation, comparability, and digitalisation of welfare monitoring. However, effective integration requires clear definitions, common measurement protocols, baseline thresholds or tools to support their establishment, and alignment with the existing Common Agricultural Policy, inspection, and private assurance data systems. AWIs must complement minimum legal standards and be supported by guidance, training, and financial mechanisms to avoid disproportionate burdens on farmers and competent authorities. We propose a staged policy pathway for EU uptake of AWIs: short-term piloting and refinement; medium-term harmonisation and protocol development, potentially supported by EU Reference Centres; and long-term embedding within legislative and enforcement frameworks. This approach aims to strengthen outcome-based welfare governance while maintaining feasibility within diverse European livestock systems. These findings contribute to ongoing debates on outcome-oriented regulation in animal production and provide concrete recommendations for integrating scientifically validated AWIs into EU animal welfare reform.

A systematic review of sensor technologies for automated welfare assessment of broilers

B. Forkman[1], P. Llonch[2], A. Ramon-Perez[2]
[1] University of Copenhagen, Dept of Veterinary and Animal Science, Groennegaardsvej 8, 1870 Frederiksberg, Denmark, [2] Autonomous University of Barcelona, Department of Animal and Food Science, School of Veterinary Science, Building V, Travessera dels Turons, 08193 Cerdanyola del Vallès, Barcelona, Spain

Animal welfare is a multidimensional concept covering many different aspects of the life of an animal, as a consequence, a variety and large number of indicators and measures are needed to assess welfare. Because of the time and effort needed to assess animal welfare, automatic registrations of indicators have a great potential. Within the European project aWISH, a systematic review of available animal based measures of broiler welfare was done. The indicators are divided into the five domains (Good feeding, Good housing, Good health, Appropriate behaviour and the Mental domain). In total, 65 measures for broilers were found. The majority of indicators (65%) were found for on-farm animal welfare challenges. While most welfare indicators were related to challenges occurring on-farm, most of them were measured at slaughter. Good health was the most represented domain with approximately 80% of indicators. The validity of the indicators that were measured was in most cases supported by literature. In the literature, there is less information about the repeatability and generality of the measures (e.g. possible differences between breeds or sexes). In the second part of the project a search was done for existing technological methodologies for measuring animal welfare indicators. Once the technologies were identified, experts were surveyed to complete the information about the technology identified to assess AWIs and their validation status, with different stakeholders related to whole meat production, including the livestock sector, academia, government, NGOs, and industry and retail. Most of the available technologies focus on animal welfare-related indicators (e.g. weight), rather than indicators specifically developed for animal welfare purposes. There are, however, a number of noteworthy exceptions, e.g. sensors for alarm call detection, assessment of gait score, foot pad dermatitis and hock burns.

Validation of an automated system for at-slaughter assessment of footpad dermatitis and hock burn in broiler chickens

N. Van Staaveren[1], K. Van Langeveld[2], J. Schulte-Landwehr[3], J. Mulder[4], P. Galliot[5], P. Créach[5], P. Sztandarski[6], J. Marchewka[6], B. Forkman[7], N. Van Noten[2], F. A. Tuyttens[2], M. F. Giersberg[1], T. B. Rodenburg[1]

[1] Utrecht University, Faculty of Veterinary Medicine, Yalelaan 2, 3584 CM Utrecht, Netherlands, [2] Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Animal Sciences Unit, Burgemeester Van Gansberghelaan 119, 9090 Merelbeke-Melle, Belgium, [3] CLK GmbH, Zur Steinkuhle 3, 48341 Altenberge, Germany, [4] Plukon Food Group, Industriewe6 36, 8091 AZ Wezep, Netherlands, [5] Institut Technique de l'aviculture - ITAVI, 41 Rue de Beaucemaine, 22440 Ploufragan, France, [6] Institute of Genetics and Animal Biotechnology of the Polish Academy of Sciences, Jastrzębiec, 05-552 Magdalenka, Poland, [7] University of Copenhagen, Department of Veterinary and Animal Sciences, Grønnegårdsvej 15, 1870 Frederiksberg, Denmark

The automated assessment of footpad dermatitis (FPD) and hock burn via computer vision at the slaughterline could allow continuous monitoring of these important welfare indicators in broiler chickens. Such a system can be used to monitor the occurrence of FPD and hock burn over subsequent flocks and allow bench marking at different aggregation levels (farms, chains, countries, etcetera). This study aimed to compare the performance of a camera system (ChickenCheck software, CLK GmbH) against three human assessors. FPD (4 point scale based on relative size of the lesions) and hock burn (3 point scale based on absolute size of the lesions) were scored on both the left and right foot/hock according to severity from images captured by the camera system. A total of 50 images (100 feet/hocks) were used in the training dataset used to train the human assessors and 500 images (1,000 feet/hocks) were used in the validation dataset to determine measures of agreement and reliability for the discrete scoring system. Additionally, 100 images were used for lesion annotation (200 feet/hock) to determine the agreement between the camera system and the human assessors in capturing the total area of the foot pad or hock affected by lesions. Despite showing substantial to good intra-observer reliability (kappa: 0.78-0.98) and moderate to substantial inter-observer reliability (kappa: 0.46-0.66) during training, the human assessors showed fair to moderate agreement (kappa: 0.33-0.47) for FPD and hock burn when the dataset included a larger number of images with greater variation in lesion severity and appearance. However, the human assessors showed moderate to substantial agreement with the scores assigned by the camera system (0.60-0.70). More importantly, human assessors and camera system indicated a similar size of lesions on the footpad (R^2: 0.93) and hock burn (R^2: 0.97), suggesting that lesion size is correctly annotated by the camera system. However, the small but systematic differences found in the size of the affected area of FPD (+2.47%) and hock burn (-0.38 cm^2) by the camera system compared to the human assessors need to be addressed to further improve the performance of the automated system. A validated system for automatic assessment of FPD and hock burn at slaughter allows continuous monitoring of all birds that are slaughtered and is a valuable tool to improve broiler welfare. This study is part of the aWISH project. The aWISH ('Animal Welfare Indicators at the SlaughterHouse') project has received funding from the European Union's Horizon Europe Research and Innovation Program under grant agreement no. 101060818.

A molecular and biochemical reference approach for validation of vision systems that automatically record catching damage in broiler chickens at slaughter

P. Sztandarski[1], A. Jaszczyk[1], J. Marchewka[1], M. Solka[1], J. Rey-Gotxi[1], A. Szprynca[1], J. Schulte-Landwehr[2], J. Mulder[3], M. Kuras-Smolnik[3], F. Tuyttens[4,5], B. Rodenburg[6]

[1] Institute of Genetics and Animal Biotechnology, Polish Academy of Sciences, Postępu 36A, 05-552 Jastrzębiec, Poland, [2] CLK GmbH Bildverarbeitung, Zur Steinkuhle 3, 48341 Altenberge, Germany, [3] Plukon Food Group, Industrieweg 36, 8091 AZ Wezep, Netherlands, [4] Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Animal Sciences Unit, Burgemeester van Gansberghelaan 92, 9820 Merelbeke-Melle, Belgium, [5] Ghent University, Department of Veterinary and Biosciences, Faculty of Veterinary Medicine, Heidestraat 19, 9820 Merelbeke-Melle, Belgium, [6] Utrecht University, Animals in Science and Society, Faculty of Veterinary Medicine, Yalelaan 2, 3584 Utrecht, Netherlands

Catching damage, defined as lesions occurring during catching and associated preslaughter handling of broiler chickens, represents a significant challenge for animal welfare and carcass quality. Automated vision systems are increasingly implemented in slaughterhouses to detect carcass lesions; however, their validation is still largely based on macroscopic appearance or inspectors' subjective visual evaluations. Visual assessment, either human or camera-based, alone does not allow reliable determination of when a lesion occurred, making it difficult to distinguish between lesions arising during rearing or during catching, crating, transport or processing. Determining the age of lesions is essential both for accurate animal welfare evaluation and for production chain participants. The aim of this study was to develop a molecular and biochemical reference methodology that allows further training of the vision system to correctly recognize the age of lesions detected at slaughter. The approach was based on the established principle that mechanical injury induces a temporally ordered local response (inflammation), including activation of pro-inflammatory pathways, subsequent recruitment of immune cells, and later extracellular matrix remodelling and tissue repair. In parallel, injured tissue undergo progressive oxidative and enzymatic degradation, generating colour changes that reflect the stage of tissue response. Together, these processes are expected to produce measurable, time-dependent molecular and biochemical signatures in injured tissue. Sampling was conducted in a commercial slaughterhouse equipped with an automatic vision-based detection system (ChickenCheck software, CLK GmbH). Tissue was collected from carcasses classified by the system as presenting catching damage lesions. Gene expression profiling is applied to quantify transcripts of early inflammatory cytokines (e.g., L1β, Il6, Tnf-α), intermediate chemokines (e.g., CXCL8, CCL2), and late remodeling/fibrosis markers (e.g., MmP9, Tgfb1) using RT-qPCR. In parallel, biochemical analyses are conducted to determine hemoglobin-related parameters by UV-Vis spectrophotometry and concentrations of heme degradation products (biliverdin, bilirubin and conjugates) using HPLC or LC-MS/MS. Integrated statistical modelling, including mixed-effects and multivariate analyses is used to derive biologically based lesion-age categories. Analyses are expected to identify distinct molecular and biochemical patterns corresponding to different stages of catching damage lesions. Final laboratory analyses are currently underway and full results are expected prior to the conference presentation. This interdisciplinary approach links poultry welfare science, molecular pathology, and processing technology. It supports standardization of catching damage lesions assessment and contributes to the development of objective tools for welfare monitoring and quality control in the poultry industry.

Toward operational heat stress monitoring in poultry transport: a CFD-trained surrogate model

Y. Guyot[1], P. Créach[1]
[1] ITAVI, 7 faubourg Poissonnière, 75009 Paris, France

Broiler chickens transported by road in summer are highly vulnerable to heat stress, with important welfare and economic implications. A previous Computational Fluid Dynamics (CFD) study have successfully characterized thermal heterogeneity inside transport vehicles, but simulation times of several hours make these approaches impractical for operational decision-making. This study developed a fast surrogate model that predicts both the spatial distribution of Effective Temperature (ET) inside transport vehicles and the time-dependent physiological response, enabling real-time estimation of stress severity across the load. A parametric CFD model was built using OpenFOAM® to simulate airflow, heat, and moisture transfer within a transport trailer. Broilers were represented as a porous medium with Ergun-derived resistance coefficients, while metabolic heat production followed CIGR (Commission International du Génie Rural, climatization of animal houses, 1984) recommendations partitioned into sensible and latent components. A Sobol sequence with rejection sampling generated 100 physically constrained scenarios spanning ambient temperature (20–40°C), relative humidity (limited by realistic western european specific humidity bounds of 5–22 g/kg), stocking density (150–230 cm²/kg), and average bird weight (1.2–3.0 kg). From each generated CFD solution, 20 ET quantiles (from q01 to q99.95) were extracted, capturing not only average conditions but also the critical upper tail where the most vulnerable animals are exposed. Kriging surrogate models were trained independently for each quantile using normalized inputs. Leave-One-Out Cross-Validation demonstrated strong predictive performance ($R^2 > 0.96$). This allows real-time reconstruction of the ET distribution across the load, though spatial localization within the vehicle is lost. By coupling this reconstructed distribution with a physiological response law linking ET to core body temperature rise, the surrogate enables rapid prediction of stress category proportions (Normal, Alert, Danger, Emergency) as a function of exposure time. The surrogate model enables rapid evaluation of mitigation strategies, supporting operational decisions such as adjusting loading density or scheduling transport during cooler periods. Future field validation will quantify the relationship between predicted stress categories and mortality outcomes. Ultimately, this approach provides a practical framework for balancing animal welfare, logistics, and economic constraints in real-time.

Impact of bird placement on Airflow Resistance in laying hen Transport Crates using a Porous Media Approach

N. Ulanowska[1], L. Rong[1], L. Van Dijk[2], A. B. Riber[2], L. Foldager[2,3], M. S. Herskin[2]
[1] Aarhus University, Department of Civil and Architectural Engineering, Inge Lehmanns Gade 10, 8000 Aarhus C, Denmark, [2] Aarhus University, Department of Animal and Veterinary Sciences, Blichers Allé 20, 8830 Tjele, Denmark, [3] Aarhus University, Section for Bioinformatics and Computational Biology, Universitetsbyen 81, 8000 Aarhus C, Denmark

Animal welfare during transport to the slaughterhouse may be challenged by inappropriate thermal conditions, potentially inducing thermal stress. There is limited knowledge of how temperature is distributed in laying hens transport vehicles. This project aims to investigate temperature distributions inside transport vehicles by applying Computational Fluid Dynamics (CFD) simulations. This study, as part of the project, is to investigate the porous medium modelling of the large number of laying hens and crates present in the transport vehicles to significantly reduce mesh numbers so that CFD simulations are feasible with our available computational resources. The objective of this study was to identify the resistance coefficients of porous medium modelling for crates with animals considering three animal placements (three scenarios designed based on observations) within crates. The actual geometry of laying hens and crates' walls were created and first simulated in CFD modelling so the correlation between the pressure drops and air speeds (five levels changing from 0.25 m/s to 1.25 m/s) could be developed along three directions of Cartesian coordinate system. This allowed us to derive resistance coefficients of porous medium regions. Then the same computational domain was used while the actual geometrical domain of laying hens and crates' walls were replaced by porous medium regions and simulations under the same air speeds were conducted. The pressure drop obtained from these simulations were compared with pressure drops from the previous simulations at the first step. The results showed that the porous medium modelling can well generate the pressure drop with discrepancies ranging from 0% to 5% for air speeds larger or equal to 0.5 m/s and up to 11% for air speed of 0.25 m/s. The different placements of laying hens could influence the resistance coefficients; thus, the pressure drops to a certain degree. The results of this study can be applied by researchers and engineers focusing on CFD modelling of laying hens transport vehicles in order to further predict the temperature field within the vehicles under different climatic conditions.

Optimizing Pig Welfare Through Digital Transparency: A Multimodal Sensor System for Real-Time Transport Monitoring

M. Ganster[1], S. Herter[1,2], V. Restrepo[2], S. C. L. Fischer[1]
[1] Fraunhofer IZFP, Campus E3 1, 66123 Saarbrücken, Germany, [2] Universität des Saarlandes, Campus, 66123 Saarbrücken, Germany

Live animal transport represents a critical welfare vulnerability in pig production, characterized by opacity and significant variability in stress and injury outcomes. While digital traceability now extends to breeding and on-farm phases, transport remains a poorly monitored black box, undermining value chain integrity and consumer trust in ethical practices. This study addresses this gap by developing a compartment specific sensor system for real-time welfare assessment during transit. The architecture integrates commercial smartphones including built in accelerometers, gyroscopes, cameras, microphones, GPS and low cost Bluetooth tags to capture spatially resolved data across transport bays. The key innovations include compartment level granularity, hybrid hardware, and multimodal fusion. Granularity is achieved by acquiring data per bay, which detects intra vehicle welfare disparities due to density, positioning, and microclimate variations. Hybrid hardware is realised by using smartphones as both sensor nodes and data hubs, leveraging their ubiquitous processing capabilities, while Bluetooth tags supplement environmental sensing of temperature, humidity, and pressure. Multimodal fusion is obtained by simultaneous capture of environmental, motion, behavioral and geospatial data to enable real time welfare indexing. Four interdependent streams are monitored. The environmental stream tracks temperature, humidity and pressure, to quantify thermal risk. The journey-dynamics stream contains of acceleration and vibration, correlating motion with physical stress. The animal-indicator stream employs bay-specific cameras and microphones to capture vocalisations, posture and visible injuries, which are analysed with machine-learning algorithms. The geospatial context stream integrates GPS with data on road quality, traffic and weather, situating each welfare event within its broader context. Data from the streams are temporally aligned, features such as vibration spectra and acoustic entropy are extracted, and supervised machine learning generates real-time welfare indices (e.g., stress level, injury risk). The system creates concrete impacts for four stakeholder groups. For producers and transport operators, it reduces mortality, enables optimized loading patterns and improves operational efficiency through proactive interventions. For slaughterhouses, it provides verifiable welfare data for quality assurance and regulatory compliance. For consumers and brands, transparent, evidence based information about ethical handling enhances trust and enables market differentiation. For regulators, the platform supplies objective high resolution data that supports evidence based welfare enforcement. Compared with existing solutions, the system replaces single-point monitoring with bay-specific analysis, revealing intra vehicle welfare differences that were previously hidden. It maximizes cost efficiency by reusing smartphones instead of installing dedicated sensors. Finally, it shifts welfare management from retrospective audits to real time monitoring. The proposed system transforms pig transport into a digitally transparent, welfare optimized segment. By delivering compartment level, real time metrics, it enables evidence-based interventions that enhance animal health, operational efficiency, and regulatory compliance. This framework establishes a scalable model for ethical meat production, demonstrating how digital innovation bridges welfare science and industrial practice. Future work will focus on field validation and standardized welfare indicators for industry adoption.

"Best Practices" to improve broiler welfare – scientific experts' vs. poultry farmers' perspectives

M. Jachens[1], N. Kemper[1], M. Fels[1]
[1] Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, University of Veterinary Medicine Hannover, Foundation, Bischofsholer Damm 15, 30173 Hannover, Germany

As part of the EU Horizon project "aWISH" (Animal Welfare Indicators at the Slaughterhouse), so called "Best Practice Guides" to improve animal welfare in poultry farming were developed. To ensure both scientific accuracy as well as suitability of the proposed "Best Practices", animal welfare experts and poultry farmers were consulted in two surveys and asked to evaluate the measures. First, a literature review was carried out to identify Best Practices to reduce the occurrence of footpad dermatitis/hock burns (FDP/HB) and catching damage (CD) in broilers. Subsequently, 15 identified Best Practices for FDP/HB and 10 for CD were integrated into two surveys: one was sent out to scientific experts (aWISH partners, the project's expert panel and external experts from 21 countries), the other to German poultry farmers. Participants were asked to rate the proposed Best Practices on a scale from 0% (unsuitable) to 100% (very suitable). Data analysis, including a mixed linear regression model, was performed with the software R. Overall, 37 completed questionnaires were collected from experts and 60 from farmers. For FPD/HB, the measures "Good ventilation in stables (e.g. ventilation rate)" (experts: 91.0% vs. farmers: 94.0%, $p>0.05$) and "Height of waterline adjusted to animal size" (80.0% vs. 86.5%, $p>0.05$) received the highest scores in both groups. Significant differences between farmers and experts were detected for "Slow growing breeds" (76.0% vs. 25.0%, $p<0.001$) and "Litter management" (77.5% vs. 46%, $p<0.001$). Experts rated all measures to reduce catching damage at ≥70%, while farmers were far more critical towards practices relating to upright catching, such as "Carrying broilers upright" (73.5% vs. 20.0%; $p<0,001$) or "Not picking broilers up by their wings or legs" (85.0% vs. 25.0%, $p<0.001$). Experts selected "Careful handling" as the top Best Practice (99.0% vs. 83.0%, $p>0.05$), while farmers favoured "Low light intensity/blue or red light during catching" (80.0% vs. 100.0%, $p>0.05$). Experts and farmers agreed on the effectiveness of most of the proposed measures. Significant differences emerged regarding practices that pose a challenge for practical implementation on farms. It is therefore important to consider practical constraints like costs, feasibility and workload when developing guides to improve animal welfare to ensure acceptance of the measures among farmers. This project has received funding from the European Union's Horizon Europe Research and Innovation Program under Grant Agreement No. 101060818.

Effect of season on pasture composition, intake, and health in horses

V. Milojevic[1], C. Omphalius[2], S. Julliand[2]
[1] Sandgrueb-Stiftung, , 8132 Egg b. Zürich, Switzerland, [2] Lab To Field, , 21000 Dijon, France

In addition to the plant cell wall polysaccharides, the aerial parts of grassland plants contain non-structural carbohydrates (NSC): starches and soluble carbohydrates including simple sugars and fructans. The NSC content in plants can account for more than half of the dry matter, which can trigger metabolic diseases in grazing horses. Epidemiologically, seasonality is observed in the incidence of metabolic laminitis, which could reflect seasonal variation in the chemical composition of pasture vegetation and ingested biomass. Some of these variations are known at the botanical species level, but in multispecies grassland ecosystem these are poorly understood. Similarly, the selection and preference for plant species by horses in such grazing environments across different seasons and the resulting impact on their metabolism are unknown. This project aims to fill these gaps. Twenty-four healthy horses (14±1 yo, 701±83 kg) grazing on multispecies pastures (n=138 species documented at the start of the project) were monitored in spring (SP, May), summer (SU, August) and autumn (AU, October). During the 4 weeks preceeding each sampling, horses were grazing exclusively on pasture and received no additional feed. In SP, SU and AU, 4 samples of pasture biomass were collected for chemical analysis. At the same time, feces and blood samples were collected from the horses. Plant DNA present in the feces was extracted and sequenced (ITS2 rRNA sequencing) to determine the composition of the ingested diet. Serum fructosamine (SF) was used as a medium-term indicator of average glycaemia over the previous weeks. The effect of the season on chemical composition of the pastures, SF, and the richness and diversity of plants ingested was measured by ANOVA, as was the effect on the structure of the plant communities ingested by PERMANOVA (SAS). Relation between SF and the chemical composition of the pasture was assessed by ACP (R). Profound changes were observed in the chemical composition of pasture throughout the seasons (Table 1). The structure of the plant communities ingested also varied greatly (P<0.001), with a particularly distinctive structure in SP. This was due mostly to plants from the family Brassicaceae, which accounted for 42.9% of the plant DNA in feces in SP, compared to 1.8% and 2.3% in SU and AU (P<0.001). Conversely, the abundance of Fabaceae increased from 3.5% in SP to 27.0% in SU and 20.7% in AU (P<0.001). The richness and diversity of plants ingested was higher in SU than in the other seasons (on average 67 species in SP, 77 in SU, 63 in AU, P<0.001; Shannon index: 1.96 in SP; 2.35 in SU, 2.05 in AU, P<0.001). Concentration of SF was higher (P=0.038) in AU compared to SP and SU (in µmol/L: SP=324.8, SU=328.2, AU=355.3), but poorly related to chemical components of the pasture. When kept in multispecies pastures, horses ingest a varied diet that changes with the seasons. While NSC concentration was the lowest in AU, SF concentration peaked during this season, suggesting that other parameters may influence this parameter in horses. Understanding these factors of variation should promote practices that reduce the risk of metabolic disturbances, thereby contributing to the health of grazing horses.

The use of shade by grazing horses

J. Auclair-Ronzaud[1], C. Lesoudard[1], E. Montginoux[1], E. Legros[1], A. Leguerre[1], S. Henry[2]
[1] IFCE, Plateau technique de Chamberet, 1 Impasse des Haras, 19370 CHAMBERET, France, [2] CNRS, UMR 6552 Centre d'Etude en Ethologie et Cognition, 263 Avenue du Général Leclerc, 35000 RENNES, France

Periods of high summer temperatures are increasingly considered a management issue for grazing horses. In this study, we investigated short-term behavioural adjustments of horses when provided with shaded areas under summer pasture conditions. This experiment was conducted at the experimental farm of Chamberet (France) in 2023 and 2024. In total, 54 adult non-pregnant and non-lactating mares aged 5-8 years (2023: N=25; 2024 N=29) were included. Behavioural observations were performed in July and August. Mares were separated in three balanced groups grazing on two plots subdivided into three adjacent plots (1.20-1.50ha) corresponding to three treatments: shade (S), with permanent access to a grove; partial shade (PS), provided by trees along the plot edges; and without shade (WS). Environmental conditions were characterized using data from on-site meteorological station. Thermal load was estimated using the THW index (temperature humidity wind, in °C). Observation sessions were classified into four THW categories: <20°C (N=20), 20-25°C (N=28), 25-30°C (N=26) and >30°C (N=22). Behavioural states (grazing, rest while standing, lateral rest, recumbency rest, walk, observation, vigilance, positive/negative social interactions and insect repletion) were recorded using instantaneous scan-sampling (1 record every 10 mn) three days a week with four daily time slots (08:30-10:00, 10:30-12:00, 13:30-15:00, 15:30-17:00). At each scan, the position of the mare (in shade or in sun) was also noted. Animal performance was lastly monitored by weighing the mares at the beginning and end of each observation week. Effect of THW and observation time on behaviours expression was studied using Kruskal-Wallis test with the Dunn test as post-hoc when needed. Across all observations, grazing and rest while standing dominated the time-budget. Significant differences between treatments emerged only when THW index exceeded 25°C. S mares spend more time grazing than mares in PS and WS treatments both at 25-30 °C (S: 62.3±5.4%; PS: 49.3±17.7%; WS: 50.3±10.4%; p-value<0.05) and >30°C (S: 60.3±11.2%; PS: 40.0±12.7%; WS: 44.4±8.6%; p-value<0.05). Correspondingly, resting while standing increased in PS and WS mares. When THW index is between 25-30°C, WS mares (36.1±11.7%) rested more (p-value<0.05) than S (24.3±8.1%) and PS (23.6±7.4%) mares. When THW index exceeded 30°C, the difference between S and WS mares increased (21.3±6.8% vs 39.1±8.9%, respectively; p-value<0.05), and a significant difference also appeared between S and PS mares (21.3±6.8% vs 45.7±12.2%; p-value<0.05). However, further analyses are needed to determine whether these behavioural differences are directly associated with actual shade use. For PS mares, the amount of time spend in the shade depends on shade availability throughout the day, but when shade was present (15:30-17:00) its use was similar (36.8±17.1%) of that of S mares (40.4±13.2%; p-value=0.82). No significant difference in body weight was observed between treatments (from 552.9±26.5 kg to 569.1±23.6kg in 2023; from 528.2±26.9kg to 554.5±37.9kg in 2024). These results highlight short terms behavioural adjustments of grazing mares when facing increased thermal load. Access to shade appears to modulate these adjustments. However, interpretation remains cautious because treatments differed not only in shade availability but in shade structure (i.e. grove microclimate) and daily shade dynamics. In addition, only daytime observations were performed. The absence of difference in body weight suggests that behavioural compensation strategies may occur outside the observed periods.

Investigation of a pivotal age in the ageing of digestive function in horses.

C. Omphalius[1], L. Marchal[1], G. Sorci[2], V. Milojevic[3], P. Grimm[1], S. Julliand[1]
[1] LAB TO FIELD, 26 bd du Docteur Petitjean, 21000 DIJON, France, [2] Biogéosciences, CNRS UMR 6282, 6 bd Gabriel, 21000 DIJON, France, [3] Sandgrueb-Stiftung, Sandgrueb 6, 8132 Egg b. Zürich, Switzerland

Elderly horses may experience health issues related to digestion and absorption, such as loss of body condition or colic. In this herbivore species, digestion in the hindgut and absorption of volatile fatty acids (VFA) through intestinal wall are crucial for energy provision and maintaining health. Digestion itself depends on the retention time (RT) of substrates and relies on microbial activity. With ageing, the alterations in the equine microbial ecosystem have only been described through linear relations and age groups comparisons. With the concept of a "pivotal age" (PA) – the age at which these changes accelerate – it is sought to anticipate the health issues associated with ageing. This study aimed to assess age-related changes in markers of digestive function, including RT, which has never been studied in this context. It was also examined whether the changes are linear or if PA can be demonstrated. A cross-sectional study was conducted with 48 horses without ingestive, digestive or metabolic diseases, evenly distributed between 4 and 33 years old. The horses were fed only hay ad libitum. To assess microbial activity, indirect proxies (VFA concentration and pH) were measured in faeces. Plasma acetate (C2) concentration and faecal dry matter (DM) were evaluated as markers of hindgut absorption. Total tract RT was measured as a reflect of the hindgut RT, by administering an indigestible marker (polypropylene balls) by nasogastric intubation on 24 horses. For 50 h, total faeces were collected and sieved to count the number of balls excreted. The mean RT (MRT) was considered as the time after which half of balls were recovered (t1/2, in h). The model was used to calculate t1/2. As the horses included in this study were of different breeds and sizes, a weight correction was applied. Four models with different complexity were tested for each variable: broken-line model (BLM; $Y = \alpha + \beta 1 \times (age - PA)(age<PA) + \beta 2 \times (age - PA)(age>PA)$), linear-plateau model (LPM; $Y = \alpha + \beta \times (age - PA)(age>PA)$), linear model (LM; $Y = \alpha + \beta \times age$) and intercept-only model (IOM; $Y = \alpha$). Models were compared based on their AICc values, the lower the better. Models with $\Delta AICc < 2$ were considered as equivalent. For MRT and plasma C2 concentration, the IOM had the lower AICc with a fixed intercept at 2.8±0.1 h.kg BW-1/3 and 0.93±0.04 nmol/µL, respectively. For fecal VFA concentration, pH and DM, the LPM had the best fit (Table 1) with a PA of 22±2 yrs, 19±3 yrs and 18±2 yrs and slopes of 2.72 mmol/L/yr, -0.07/yr, and 0.64 %/yr after the breakpoint, respectively. Using the chosen marker method, MRT did not vary with age. Thus, ageing of digestive function might be more related to changes in the composition and activity of the hindgut microbiota. Although this cross-sectional study cannot assess intra-individual ageing trajectories, its modelling approach could further explore microbial changes. A PA of around 20 yrs has been identified for the indirect proxies of microbial activity, consistent with the PA observed for one of the absorption markers (DM). Confirmation of age-related changes in absorption using more specific markers would be valuable. This modelling approach could also help identify trajectories of physiological functions during ageing and early contributors to frailty.

Table 1. AICc of models tested for different parameters

	Total fecal VFA	Fecal pH	Fecal DM	Plasma C2	MRT

Chicory as an Antiparasitic Driver: Shaping the Parasite–Microbiota–Host Triad in the Equine Holobiont

N. Mach[1], S. Méndez[1], J. Malsa[1], J. Auclair-Ronzaud[5], D. Bars[1], M. A. Sevillia-Boisferon[1], G. Pot[1], H. Robert[1], M. Monié--Ibanes[1], A. Velarde[6], L. Lansade[2], A. R. Williams[7], E. Richard[4], G. Yannic[3], G. Bourgoin[8], G. Fleurance[5]

Anthelmintic resistance in cyathostomins is a growing global threat to equine health and welfare, underscoring the need for sustainable, ecology-based parasite-control strategies. Chicory (Cichorium intybus, Puna II) has been proposed as an antiparasitic forage, yet its effects on the parasite–microbiota–host system remain uncharacterized. We conducted a longitudinal study to evaluate how chicory grazing influences parasitological outcomes, gut microbial communities, and host responses and behavior in horses. Twenty-six naturally infected 2-year-old Anglo-Arab foals were monitored over a 32-day grazing trial, with 13 horses grazing ~ 80% chicory-based sward and 13 grazing a permanent pasture. Both groups were followed concomitantly. Animals were monitored weekly for clinical and behavioral indicators, fecal egg counts, larval development, blood biomarkers (inflammation, immunity, metabolism), and high-resolution dynamics of the microbiota and nemabiome. Statistical analyses combined linear and generalized mixed-effects models for parasitological, physiological, immunological, and behavioral variables, and multivariate ecological approaches for microbiota and nemabiome data (PERMANOVA, β-dispersion, differential abundance tests, and longitudinal stability metrics). Physiological parameters remained stable across treatments, with no differences in body weight or major clinical markers. Immune profiles showed limited variation, although IL-4 increased in chicory-fed horses, suggesting subtle Th2 modulation. Behavioral assessments confirmed the absence of discomfort. Feeding duration was similar between groups (≈18 h/day), and chicory-fed horses showed slightly greater displacement and more positive social interactions. Importantly, horses grazing chicory exhibited a marked reduction in cyathostomin egg excretion, accompanied by functional shifts in the intestinal ecosystem. While nemabiome composition remained stable in controls, the relative proportion of several cyathostomin species – notably Cyathostomum pateratum and multiple Cylicocyclus taxa (C. nassatus, C. ashworthi, C. leptostomus, C. insigne) – decreased in chicory-fed horses. A few taxa, including Cylicostephanus calicatus, C. minutus, and C. longibursatus, persisted or increased, indicating species-specific sensitivity to chicory rather than uniform suppression. Concomitantly, chicory induced profound ecological shifts in the gut microbiota, including reduced α-diversity, increased β-dispersion, and destabilized individual microbial trajectories. Several bacterial lineages, namely Oscillospiraceae, Clostridiaceae, Lachnospiraceae, and Bacteroidales, were differentially enriched in chicory-fed horses, indicating a functional reorganization of the intestinal environment. Together, these results show that while chicory reduces nematode fertility and reshapes nemabiome composition, it also induces substantial shifts in the gut microbiota and host responses whose overall impact is not necessarily beneficial. Chicory may offer ecological leverage for parasite control, though its broader effects on the holobiont warrant caution.

The maternal vertical transmission of the bacterial microbiota shapes the foal microbiota on the long-term

L. Marchal[1,2], S. Julliand[2], G. Sorci[1], P. Grimm[2]
[1] Biogéosciences, CNRS UMR 6282, Université de Bourgogne, 6 bd Gabriel, 21000 Dijon, France, [2] Lab To Field, 26 bd Dr Petitjean, 21000 Dijon, France

Maternal intestinal microbiota is transmitted to the foal prenatally and postnatally via amniotic fluid, milk, and coprophagy. The microbiota of foals undergoes progressive maturation during the first months of life, leading to a structure similar to that observed in mares from 2 months of age. By this age, the foal microbiota has reached a stable state, yet it continues to evolve alongside the dietary transition until weaning. This study explores whether vertical bacterial transmission is merely a route of colonization of the immature foal gastrointestinal tract or whether it shapes the individual bacterial structure. Although mare-foal microbiota similarity has been investigated at the cohort level, information at the level of individual pairs remains limited. The aims of this study were to determine the degree of similarity of dam-foal pairs and to assess the contribution of the maternal microbiota to a distinct microbial signature in foals over time. Twelve French Trotter dam-foal pairs from a single farm and sharing common pastures were enrolled in the study. Fecal samples were collected from dams in May and November, and from foals at 2 (61±3 days, May-July) and 7 months (227±14 days, November-December). Foals were weaned gradually between 5 and 6 months (171±21 days). Bacterial community structure was characterized using 16S rRNA gene sequencing. Inter-individual diversity (β-diversity) was assessed using Bray-Curtis dissimilarity index (0=similar; 1=dissimilar). For each sampling period, the observed mean dissimilarity index between dams and their foals was compared against a null distribution generated from one million simulations of the mean index calculated from 12 randomly paired unrelated mare-foal or foal-foal combinations. Age-related differences in dam-foal similarity were evaluated using a paired Wilcoxon signed-rank test. Intra-individual diversity (α-diversity) was assessed using Shannon index. Pearson correlations were used to test linear relationships between dams and foals α-diversity. At 2 months, foals' bacterial microbiota was more similar to that of their own dams than to that of unrelated mares (0.684±0.101 vs 0.755±0.017, $p<0.0001$) or other foals (0.684±0.101 vs 0.725±0.015, $p=0.0022$). Similarly, at 7 months, foals' microbiota remained more similar to that of their own dams than to unrelated mares (0.585±0.015 vs 0.672±0.019, $p<0.0001$) or other foals (0.585±0.015 vs 0.653±0.018, $p<0.0001$). Dam-foal similarity was stronger at 7 compared to 2 months ($p=0.0024$). No correlation was observed between dam and foal α-diversity at 2 months ($r=0.503$, $p=0.0954$) but a significant positive one at 7 months ($r=0.775$, $p=0.0031$). At 2 months, foal microbiota is more similar to that of its own dams than to that of unrelated mares or other foals. This pattern persists after weaning, despite shared environmental exposure, highlighting a stronger maternal influence compared to environmental factors. Additionally, the results indicate that α-diversity is vertically transmitted. It would be interesting to investigate whether the resistance and resilience properties, often associated with α-diversity, are also transmitted. Optimizing maternal microbiota and potentially selecting breeding mares based on their microbial profile, may therefore represent a promising strategy to promote the health and performance of foals.

Effect of alkaline reduced water on gastrointestinal inflammation in horses

S. Julliand[1], V. Milojevic[2], B. Von Rechenberg[2], A. Martin[1], P. Grimm[1]
[1] Lab To Field, , 21000 Dijon, France, [2] Sandgrueb-Stiftung, , 8132 Egg b. Zürich, Switzerland

Gastritis affecting the squamous and glandular mucosae can originate from starch fermentation in the stomach of horses. Respectively, starch bypassing antececal digestion ferments rapidly in the hindgut, which can lead to dysbiosis. Horses may exhibit diarrhea and systemic inflammation due to hindgut barrier permeability. Based on observations made in other species, drinking alkaline reduced water (ARW) may help reduce gastrointestinal inflammation. It is currently unclear whether horses willingly drink ARW and what effect it has on their health. Thus, this study aimed to evaluate voluntary consumption of ARW and assess its impact on gastrointestinal health in horses fed a high-starch diet. A longitudinal study composed of two periods (P1 and P2) of 4 weeks each was conducted on 12 geldings (French Trotter, 10±1 yo, 556±40 kg). Throughout the study, horses were fed a high-starch diet (1.8 g/kg BW starch/meal, twice daily) at an ingestion level of 2.0% BW, consisting of hay (61% DMI), rolled barley (29%), and wheat bran (10%). Horses were housed individually in boxes and had free access to water in 80L buckets to measure consumption. During P1, all received standard tap water. In P2, horses were divided into 2 groups: the control remained on tap water while the other received ARW (mixture of 2/3 tap water and 1/3 Xeral [Watair GmbH]). At the end of each period, blood was taken to count cells and assess electrolytes, gases, plasma acetate and lipopolysaccharides (LPS) concentration. Likewise, feces were collected to measure DM and calprotectin. On the last day of each period, lesions in both mucosae were assessed during gastroscopy. Microbiopsies were collected to evaluate vascular congestion, edema, crypt atrophy in the glandular mucosae (H&E coloration) and NF-κB expression in both mucosae (immunohistochemistry). Data from P2 were analyzed using the GLIMMIX procedure with values from P1 as covariates. During P2, horses consumed same amounts of both waters, confirming that ARW was readily accepted. Horses receiving ARW showed lower RBC (P=0.008), hematocrit (P=0.022) and hemoglobin (P=0.005), suggesting hemodilution, which might be related to the increased concentration of blood sodium (P=0.077). They also had higher base excess (P=0.048), probably resulting from the alkalinity of ARW (pH=11.2), which could be beneficial in cases of metabolic acidosis. No significant effect of ARW was observed on gastric or hindgut inflammation markers (Table 1). However, in horses receiving ARW, numerically lower scores for glandular vascular congestion and crypt atrophy, along with reduced NF-κB-positive surfaces in squamous mucosa, hypothesize decreased inflammation. The higher fecal DM and plasma acetate concentration suggest that ARW may also improve hindgut barrier integrity and absorption capacity. As such, the gastrointestinal benefits of ARW were not clearly demonstrated in horses experiencing subclinical, chronic dietary stress. However, this data supports further studies to assess the impact of ARW on animals facing acute stress or diseases.

Table 1: Effect of water drunk on markers of gastric and hindgut inflammation

	Control	ARW	SE	P-value
Glandular mucosa				
Histologic Scores1:				
– Congestion	1.69	1.23	0.20	0.140
– Edema	1.84	1.41	0.28	0.311
– Crypt atrophy	1.75	1.17	0.30	0.200
NF-κB (% of area)	3.71	2.95	1.10	0.639

Horse feeding in relation to gastric health – nature does it best

M. Bachmann[1], G. F. Schusser[1,2], M. Wensch-Dorendorf[1], C. Pisch[1], M. Bochnia[1], M. M. Santo[1], G. Köller[2], M. Schmicke[3], K. Heinichen[2], A. Zeyner[1]

[1] Martin-Luther-University Halle-Wittenberg, Institute of Agricultural and Nutritional Sciences, T.-Lieser-Str.11, 06120 Halle/Saale, Germany, [2] University of Leipzig, Faculty of Veterinary Medicine, An den Tierkliniken 11, 04103 Leipzig, Germany, [3] University of Veterinary Medicine Hannover, Foundation, Veterinary Endocrinology and Laboratory Diagnostics, Clinical Centre for Farm Animals, Bünteweg 2, 30559 Hannover, Germany

Feeding plays a crucial role in the etiology of gastrointestinal and metabolic diseases. In horses, many common diseases are related to feeding excessive amounts of soluble carbohydrates in cereal grain-rich meals, to which horses as grassland inhabitants are not well adapted. The objective was to assess changes in grades for equine squamous/glandular gastric disease (ESGD/EGGD) as well as biochemical and physicochemical parameters of gastric digesta in relation to the type of ration. In 24 horses (13 m/11 f), 11 ± 6.0 years, 471 ± 63.4 kg body weight (BW), gastric mucosa was examined by gastroscopy before a feeding period of at least 34 days and afterwards after dissection. The horses were on pasture 24 h/day (PST) or received hay ad libitum (HAY), hay plus oats at 1 or 2 g starch/kg BW/meal (OS1/OS2) in the stable (n = 4/8/6/6). Stabled horses had straw as bedding and daily paddock access. The horses were not exercised. The shift in grades from the initial to final examination was calculated. The grades were transformed into a binary trait for deterioration and odds ratios calculated with reference to PST. Dry matter (DM), swelling capacity (SC), water binding capacity (WBC), buffering capacity (BC), percentage of particles less than or equal 1 mm (Ple1), pH, chloride and mucus were determined in digesta of Pars nonglandularis/glandularis (PNG/PG) and gastrin in blood serum. In the stabled horses, last hay was offered 2 h and oats 1 h prior to sedation, euthanasia and sampling. The shift in ESGD and EGGD grades and changes in digesta constituents were analyzed using mixed linear models. Moreover, linear regression was carried out to unveil the effect of an oat meal in addition to hay ad libitum considering the supplementary levels of oats at 0, 1 and 2 g starch/kg BW/meal (HAY/OS1/OS2) for DM, WBC, SC, BC, Ple1, pH, chloride, mucus and gastrin. The shift in ESGD and EGGD grades differed among the rations ($p < 0.05$) and was specific in individual stomach sections. While horses benefited in the PST and HAY groups, deterioration in OS1 was observed exclusively in the antrum and in OS2 irrespective of the section. In relation to PST, odds ratios for horses to deteriorate in terms of mucosal lesions were 1.0 (HAY), 2.9 (OS1) and 20.2 (OS2; $p < 0.01$). Addition of oats led to considerable changes in biochemical and physicochemical parameters. Especially WBC was lower with oat feeding ($p < 0.001$). Digesta pH was highest in OS1 and OS2 ($p < 0.05$) and mucus concentration was upregulated ($p < 0.001$). Linear regression revealed that the changes resulting from additional oat feeding were primarily due to shifts in DM, WBC and Ple1 in PNG, and DM, mucus concentration, WBC, SC and Ple1 in PG ($p < 0.01$). For the other analytes, an effect of oat supplementation was not evident. Feeding concentrates seemed to disturb the natural sponge effect of digesta, whereupon gastric acids remain on the mucosal surface. This could be one major reason for lesions that occur both in the squamous and the glandular mucosa. Even a proportion of oats referring to 1 g starch/kg BW/meal cannot be fed without hesitation and twice this in one meal is assured detrimental for gastric health. The study was approved by Saxon Federal Administration Authority (TVV 63/21) and funded by the German Research Foundation (project no. 434510792).

Wash it all away - Evaluation of the efficiency of different cleaning methods on drinking water quality in automatic bowl drinkers for horses under practical conditions

M. S. Wiese[1], A. C. Heitgreß[3], S. Kuhnke[3], U. Müller[1], J. Stracke[2], C. Heinemann[1]
[1] University of Bonn, Institute of Animal Science, Katzenburgweg 7-9, 53115 Bonn, Germany, [2] University of Bonn, Institute of Animal Science, Endenicher Allee 15, 53115 Bonn, Germany, [3] LUFA NRW - Analysenlabor der Landwirtschaftskammer Nordrhein-Westfalen, Nevinghoff 40, 48108 Münster, Germany

Water is an essential nutrient for maintaining physical functions and the health of horses and must always be available in sufficient quantity and quality. But there is neither a clear definition what is meant by sufficient water quality, nor is there a specific guidance on measures to maintain sufficient water quality. Therefore, the aims of the experimental study were to collect data on microbiological water quality in bowl drinkers under practical horse husbandry conditions and to compare different cleaning methods for keeping automatic bowl drinkers clean. A total of 30 bowl drinkers with tube valves used by horses kept in individual boxes at a horse farm in North Rhine-Westphalia were examined for the study. Firstly, a sample of the stagnant water was taken from each bowl drinker to determine the initial bacteria content. The following 5 cleaning methods were carried out in respectively n=6 bowl drinker: (a) scooping out the residual water by hand (control group), (b) wiping the surface by hand, (c) wiping with a paper towel, (d) cleaning with a dish brush, (e) cleaning with a brush and subsequent application of a commercially available chlorine-based disinfectant for use in horse husbandry. After cleaning, the bowl drinkers were emptied by hand and then refilled with fresh water to the previous level. Finally, a second sample per bowl drinker was taken from the fresh water immediately after refilling. All samples were microbiologically tested for the total aerobic count at 20°C and 37°C, as well as the content of coliform bacteria and Escherichia coli. The results were evaluated descriptively and are shown as mean ± SE or respective as Δ of the mean ± SE. Initial bacterial concentration varied between 4.0 and 7.48 log (10) cfu/mL for total aerobic count at 20°C and between 3.0 and 6.48 log (10) cfu/mL for total aerobic count at 37°C. Comparing the reduction for total aerobic count at 20°C of the different cleaning methods showed, that cleaning with the brush and subsequent disinfection (e) had the greatest effect (-1.57 ± 0.17 log (10) cfu/mL, followed by cleaning with a brush (d) (-0.85 ± 0.18 log (10) cfu/mL), scooping out the water by hand (a) (-0.75 ± 0.09 log (10) cfu/mL), wiping with a paper towel (c) (-0.54 ± 0.25 log (10) cfu/mL), and wiping the surface by hand (b) (-0.06 ± 0.26 log (10) cfu/mL). Total aerobic count at 37°C showed similar results. Coliform bacteria were detected in 13 bowl drinkers before cleaning. After cleaning, coliform bacteria only remained in 2 bowl drinkers, both which had been cleaned by (b) wiping the surface by hand. In all water samples E. coli was below the detection limit of 1.0 log (10) cfu/mL. Therefore, it can be concluded, that cleaning the drinkers using a cleaning tool is more effective than simply scooping out the water by hand. After comparing the effort and benefits, the use of a brush as a cleaning tool can be recommended for further studies. In order to keep the measures practice-oriented, regular cleaning with a clean rinsing brush appears to be advisable. In the case of illness, disinfectant should be used additionally. Furthermore, the study provides initial results on microbiological water quality parameters under practical conditions as a basis for defining sufficient water quality for horses. This research is part of the project Aqua Equidae, funded by the Gesellschaft zur Förderung der Wissenschaft um das Pferd eV (GWP).

Alternative control against Stomoxys calcitrans: efficacy assessment of a litter-desiccant on its life cycle

G. Weis Servat[1], A. Salem[1], E. Coudert[2], A. Dall'orsoletta[2], A. Juanchich[2], E. Liénard[1], É. Bouhsira[1]
[1] INTHERES, Université de Toulouse, INRAE, ENVT, 23 chemin des Capelles, 31076 Toulouse, France, [2] Centre Mondial de l'Innovation, Groupe Roullier, 18 Av. Franklin Roosevelt, 35400 Saint-Malo, France

Stomoxys calcitrans is a cosmopolitan hematophagous fly and a major pest of cattle and horses, also biting other mammals and birds. It impairs animal welfare, transmits pathogens and causes economic losses. Immature stages develop mainly in litter soiled with urine and feces, manure and feed refusals. Intensive chemical control of adult flies has led to insecticide resistance and, since then, current recommendations promote integrated pest management (IPM) combining repellents on animals, selective traps, parasitoid releases and improved litter hygiene. In cattle farming, farmers use litter drying and sanitizing agents to control the development of pathogenic microorganisms and improve long-term litter quality (e.g., humidity and pH). However, they also reported a decrease in the number of adult flies, although this has not been clearly measured yet. The aim of our study was to assess the efficacy of the litter desiccant Actisan 360® (Timac Agro, Saint-Malo, France), on the life cycle (egg laying and development of immature stages) of S. calcitrans under laboratory conditions. First, the egg-laying (or oviposition) preference of adult flies was tested between a treated and an untreated substrate. To this end, 100 adult flies (sex ratio 1:1) were placed in a cage containing two oviposition trays, one control and one treated with Actisan 360®. Flies were fed daily with cattle blood, and eggs laid on each tray were collected and counted. Measures were followed up until all flies had died. Six replicates were performed. Egg counts were compared between treatments using a negative binomial mixed model (with a significance threshold of $p < 0.05$). Secondly, the effect on immature stages development was assessed. Thus, six treated trays and two control trays each received 500 eggs (3000 and 1000 eggs total, respectively). Newly emerged adults were collected daily, and then the sex, weight and size were determined. The trial ended after two consecutive days without emergence. The remaining pupae were then collected from each tray, counted, weighed and measured. All data were analysed using generalised linear models, mixed linear models, ANCOVA and survival analysis ($p < 0.05$). Egg laying was significantly reduced on the treated substrate (mean reduction: 94%; $p < 0.001$), indicating a strong repulsive effect from the treatment substrate. Pupal formation decreased by 63.7% in the treated larval medium ($p < 0.001$), indicating reduced larval survival. However, no pupicidal effect ($p = 0.869$) or inhibition of adult emergence ($p = 0.375$) was observed. The size for adults and pupae did not vary between conditions. However, adults were significantly lighter in the treated group ($p < 0.01$), whereas pupae were significantly heavier ($p = 0.010$), possibly reflecting reduced larval competition within the treated substrate. In conclusion, this study demonstrates that Actisan 360® exerts a strong repellent effect on oviposition site selection, together with a significant larvicidal activity. These findings suggest that Actisan 360® could be integrated as a complementary tool within an environmentally friendly IPM strategy.

Case Study: Mineral Content of Trimmings from Different Hoof Parts Using TXRF in an Oldenburg Sport Horse With and Without Mineral Feed Supplement

M. Kerst[1], S. Pauling[1]
[1] Rhine-Waal University of Applied Sciences, Life Sciences, Marie-Curie-Straße 1, 47533 Kleve, Germany

Nutritional supplements are common in horse feed to improve health and performance, including hoof stability. Several minerals such as zinc, copper and manganese are known to positively influence hoof health and are often supplemented in special formulations. Minerals act as co-factors or inhibitors in healthy hoof keratinization and mineral tracing could reveal if and how feed supplements impact hoof composition. Methods to verify mineral uptake and long-term incorporation from supplements into hoof material remain limited. The aim of this case study is twofold: it (1) evaluates potential variations in mineral uptake in different parts of the hoof such as wall, frog and sole over time with and without mineral supplementation and (2) investigates the feasibility of using Total Reflection X-ray Fluorescence (TXRF) to analyse mineral content in hoof trimmings. If feasible, a simpler handheld XRF device could be used in a next step to verify mineral composition of hoof material without costly laboratory analysis. The study is based on the case of an Oldenburg sport horse transferred from a standard diet optimized for sport horses with additional mineral supplementation including biotin, zinc, copper and manganese to a purely grass-fed diet with roughage for 6 months. Horse shoes from the front legs were removed 3 months after the transition. From that point onward, regular trimmings from the front left hoof were taken by a farrier using nippers for 18 months, specifically from the hoof tip, side wall, sole and frog. After the 6 month period, the horse was again transitioned to stable housing with feed supplements. Samples were taken at an average of 36 ± 6 days. All hoof samples were washed with ultrapure water (>21 MΩ/cm). The samples were milled in a cup mill using tungsten carbide cups and balls. Milled samples were stored in PP tubes under vacuum. 250 ± 1 mg per sample were acid digested in a microwave digestion system using HNO3 and measured in TXRF using molybdenum and tungsten excitation. The TXRF was calibrated using six reference materials and verified using ICP-OES. In the sole, concentrations for zinc, copper and manganese were 93.47 ± 14.01 ppm, 3.59 ± 1.86 ppm and 38.24 ± 36.26 ppm respectively. In the frog, concentrations were 35.81 ± 4.85 ppm (Zn), 2.98 ± 2.06 ppm (Cu) and 46.68 ± 38.32 ppm (Mn) and in the hoof wall 104.09 ± 33.30 ppm (Zn), 5.99 ± 3.61 ppm (Cu) and 90.44 ± 54.51 ppm (Mn). A one-way ANOVA showed no significant difference for zinc, copper and manganese in samples from the two feeding regimes in the sole. However, in the hoof wall differences were found for copper ($F = 10.449$, $p = 0.0045$) and manganese ($F = 12.7410$, $p = 0.0024$). In the frog differences were found only for zinc ($F = 11.4427$, $p = 0.0062$). The TXRF results were validated using reference material with acceptable recovery and variance, comparable to methods such as ICP-OES (R2: > 0.95) and showing similar ranges as reported in literature (Spörndly-Nees, 2023; Stanek, 2025; Litzke, 2020), demonstrating the feasibility of TXRF for mineral determination in horse hoof. The evaluation shows a significant reduction in copper and manganese concentrations in the hoof wall and zinc in the frog after switching from supplemented feed to a grass-fed diet, but not in the sole. This highlights the need to distinguish sample material in further analysis. This study is limited to a single-horse case with significant diet changes. Results should be verified with more individuals and extended to additional material such as mane and tail hair. The present results can serve as a basis to calibrate a simplified handheld XRF device to analyze more samples in situ.

Data science and innovation – from academic research to industrial applications

I. Adriaens[1]
[1] *CRV BV, Global Information Solutions, Rijksweg-West 2, 6842BP Arnhem, Netherlands*

In the Data Science team at CRV, we develop, test and productize data-informed solutions that can help farmers, business partners as well as serve internal CRV processes. For example, we have recently developed risk metrics based on milk fatty acids that alert farmers to cows with poor rumen health and high negative energy balance. To this end, we integrated existing data on milk production with milk fatty acids and tested the results in practice in collaboration with feed advisors. CRV has a long history of collecting data, and has fully committed to professionalizing its applications in the past decade. In this talk I will give an insight into some of the experiences I had in the past 2 years since my move to industry after 10 years in academic research. I will share some of the differences in doing independent academic and company-embedded research and dive into some key lessons I have learned. Topics will be for example the professional process of bringing innovations to the market, legal and other boundaries of commercial development, important hard and soft skills I had and I lacked from working in academia. I will share about some of the projects I have been involved in, and how we test new ideas in the market. I will also touch upon potential opportunities for more and better collaboration between industry and academia.

Practical application of PLF technologies in pasture based production systems, from academia to startups

M. Odintsov Vaintrub[1]
[1] *Regrowth, Contrada Specola, 64100 Teramo, Italy*

The European livestock research landscape has produced a substantial body of work in Precision Livestock Farming (PLF), yet the translation of academic prototypes into scalable, market-ready technologies remains limited. While crop-oriented agritech and food-tech sectors have attracted significant venture capital and deep-tech development, animal agriculture has comparatively lagged in the emergence of research-driven startups. This gap is particularly evident in extensive, pasture-based, and small-scale systems, where technological innovation often remains confined to experimental or pilot-stage deployments. Regrowth originated from applied academic research on pasture-based poultry and integrated agroecological livestock systems in central Italy. Initial development focused on a low-cost weight-on-weighing (WoW) platform designed to provide growth and welfare data within mobile and pasture environments. The early phase followed a conventional parameter-driven PLF logic used as a standard in PLF development. However, direct implementation across diverse contexts including upland systems in the Alps and Apennines and smallholder poultry farms in Kenya revealed that technical validity alone does not guarantee adoption. Instead, infrastructural constraints, user experience, and economic thresholds shaped real-world viability. Through iterative field engagement and human-centric design methodologies, Regrowth reframed its development process. Rather than positioning sensors as the primary innovation output, the project adopted an infrastructure-first architecture centered on edge computing, modular sensor integration, and offline functionality. This shift enabled adaptation across heterogeneous environments, from high-altitude transhumant grazing systems to low-infrastructure rural farms, demonstrating that technological flexibility is critical for scalability. The transition from academic initiative to startup entity provided reciprocal value to scientific research. Direct market exposure enabled rapid validation cycles, stress-testing of theoretical assumptions, and identification of adoption barriers that are rarely visible within controlled research environments. Entrepreneurial activities required the transfer of research competencies such as experimental design, systems thinking, data modeling, and validation protocols into product development, stakeholder communication, and sustainable business structuring. This process generated feedback loops that enriched ongoing research activities, aligning scientific inquiry more closely with field-level realities. Consumer and farmer engagement further shaped innovation pathways. Participatory discussions, co-design sessions, and on-farm prototyping highlighted that end users prioritize reliability, transparency, and incremental investment capacity over high-resolution physiological analytics. By embedding human-centric design principles into the core architecture, Regrowth sought to reduce the structural gap between academic innovation and operational livestock systems. This case study argues that fostering deep-tech development in animal agriculture requires stronger integration between research institutions and entrepreneurial mechanisms. Embedding market validation within early-stage scientific development can enhance both impact and scientific robustness. The Regrowth pathway illustrates how academic livestock research can evolve into a context-responsive, scalable innovation framework capable of serving diverse production environments while contributing back to the scientific ecosystem.

AgrifoodTEF after three years: Lessons learned by researchers providing innovation services to agrifood tech companies

Z. Guy[1], D. Faradji[1], J. Ménadi[2], J. M. Gautier[1]
[1] Institut de l'Elevage, 149 rue de Bercy, 75595 Paris, France, [2] Acta, 149 rue de Bercy, 75595 Paris, France

AgrifoodTEF aims to accelerate the adoption of Artificial Intelligence (AI) and robotics in the agrifood sector by providing access to testing and experimentation facilities across Europe. The project creates a collaborative environment where research organizations support companies by offering services such as testing, validation, and performance assessment of emerging technologies. In doing so, it strengthens the link between academic expertise and industrial innovation, positioning research institutions as providers of applied technological services. Since its launch in 2023, AgrifoodTEF has progressively developed a European ecosystem dedicated to support innovation. After 3 years, the project provides an opportunity to reflect on what researchers have learned from this new service-oriented approach. To date, more than 400 services have been delivered to over 200 companies, with an average value of about €13,000 per service. Most of these companies are European Small and Medium-sized Enterprises (SMEs). Thanks to the TEF funding mechanism, many of them benefited from financial support covering up to 100% of the service cost, enabling them to access high-level scientific expertise and experimental infrastructures. These services highlight key strengths of research institutions: advanced experimental infrastructures, multidisciplinary scientific expertise, and the ability to evaluate technologies across a wide range of environments. For companies developing AI or robotic solutions, AgrifoodTEF offers a reliable framework to test and validate innovations. Activities can range from simulation and laboratory experimentation to trials in controlled facilities and experimental farms. This allows companies to progressively assess and refine their technologies, making research organizations particularly valuable partners in preparing innovations for market deployment. However, this experience has highlighted several challenges. Moving from a traditional research role to that of a service provider for industry requires significant adjustments. Companies expect clear added value, rapid engagement, and concrete results, which often challenges the timelines and procedures of research organizations. Another important shift for researchers is adopting a more client-oriented posture: instead of primarily proposing and promoting their own scientific ideas, they must first listen to the company's expectations and needs, and tailor the service accordingly. Our capacity to evaluate the real market for these services is also challenged as AgrifoodTEF framework introduces a structural bias. The targeted audience is relatively narrow, focusing mainly on SMEs developing AI and robotics solutions, and many do not directly pay for the services because the costs are covered through the project's funding mechanism. While this support greatly facilitates access to research infrastructures, it also makes it difficult to assess the actual demand and willingness to pay for such services outside the project context. To ensure the long-term sustainability of service activities within research institutions, it is essential to continue working on the specific value researchers bring to industrial partners. It is equally important to better understand the needs of different types of companies—start-ups, SMEs, and large enterprises—which may require distinct types of services, collaboration models, and financing mechanisms. AgrifoodTEF thus not only supports technological innovation but also provides valuable lessons on how research organizations can adapt to effectively engage with industry and support the deployment of new technologies in the agrifood sector.

Development of an interactive sensor system for recording animal activity for intelligent, group-specific optimization of the barn environment in pig farming

I. Hennig-Pauka[1], S. Retz[2], F. Lohkamp[3], L. Müter[1], A. Zuber[1], J. Schmidt-Moßig[4], S. Fischer[5], M. Ganster[5], S. Herter[5], C. Visscher[3]

[1] Stiftung Tierärztliche Hochschule Hannover, Außenstelle für Epidemiologie, Büscheler Str. 9, 49456 Bakum, Germany, [2] University of Vechta, Center for Sustainability Transformation Research in AgriFood Systems, Driverstraße 22, 49377 Vechta, Germany, [3] Stiftung Tierärztliche Hochschule Hannover, Institut für Tierernährung, Bischofsholer Damm 15, 30173 Hannover, Germany, [4] VetVise GmbH, Bünteweg 2, 30559 Hannover, Germany, [5] Fraunhofer IZFP, Campus E3 1, 66123 Saarbrücken, Germany

Modern pig farming is currently the focus of considerable public and political interest. There is a demand for the production of safe, high-quality food in conjunction with climate-friendly and resource-efficient production systems, while at the same time maintaining high animal welfare standards. At the same time, digitalization offers growing potential for livestock farmers through the management and bundling of data streams. Additionally, it also offers solutions to the growing demands in the upstream and downstream stages of the value chain. At the same time, the opportunities for pigs to express their natural exploratory behavior, which can be significantly improved to meet the needs of pigs, which are considered intelligent animals. The SmartPigHome project aimed to develop an interactive sensor system for pig farming to intervene in situations with agonistic behavior to reduce stress in pigs. Therefore, cameras and acoustic sensors should record animal activities and use this information to start an innovative "activity tool" on demand. The tool – consisting of buzzers, light and acoustic stimuli, and reward feeding – was designed to encourage natural exploratory behavior and to reduce aggressive behavior (e.g., tail biting). The core components were: optical recording of activity and lying behavior using 2D cameras and acoustic analysis to distinguish between positive and negative pig sounds – both signals serving as a trigger for an automatic intervention by sound and light scenes and a final reward feeding if a correct buzzer was used by a pig. Following preliminary studies on light colour preferences in pigs and the development and testing of SmartPigHome components on a laboratory scale with animals, a prototype of the interactive activity tool was tested under field conditions in a piggery with fattening pigs. Results: Acoustic and optical triggers were successfully combined to detect stressful situations. Initial tests showed that pigs can learn to use buzzers and that haptic stimuli in combination with feed proved to be particularly attractive. Challenges lay in the robustness of the hardware in the corrosive stable climate, variable lighting conditions, and the validation of the algorithms. Overall, the prototype of a SmartPigHome shows that a sensor- and AI-supported adaptive barn environment can be used under field conditions. Future developmental steps must lead to a reduction in system complexity and further optimization of technical components. The project "SmartPigHome" (28N602901) was funded by the German Federal Office for Agriculture and Food.

Automated detection of boar taint to enable sustainable pig production

L. Morgan[1], R. I. D. Birkler[1]
[1] PigO FoodTech, 71 Hagefen st., 7079500 Qidron, Israel

Pork is one of the most widely consumed animal proteins globally, with over 120 million tonnes produced annually worldwide in a market valued at around $300 billion. As demand for affordable, high-quality animal protein continues to grow, the pork industry faces increasing pressure to improve efficiency, sustainability, and animal welfare. One of the key challenges is the continued use of surgical castration of piglets to prevent boar taint, an unpleasant odour in cooked pork that occurs in a small percentage of entire male pigs. While raising entire male pigs is considered the most sustainable and welfare-friendly production system, the transition is limited by the lack of rapid and objective methods to identify tainted carcasses during slaughter. PigO FoodTech is a startup company, developing an automated solution for real-time classification of meat quality attributes, including boar taint, directly within industrial workflows. The system enables objective decision making at processing speed. With increasing regulatory pressure and rising expectations for animal welfare, the meat industry requires scalable tools for objective quality assessment. By enabling rapid detection and classification during processing, PigO FoodTech aims to support the transition toward more sustainable pig production while protecting product quality, operational efficiency, and consumer confidence.

From Compliance to Sustainable Continuous Improvement: Embedding AI-Enhanced Post-Mortem Assessment into a Structured Program to Advance Herd Health and Welfare in Pigs

M. Krieger[1], D. Rhen[2]
[1] Goldschmaus Group, Industriestraße 10-12, 49681 Garrel, Germany, [2] SLA Software Logistik Artland GmbH, Friedrichstraße 30, 49610 Quakenbrück, Germany

High-throughput slaughter inspection of pigs is primarily designed to ensure regulatory compliance, yet the large volume of routinely collected information also represents an underused resource for improving herd health and animal welfare. This contribution presents a co-innovation project between the Goldschmaus Group and SLA Software Logistik GmbH aimed at embedding AI-enhanced post-mortem assessment into a structured program for advancing herd health and animal welfare. The initiative forms part of the slaughterhouse's "Program for Animal Welfare and Animal Health," within which slaughter findings represent one important component of a broader set of advisory and improvement activities involving farmers, veterinarians, and regulatory authorities. Within this program, industrial AI-based computer vision systems were implemented directly in the slaughter process. These systems combine fully automated classification with assistant-supported assessment and structured image documentation. Nine standardized animal welfare indicators are collected per pig, such as ear condition, tail length, external injuries, and organ findings. This enables consistent collection of defined indicators for each animal and reduces the variability that can arise from high-frequency assessments, cognitively demanding examinations, and individual interpretations. The project was developed in close cooperation with the Veterinary Office of Cloppenburg and in dialogue with practicing veterinarians. Continuous image-based documentation enhances transparency, supports official inspection procedures, and provides a reliable basis for professional evaluation. Data generated within the slaughter process are aggregated and interpreted within the program's structured feedback processes, enabling earlier identification of recurring herd-level challenges and supporting targeted advisory discussions with farmers and herd veterinarians. As a result, advisory farm visits and veterinary consultations are increasingly guided by objective herd-level evidence rather than isolated findings. The implemented systems include automated welfare indicator detection as well as assistant-supported organ assessment, strengthening the linkage between slaughter findings and systematic herd health analysis by practicing veterinarians while also supporting veterinary inspectors in documenting and reviewing post-mortem findings under high-throughput conditions. This case illustrates how slaughterhouses can evolve into structured animal health partners within the livestock value chain. By harmonizing procedures and integrating AI-enhanced post-mortem assessment within advisory and regulatory collaboration, slaughter data can support targeted herd health interventions, reduce production losses, and contribute to more sustainable livestock production systems. The presentation will illustrate this approach using practical examples, showing how slaughter findings are translated into herd-level health management and targeted advisory interventions.

Fostering Data Sharing to Construct High-Quality Datasets: Unlocking AI Potential for Livestock Behavior Studies

M. Bonneau[1], C. Coupechoux[1], E. Desterbecq[1], F. Laperruque[2], T. Cochou[2]
[1] INRAE, ASSET, UR0143, 9170 Petit-Bourg, Guadeloupe, [2] INRAE, GENPHYSE, UMR1388, 31320 Castanet-Tolosan, France

Common CCTV cameras can be transformed into automated livestock monitoring systems using convolutional neural networks (CNNs). This has been demonstrated in numerous studies with applications for animal welfare, health, behavior, and, more generally, precision livestock farming. Most studies rely on common CNN architectures, such as YOLO, which are available as open-source tools. Although YOLO features a powerful architecture and has proven to be generic and robust, its accuracy is often too low—meaning animals are not detected properly—for many specific livestock applications. Consequently, these models often require re-training for each specific farm condition, which limits their widespread use in animal studies. To unlock the full potential of CNNs for livestock monitoring, it is necessary to rely on robust models specifically designed to operate in diverse farm environments.To achieve this goal, one approach is to construct a high-quality dataset combining images of animals across a wide variety of conditions. Indeed, the primary focus should be diversity: including as many breeds, camera types, angles of view, lighting conditions, backgrounds, and animal colors as possible. Combined with high-quality annotations, this could lead to a trained YOLO model that could be used across virtually all livestock applications with little to no fine-tuning. Interestingly, such datasets likely already exist within the numerous "proof-of-concept" studies developed by researchers over the last decade. What is currently lacking is a willingness to share data, the infrastructure to do so, and a shared definition of labels.As we enter the AI era, the key role of data has been underlined numerous times. The successful development of AI tools, particularly for livestock, depends on our ability to collaborate and construct datasets that can serve as benchmarks for training and comparing new methods. The LIB (Livestock Images Behavior) project was initiated to foster this dynamic by constructing a comprehensive dataset for livestock detection. It serves as an example of how collaborative work can help overcome common challenges in the field. We hope it will stimulate computer vision applications for livestock and serve as a foundation for generalizing practices such as data sharing, infrastructure development, and standardized label definitions.While the long-term success of the project remains to be seen, LIB has already successfully collected nearly 50,000 images associated with over 800,000 labels. Specifically, 20,011 images were collected for small ruminants (including sheep and goats), 20,924 for pigs, 6,433 for cattle, and 1,712 for chickens. These images were shared by multiple institutions, primarily across Europe. The project's impact could be further enhanced by involving more institutions during the initial design phase to improve visibility and encourage institutional incentive policies.All images were labeled manually by two full-time employees over one year, including the location (bounding box) of the animal's body and head, as well as their posture (standing, lying, or transitioning). Annotation quality was verified by re-labeling a random subset of images, yielding a precision of 99.7% and a recall of 98.6%. The dataset will be publicly released alongside pre-trained YOLO models for detection and segmentation. Furthermore, it will include an Ultralytics-based solution to facilitate the analysis of multiple videos for livestock behavior monitoring. Specifically, it can be used to measure inter-individual distances, zone occupancy, and heat maps, with results exportable to CSV files for direct use in behavioral analysis.

Digital animal welfare data in pig production: Collection practices, data-sharing patterns and determinants of farmers' willingness to provide data

C. Achilles[1], H. Grotsch[1,2], S. Lehde[1], A. Schütz[1], H. Schulze[2], M. Mergenthaler[3], S. Kühl[4]
[1] University of Göttingen, Marketing for Food and Agricultural Products, Platz der Göttinger Sieben 5, 37073 Göttingen, Germany, [2] University of Applied Sciences Kiel, Faculty of Agriculture, Grüner Kamp 11, 24783 Osterrönfeld, Germany, [3] South Westphalia University of Applied Sciences, Faculty of Agriculture, Lübecker Ring 2, 59494 Soest, Germany, [4] University of Applied Sciences Weihenstephan-Triesdorf, Agricultural Marketing, Markgrafenstr. 16, 91746 Weidenbach, Germany

Background Animal welfare has become a central concern in pig production with increasing demands for transparency from consumers, policymakers, and retailers. In response, digital documentation systems and precision livestock farming (PLF) technologies support data-based monitoring and reporting. However, their implementation depends on how animal welfare data are governed, shared, and perceived by farmers, while empirical evidence on farmers' perceptions and data-sharing intentions within PLF data ecosystems remains limited. Objectives This study investigates (1) how digital animal welfare data are collected and used on pig farms in Germany, (2) how farmers' willingness to provide such data, including perceived advantages and disadvantages, varies across potential data recipients, and (3) which factors drive or hinder data-sharing intentions within PLF-based data ecosystems. Methods From June to September 2024, an online survey of 103 German pig farmers was conducted within the "Transparency in Pig Production" project. Data were analysed using descriptive statistics, bivariate tests, and regression analysis based on validated constructs derived from an extended UTAUT model. Results Although animal welfare data are increasingly collected, digital evaluation and automation remain rare. The most strongly perceived advantages of providing digital animal welfare data are benchmarking opportunities, fewer on-farm inspections, and improved transparency, whereas key disadvantages relate to surveillance, loss of autonomy, and concerns about data security and privacy. Farmers' willingness to share data varies by the intended recipient, with low acceptance of data sharing with governmental institutions and higher acceptance for veterinarians and farm advisors, alongside a clear preference for anonymous and controlled data-sharing arrangements. Regression analysis reveals that positive attitudes towards digital animal welfare data and low technology-related anxiety are the strongest predictors of behavioural intention (to provide data), complemented by trust in data governance, attitudes towards animal welfare programs, and farm size (measured by number of fattening pigs). Notably, classic UTAUT constructs such as performance expectancy, effort expectancy, facilitating conditions, and social influence, as well as age and current animal welfare program participation, do not significantly influence farmers' willingness to provide such data. Discussion & Conclusion The findings show that the willingness to provide digital animal welfare data within PLF systems depends less on performance- and effort-related technology expectations and more on farmers´ trust in data governance arrangements and their perceived control over data sharing, indicating the need to shift PLF development from a technology-driven to a governance-oriented perspective. This underlines the importance of transparent data governance frameworks, robust data protection mechanisms, and clear rules on data access and control to enable trustworthy, interoperable, and widely accepted PLF data ecosystems that support responsible innovation in livestock production. These aspects have key implications for PLF adoption in European livestock production.

Building environment diagnostics in cattle farming in the Upper Rhine region

C. Eck[1], P. Massabie[2], S. Weidmann[1], J. Weller[1], L. M. Dale[3]
[1] Chambre d'agriculture Alsace, Espace européen de l'Entreprise 2 rue de Rome, 67300 Schiltigheim, France, [2] Institut de l'Elevage, 149 rue de Bercy, 75012 Paris, France, [3] Landesverband Baden-Württemberg für Leistungsprüfungen in der Tierzucht e. V., Heinrich-Baumann-Str. 1-3, 70190 Stuttgart, Germany

Climate change in the Upper Rhine region will manifest as a rise in average temperatures of between 1.5 and 3.0°C by 2050, as well as an increased frequency of heatwaves. These conditions directly affect the sustainability of cattle farming systems. High-yielding dairy cows are particularly sensitive to elevated temperatures. The Temperature Humidity Index (THI), which combines temperature (T) and relative humidity (RH), is commonly used as a warning tool. Another climate index such as the Heat Load Index (HLI) was developed. Although less widely used than the THI, it is calculated based on relative humidity, wind speed (WS), and the impact of solar radiation. Consequently, to improve animal welfare and support cattle farmers in their operations, the Chamber of Agriculture Alsace and the LKV Baden Württemberg, in collaboration with the IDELE, have decided to implement indoor climate diagnostics as part of the Upper Rhine Interreg project A1-9 “ResKuh.” The methodology used is the one previously developed by IDELE within the framework of the CLIMALAIT program conducted for the French Interprofessional Centre for the Dairy Economy (CNIEL). 10 farms were diagnosed during the summers of 2024 and 2025. Measurements are taken inside the building every 4 meters across both its length and width to create a complete grid of the space. The recorded data include T, RH, WS, and radiation levels obtained using a black globe thermometer. This data collection enables the mapping of the buildings, well as providing a representation of the THI and HLI within the livestock housing. The same measurements were taken outside at the beginning and end of the diagnostic process to establish an outdoor reference. Outside T and RH ranged respectively between 22.8 and 30.9 °C and 29 and 77 % and were an average 26.6 °C +/- 2.05 and 51.9% +/- 12.9. Inside T and RH ranged respectively between 21.9 and 31.1 °C and 30 and 81 % and were an average 26.2 °C +/- 2.18 and 55.2% +/- 12.2. The mean black globe T was 28.9 °C+/- 2.28, representing a 2.7 °C increase over the ambient T. The internal air velocity ranged between 0 and 1.68 m/s and was an average 0.52 m/s +/- 0.37. The average THI and HLI were 73.7 and 79.0 respectively, representing heat stress for the cows and a potential decreases in production. THI reached 79.0, corresponding to a high stress level. Regarding the HLI, the maximum observed value was 92.3, which is close to extreme stress. The standard deviation was 2.26 for the THI, compared to 6.34 for the HLI. This demonstrates that the HLI is a more suitable indicator for characterizing the heterogeneity of environmental conditions within a livestock building. The resulting maps allow the livestock advisor to identify the building’s strengths and weaknesses with the farmer to propose improvements: replacing materials, creating openings, or installing new equipment. This method supports farmers in adapting cattle farming to climate change and improves the resilience of this sector in the Upper Rhine region.

Why has progress stalled in reducing morbidity and mortality in dairy calves?

D. Renaud[1]
[1] *University of Guelph, 50 Stone Rd E, N1S2W1 Guelph, Canada*

Neonatal diarrhea and respiratory disease remain leading causes of morbidity, mortality, antimicrobial use, and economic loss in preweaned dairy calves. Despite decades of research identifying major risk factors, including inadequate passive immunity, suboptimal nutrition, and environmental stress, population-level reductions in disease have been inconsistent across production systems. This persistent gap between scientific knowledge and on-farm outcomes warrants critical examination. This presentation examines scientific and structural factors contributing to limited progress in neonatal calf health. Inconsistent disease definitions and outcome measures reduce comparability across studies, limit meaningful synthesis through meta-analysis, and obscure clear benchmarks for success. Greater standardization of disease definitions and outcomes is needed to improve interpretability and translation. Although pathogens initiate disease, control strategies often emphasize pathogen identification and antimicrobial treatment rather than strengthening host resilience and management conditions that prevent disease development. Furthermore, experimental studies frequently evaluate isolated interventions under controlled conditions, whereas commercial calf-rearing systems operate within complex biological, labor, and economic constraints that are rarely incorporated into study design. Substantial advances have been made in understanding passive immunity, nutrition, and environmental risk; however, neonatal morbidity and mortality remain largely unchanged because knowledge generation has outpaced knowledge translation. Research findings are frequently disseminated through scientific publications yet insufficiently integrated into practical, economically viable decision-making on farms. Bridging this gap requires deliberate incorporation of implementation science and qualitative approaches to better understand producer decision-making, along with stronger engagement of advisory networks such as veterinarians and nutritionists. Sustained reductions in neonatal morbidity and mortality will depend not only on further biological discovery, but on improving how evidence is defined, measured, and translated into consistent on-farm practice.

Impact of early dam–calf separation on serum ghrelin in dairy calves

N. Mejuto-Vázquez[1], C. López-Novo[1], S. Rojo-Montejo[1], M. Rico[1], R. Rodríguez-Bermúdez[1], F. Dieguez[1], R. Fouz[1]
[1] Universidade de Santiago de Compostela, Anatomía, Produción Animal e Ciencias Clínicas Veterinarias, Av. Carvalho Calero, s/n, 27002 Lugo, Spain

This study aimed to evaluate serum ghrelin concentrations in dairy calves managed under two different systems: (1) conventional separation from the dam immediately after birth and (2) dam–calf contact for at least 24 hours postpartum. We hypothesized that calves allowed early dam–calf contact would exhibit lower serum ghrelin concentrations than calves separated immediately after birth, reflecting improved satiety and reduced stress. We further hypothesized that these differences would persist during the first week after separation. Data were collected from eight Holstein dairy farms in Galicia, Spain. Serum samples were taken from 24 calves in the dam-calf contact system and 24 calves in the conventional system at three time points: just before separation (T1), two days after separation (T2), and seven days after separation (T3). Ghrelin concentrations were measured using a commercial ELISA kit, and statistical analyses were conducted using mixed linear models. Results revealed that calves allowed dam contact exhibited significantly lower ghrelin concentrations at all sampling times compared to those separated immediately after birth. These findings suggest that early maternal contact may reduce hunger-driven ghrelin secretion, likely due to improved satiety, reduced stress, and enhanced gut development. This study highlights the influence of early-life management on endocrine responses in dairy calves and supports the potential welfare and metabolic benefits of dam–calf contact systems. Further research is needed to explore the long-term impacts on calf development and production efficiency.

Early dynamics of immune, stress and redox biomarkers in serum and saliva of dairy calves with and without neonatal calf diarrhea

F. G. Silva[1,2,3], J. Cerón[4], L. E. Hernández-Castellano[5], M. González-Cabrera[5], C. Conceição[1], L. Pardo-Marín[4], A. Muñoz[4], J. Cerqueira[2,3], S. Silva[2], E. Lamy[1]

Neonatal calf diarrhea (NCD) is one of the most common causes of morbidity in dairy calves during the first weeks of life and represents a major welfare and economic concern for the dairy industry. Adequate colostrum intake is essential for the transfer of passive immunity and for the development of early immune competence, influencing physiological responses to disease during the neonatal period. While blood biomarkers have been widely studied in calves, information on salivary biomarkers in newborn animals remains scarce, despite saliva representing a promising non-invasive matrix for health monitoring. This study aimed to characterize the early dynamics of immune, stress, and redox biomarkers in serum and saliva of newborn dairy calves during the first week of life and to compare healthy animals with calves developing NCD. Paired blood and saliva samples were collected from 20 newborn dairy calves on days 0, 1, 2, and 7 after birth. Biomarkers related to innate immunity (myeloperoxidase and calprotectin), cellular immunity (adenosine deaminase; ADA), humoral immunity (IgG and IgA), gamma-glutamyl transferase (GGT), stress (α-amylase), and redox status (ferric reducing ability; FRA) were analysed. IgG and IgA concentrations were determined by ELISA while other biomarkers were measured using an automated chemistry analyser. Calves received 3.8 ± 0.64 L of colostrum within 96 ± 73 min after birth, and health status was monitored daily using an adapted Wisconsin calf health scoring system. All biomarkers were measurable from birth in both fluids. Innate and cellular immunity biomarkers were generally present at higher concentrations in saliva than in serum, whereas humoral, stress, and redox biomarkers were higher in serum. Following colostrum intake, increases were observed in saliva calprotectin, saliva and serum ADA, serum GGT, and both serum and saliva IgG and IgA concentrations, reflecting early immune activation and transfer of passive immunity. By day 7, nine calves showed signs of NCD, with the first clinical signs appearing from day 4. Calves with NCD showed higher serum myeloperoxidase (73.8 [33.6, 162.2] UI/L) and α-amylase (182 ± 14.2 UI/L) activities than healthy calves (20.5 [10.0, 41.7] and 115.0 ± 12.9 UI/L, respectively; $P < 0.05$). In saliva, calves with NCD tended to show higher GGT ($P = 0.09$) and FRA ($P = 0.059$) activities. These findings highlight the influence of colostrum intake on early biomarker dynamics and support saliva as a promising non-invasive matrix to monitor neonatal calf health. However, as clinical signs of NCD appeared between days 4 and 7 and biomarker measurements before disease onset were limited to day 2, further studies with higher sampling frequency during the first week of life are needed to better characterize biomarker changes preceding disease development. Funding: This work is funded by National Funds through FCT – Foundation for Science and Technology under the Project UID/05183/2025.

Maternal metabolic status during late gestation of dairy cows and its association with off-spring birth weight and growth.

T. Fokkema-Van Der Ploeg[1,2], J. Roelofs[1], J. Gross[3], W. Voskamp-Harkema[2], A. Van Knegsel[1]
[1] Wageningen University & Research, Adaptation Physiology Group, De Elst 1, 6708 WD Wageningen, Netherlands, [2] Van Hall Larenstein, University of Applied Sciences, Animal & Environment, Agora 1, 8934 CJ Leeuwarden, Netherlands, [3] University of Bern, Veterinary Physiology, Vetsuisse Faculty, Bremgartenstrasse 109a, 3001 Bern, Switzerland

Good care of calves on a dairy farm ensures that calves are healthy and grow up and develop well. Extensive knowledge is present how the farmer can manage calf health and development. Some knowledge exists on the relation between maternal physiological status and calf characteristics. For example, elevated non-esterified fatty acids (NEFA) in plasma of cows during late gestation have been associated with lower birth weight of the calf (Ling et al.,2018). It can be hypothesized that the metabolic status of dry cows is associated with offspring birth weight and postnatal growth. The aim of this study was to evaluate the relationships between metabolic characteristics of dairy cows during late-gestation and birth weight and growth of their offspring. This observational study was conducted on a Dutch dairy farm from February 2024 to June 2025. For the current study prepartum metabolic status of 173 Holstein Friesian cows was evaluated by measuring plasma non-esterified fatty acids (NEFA), β-hydroxybutyrate (BHB) and assessing body condition score (BCS, 1-5 scale) at 14 d and 7 d before expected calving date. Body weight of the calves was recorded at birth and weekly until 3 weeks of age, and postnatal growth was calculated as the average daily gain (g/d) between birth and 3 wks of age. Retrospectively, cows were classified into a low and a high class for each variable. For NEFA, cows were classified based on the median (0.15 mmol/L) into low NEFA (mean ± SD: 0.10 ± 0.02 mmol/L, n=86) and high NEFA (0.27 ± 0.15 mmol/L, n=87). For BHB, cows were classified based on the median (0.49 mmol/L) into low BHB (0.42 ± 0.06 mmol/L, n=86) and high BHB (0.59 ± 0.14 mol/L, n=87). For BCS, cows were classified based on the median (3.3) into low BCS (2.8 ± 0.29, n=81) and high BCS (3.6 ± 0.37, n=92). Body weight at birth and calf growth were analysed using a mixed model (PROC MIXED, SAS), with parity (1, 2, 3, or >3), calf breed (Holstein Friesian (HF) or Holstein Friesian × Belgian Blue cross (HFBB)), calf sex (male or female) and twin status (yes or no) and either NEFA, BHB, or BCS class (high or low) as fixed effects in three separate models. Birth weight of female calves born to cows with high NEFA was higher than that of female calves born to cows with low NEFA (40.9 kg vs 36.5 kg, $P<0.01$), while this relationship was not present in male calves. No differences in birth weight were observed among calves born to cows with different BHB or BCS classes. For all models, parity, calf breed, and calf sex ($P<0.05$) were related to birth weight. For the models with NEFA and BHB, twin status was also related to birth weight ($P<0.05$). Prepartum NEFA, BHB or BCS class were not related to offspring growth in the first 3 weeks. For all three models, an interaction between parity and calf sex ($P<0.05$) was present. In conclusion, maternal NEFA status during late gestation, but not BHB or BCS status, was associated with birth weight, and exclusively in female offspring. These findings contrast with those of Ling et al. (2018), which may be explained by differences in parity distribution in the study population or class cut-off values. In the current study maternal metabolic status was not related to growth of the calves till 3 weeks of age. Maternal metabolic status as a predictor of offspring birth weight may enable farmers and advisors to further optimise the care of both cow and calf.

Do dairy calves reared by foster cows benefit from the additional provision of milk from an automatic feeder?

M. Gurny[1], L. Wieczorreck[2], L. Gygax[2], E. Hillmann[2], U. Knierim[1]
[1] University of Kassel, Farm Animal Behavior and Husbandry, Nordbahnhofstraße 1a, 37213 Witzenhausen, Germany, [2] Humboldt University of Berlin, Animal Husbandry and Ethology, Unter den Linden 6, 10099 Berlin, Germany

In foster cow systems, cows typically nurse several foster calves (FC) in addition to their own calf (OC). Differences in cow-calf bonding may disadvantage foster calves in terms of growth and health. The aim of this study was to investigate whether providing supplementary milk via an automatic milk feeder (AMF) could mitigate this risk. We hypothesized that (1) FC would use the AMF more than OC, and (2) differences in growth and health between OC and FC would be less pronounced in groups with AMF access. On a large commercial dairy farm, two treatments (access to AMF versus control, CON) were compared, with one repetition (April–August 2025 and July–December 2025). Out of the 29 OC and 29 FC in total, 18 pairs of OC and FC control calves and 11 pairs of OC and FC AMF calves were monitored from birth to weaning. AMF calves were trained to use the AMF during the first two weeks of life. Milk allowance started at 1 L/day (weeks 1-2), increased to 4 L/day until week 6, and was reduced gradually from week 12 until weaned (week 20). Health indicators were assessed six times per calf as absent (0) or present (1) with respect to impaired vitality, poor hair and body condition, gastrointestinal and respiratory symptoms, and they were summed to a composite health impairment score (0-8). Concurrently, the calves were weighed to derive individual daily weight gains per suckling phase, as well as weaning weights. Individual milk intake and visit frequency at the AMF were recorded automatically. Linear mixed models were used to test effects of calf status (FC vs. OC), treatment (AMF vs. CON), suckling phase (beginning of rearing, middle of rearing, pre-, and post-weaning), and interactions. After training (beginning of rearing), all calves continued visiting the AMF, yet on average only on 26 ± 16 and 29 ± 9 days (FC and OC) from a maximum of about 130 days in total. The average total milk intake was substantially lower than expected and lower than the milk allowance (FC: 3.17 L, OC: 3.15 L from potentially about 380 L) (status: p=0.979). ADWG increased with age (phase: p= 0.025). At the beginning of rearing, ADWG was comparable within FC (AMF: 0.66 kg/day, CON: 0.65 kg/day) and OC (AMF: 0.81 kg/day, CON: 0.78 kg/day). At the middle of rearing, AMF calves had numerically higher weight gains (FC: 1.09 kg/day, OC: 1.23 kg/day) than control calves (FC: 1.00 kg/day, OC: 0.99 kg/day), yet, differences in ADWG were not statistically supported for status (p=0.734), nor treatment (p=0.752). Nevertheless, preliminary results show numerically higher weaning weights in AMF calves (FC: 175 kg, OC: 182 kg) compared to controls (FC: 155 kg, OC: 152 kg). However, there was high variance in weights within all groups, especially within control FC. Health impairment scores were not affected by calf status (p=0.956) or treatment (p=0.777), but at each suckling phase, half of the calves (median) showed clinical symptoms in at least two health indicators, in particular nasal and ocular discharge. Overall, AMF use was substantially lower than anticipated. Nevertheless, calves with access to an AMF had numerically higher weaning weights. There was no evidence for FC being disadvantaged in either treatment. In general, the need to improve health management became apparent. The reasons for the low AMF use should be further investigated, including taking a closer look at calf behavior.

Progressive delay of suckling opportunities: effect on weaning distress in a cow-calf contact system

R. Gillet[1,2], K. Barth[1]
[1] Johann Heinrich von Thünen Institute, Federal Research Institute for Rural Areas Forestry and Fisheries, Institute of Organic Farming, Trenthorst 32, 23847 Westerau, Germany, [2] Christian-Albrechts-University of Kiel, Institute of Agricultural Engineering, Max-Eyth-Straße 6, 24118 Kiel, Germany

In cow-calf contact (CCC) systems, human-induced weaning before the natural weaning age exposes calves to both physiological and social distress. In a calf-driven CCC system, in which suckling usually occurred after the partial separation due to morning and evening milking, we tested whether postponing suckling opportunities in weekly or daily steps could further alleviate distress at weaning. We hypothesized that postponing suckling opportunities daily would lead to fewer access-trial to enter the cow herd than postponing it weekly. Until the 9th week of age, calves were free to meet and to suckle their dams in the cow herd for 17 h d^{-1}. From the 10th week of age, the access time to the cow herd was postponed after morning milking by 35 min per day (Smooth, n = 10 calves) or weekly in 4-h steps (Gradual, n = 10 calves). Similarly, from the 12th week of age, the access time was postponed after evening milking. In the 14th week of age, calves were weaned and fence-line separated from their dams. Data were collected from the 9th until the 14th week of age. The time spent in the cow herd and the hourly count of calves' denied access to the cow herd were recorded daily. A statistical analysis was conducted using (generalized) linear mixed models. On a weekly basis, the time spent in the cow herd and the number of denied access to the cow herd did not differ between treatments. However, the distribution of denied accesses over time differed between treatments (3-way interaction between treatment, day and time, $P < 0.001$). On the first day that the access to the cow herd was postponed after morning milking, Gradual calves had more denied access compared with the seventh day after the initiation of the postponed access. This difference was noticeable for both the first and fourth hours following the end of the morning milking (odds ratios for the first hour of delay: 4.3, $P = 0.007$ and the fourth hour of delay: 2.3, $P = 0.011$). Among Smooth calves, during the first hour following the end of the morning milking, the number of denied accesses was similar between the first and the seventh day following the initiation of postponed access. However, during the fourth hour following the end of the morning milking, less denied accesses were recorded on the first day compared with the seventh day (odds ratio: 0.002, $P < 0.001$). In both treatments, the pattern of access-trial following the initiation of postponed access after evening milking was similar to that observed when the access was postponed after morning milking. The decline in the number of denied access over the days following the initiation of postponed access suggests that Gradual calves did not attempt to join the cow herd continuously and might have learned a new entry time. However, the number of denied access of Smooth calves increased during the later hours of delay over the days. Smooth calves might have continued attempting to access the cow herd until access was allowed. Because of the experimental design, Smooth calves must wait every day for a longer time before entering the cow herd and they might lack a consistent reference entry time. On a weekly basis, the absence of difference between treatments in the number of denied access to the cow herd indicates that postponing suckling opportunities with daily steps did not reduce the number of denied access to the cow herd when compared with weekly steps. To conclude, postponing suckling opportunities with daily steps did not further reduce calves' motivation to enter the cow herd during weaning.

Feasibility of using a mobile platform application for farmers to submit observations of Maternal Protective Behaviour in Cow-calf contact herds.

J. Johnsen, Føske[1], B. Heringstad[2], S. Kischel, Grønmo[3], R. T. Garmo[3], S. M. Stubsjøen[1]
[1] Norwegian Veterinary Institute, PO Box 64, 1431 Aas, Norway, [2] Geno SA, Storhamargata 44, 2317 Hamar, Norway, [3] TINE SA, Postbox 58, 1431 Aa, Norway

With the growing interest in cow-calf contact (CCC) systems in dairy production, novel methods to research on-farm CCC events are relevant. A mobile platform application may facilitate farmer self-reports of CCC-related variables but its feasibility (e.g validity) need to be tested. The objective of this experimental study was to evaluate the feasibility of using a mobile platform application for farmers to submit observations of Maternal Protective Behaviour (MBP). More specifically to study the proportion of cows calving in a herd during the study period for which MPB was scored and registered by the farmer. Since Norwegian farmers are already accustomed to the use of mobile platform applications to submit dairy herd relevant data, we hypothesized that the use of another application would be feasible for farmers. A cohort study was initiated with the following inclusion criteria for cohort farms: commercial dairy herd milk delivery to TINE Dairies, cow breed (Norwegian Red), main CCC system (dam-calf contact), milking cows in an automatic milking system (AMS), willingness to share data from the national dairy herd recording system and farmers having time to submit registrations. Ten farms were included in the study. For all cows calving within an 18-month study period, farmers were instructed to submit self-reported MBP assessed 0-48 hours after parturition by observation at two contexts: in the calving pen (undisturbed) and when the cow was fixated in the maternity pen for milking and the calf handled (fixated). To evaluate the feasibility of using a mobile platform application for farmers to submit observations of MPB, we divided the herd number of cows for which MPB was registered in the study period by the herds total number of calvings recorded in the National Dairy Herd Recording System during the same period. The mean (±SD) herd number of observations was 43 (25). One herd submitted zero registrations, and one herd submitted two registrations. Mean herd number of calvings per herd was 67 (21). The mean herd proportion of calvings for which MBP was registered in the mobile application was 67 (37) %, with two herds submitting 0 or only ≈ 2%. The feasibility of using a mobile platform application for farmers to submit observations of MBP appears high for most farms, but two farms submitted no or very few registrations despite receiving close follow-up. The feasibility of using the mobile platform application appears to be relatively high but also farmer-dependent. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW. Milk yield and composition changes in cows following short-term separation after one-week of cow-calf contact compared with early separated cows

J. Kurek[1], A. Kurek[1], J. Harms[3], E. Zeiler[2], J. Steinhoff-Wagner[1,4]
[1] Professorship of Animal Nutrition and Metabolism, TUM School of Life Sciences, Liesel-Beckmann-Str. 2, 85354 Freising-Weihenstephan, Germany, [2] University of Applied Sciences Weihenstephan-Triesdorf, Am Staudengarten 1, 85354 Freising-Weihenstephan, Germany, [3] Institute for Agricultural Engineering and Animal Husbandry, Prof.-Dürrwaechter-Platz 3, 85586 Poing-Grub, Germany, [4] HEF World Agricultural Systems Center, TUM School of Life Sciences, Liesel-Beckmann-Str. 2, 85354 Freising-Weihenstephan, Germany

Cow–calf contact provides benefits for calf development and welfare, but short or long-term separation often leads to alterations in cows performance and metabolic parameters. The aim of this study was to investigate the effects of separation after one-week cow-calf contact (CCC group) on milk yield and composition and to compare these outcomes with those of early-separated cows (ESG group). The study was conducted at the experimental farm Veitshof of the Technical University Munich in Freising-Weihenstephan. Twenty clinically healthy cows without dystocia were enrolled, blocked by parity, and randomly assigned to either the CCC group (n = 10) or the ESG group (n = 10). All cows received a partially mixed ration formulated to meet their nutritional requirements. In the ESG group, calves were separated within ≤ 2 hours (h) after birth and housed individually in calf igloos, while cows remained in the calving box for health monitoring before reintegration into the lactating herd, at the same postpartum (p.p.) time point as CCC cows (day 8 p.p.). Calves in the CCC group had unrestricted access to their dams except during twice-daily milking (< 1 h/day). Milk yield was recorded at each milking using a calibrated floor scale. Milk samples from days 4-10 p.p. were analyzed for dry matter and ash content, and for milk components. Fat, protein, lactose, urea, and pH were determined using a MilkoScan 7 RM (FOSS, Denmark), and somatic cell count was measured using a Fossomatic 7 (FOSS, Denmark). A linear mixed-effects model was applied with time, group, and the group × time interaction as fixed effects, and cow as a random intercept (~1 | cow). Across the first week, collected milk yield was higher in ESG cows than in CCC cows, with an average difference of 12.86 ± 1.04 L/day between days 1 and 7 p.p., converging only around days 9-10. Following separation on day 8, CCC cows displayed metabolic stress indicators, such as higher milk fat, an elevated fat-to-protein ratio, and increased milk urea, indicating a transient negative energy balance and short-term risk of ketosis. Lactose concentrations were lower in the CCC group until day 8, but increased thereafter to levels comparable to those of the ESG group. The somatic cell count remained largely comparable between groups, except for an isolated increase on day 7 in CCC cows. Overall, milk yield and composition patterns indicated that lower measured yields under pre-separation CCC conditions were attributable to milk removal by calves rather than reduced milk synthesis, and that targeted energy supply and stress mitigation following separation are critical for maintaining post-separation performance and cow health.

First-lactation milk yield and growth performance of dairy heifers reared with prolonged dam-calf contact

C. S. Wegner[1], H. K. Eriksson[1], A. Edvardsson Rasmussen[2], S. Agenäs[1], L. Rönnegård[3], S. Ferneborg[4]
[1] Swedish University of Agricultural Sciences, Department of Applied Animal Science and Welfare, Box 7024, 75007 Uppsala, Sweden, [2] Swedish University of Agricultural Sciences, Department of Clinical Sciences, Box 7054, 75007 Uppsala, Sweden, [3] Swedish University of Agricultural Sciences, Department of Animal Biosciences, Box 7023, 75007 Uppsala, Sweden, [4] Norwegian University of Life Sciences, Faculty of Biosciences, Box 5003, 1432 Ås, Norway

In artificially reared calves, greater preweaning growth has been associated with higher milk yield during the first lactation. Dairy calves that are instead reared with prolonged dam-calf contact demonstrate high growth rates during the preweaning period, likely due to consuming large volumes of milk. However, the long-term effects of dam rearing on later productive performance remain unclear. This study used a retrospective cohort study design to (1) explore milk yield of dam-reared heifers during their first lactation, and (2) evaluate the effects of preweaning management (artificial vs dam rearing) on average daily gain (ADG) before and after weaning. A total of 61 heifers reared with 3–6 months of dam-calf contact (dam-reared; DR) were matched 1:1 to artificially-reared heifers (AR; 221 candidates) using propensity scores. Only animals that had calved at least once were eligible for matching. Preweaning management differed between cohorts: DR heifers were raised with whole-day dam-calf contact across 5 experimental trials, whereas AR heifers were individually and/or group-housed and fed 6–9 L/d of whole milk until weaning at 2.5 months. After weaning, all heifers were managed the same way. Body weight data was used to calculate ADG during the pre- (birth to weaning) and postweaning (weaning to first insemination) periods. Linear mixed-effects models were run to test for differences in ADG between cohorts, while exploratory linear models were used to assess daily and 305-d energy-corrected milk yield (ECM; kg) as well as lactation persistency (Δ kg/d between 100 and 250 days in milk). Importantly, the study was underpowered for milk yield outcomes; however, the scarcity of long-term research justifies exploratory analyses. Results showed that DR heifers grew at higher rates until weaning (1.3 vs 0.9 kg/d for AR heifers; $P < 0.001$) but experienced growth checks during the subsequent 2 weeks, which were not observed in the AR cohort. During the postweaning period, this pattern was reversed (DR: 0.8 kg/d, AR: 0.9 kg/d; $P = 0.005$), although DR heifers were numerically heavier both at first insemination and immediately after first calving. Differences in milk yield were also evident, with DR primiparous cows showing lower 305-d ECM yield ([estimated marginal mean] DR: 8957 kg, AR: 9455 kg; 95% CI for DR: −987 to −8 kg), daily ECM yield (DR: 29.8 kg/d, AR: 31.7 kg/d; 95% CI: −3.6 to −0.1 kg/d) and persistency (DR: −0.033 kg/d, AR: −0.014 kg/d; 95% CI: −0.035 to −0.005 kg/d). Quartile-level analyses revealed that 305-d yield was numerically similar among the 25% highest-yielding cows within each cohort (mean [SD]; DR: 10789 [694] kg, AR: 10870 [708] kg), whereas differences increased progressively toward the bottom quartile interval (25% lowest; DR: 6620 [661] kg, AR: 8033 [730] kg). Interestingly, 9 of the 13 lowest-yielding DR cows were reared within the same experimental trial. While this study provides preliminary evidence of potential milk yield losses associated with prolonged dam-calf contact (i.e., 3–6 months), at least in some animals, further longitudinal research is needed to evaluate how different dam-rearing management strategies influence later productive performance.

Two paths to one estimate: Cow- and calf-derived methods to quantify milk production in full cow-calf contact systems

C. L. Van Zyl[1,2], A. T. M. Van Knegsel[1], S. Agenäs[3,4], E. A. M. Bokkers[2]

Dairy cows in full cow-calf contact systems can nurse their calves and perform maternal behaviours throughout the day. However, quantifying total daily milk production of suckled cows is challenging, as machine-recorded milk yield excludes the milk consumed by the calf. We aimed to determine total daily milk production of dairy cows with full cow-calf contact during the suckling period, using two methods based on cow and calf performance data. Dairy cows at the Swedish Livestock Research Centre either had full contact (FC, n = 18) with their 19 calves until gradual fence-line weaning at 13.0 ± 1.1 wk of age, or were conventionally managed with no contact (NC, n = 20) with their 22 calves beyond 13.5 h after birth. Individual daily milk yield to the automatic milking unit and cow roughage and concentrate intake were recorded throughout. Daily milk production of the cows during the FC suckling period was estimated from recorded milk yield and cow energy intake data (Method 1) or from recorded milk yield and calf performance data (Method 2). Method 1: Individual milk production was calculated as the product of daily energy intake during suckling and the median ratio of recorded milk yield to previous-day energy intake from the 8-wk post-suckling period. Recorded milk yield and estimated milk production of all cows were analysed with linear mixed models. Estimated FC milk production averaged 35.3 ± 1.40 kg/d during the suckling period, first 12 wk of lactation, while their recorded machine milk yield averaged 24.7 ± 1.60 kg/d. Estimated NC milk production averaged 33.3 ± 1.40 kg/d (not different from FC; P = 0.29) during the first 12 wk of lactation, while their recorded machine milk yield averaged 37.7 ± 1.40 kg/d (greater than FC; P < 0.001). This discrepancy between recorded and estimated milk yield of NC cows may reflect unaccounted negative energy balance likely experienced. Method 2: Individual milk production was calculated as the sum of daily recorded milk yield and estimated calf milk consumption. Calf milk consumption was estimated by subtracting concentrate-derived energy from total energy requirements of the calves for maintenance and growth, subsequently dividing this residual energy by the calculated milk energy content. Estimated FC cow milk production and recorded NC milk yield were analysed with a linear mixed model. Average FC calf milk consumption during the suckling period was estimated at 14.9 ± 2.9 kg/d, whereby FC cow milk production was estimated at 37.9 ± 1.80 kg/d during the suckling period of the first 12 wk of lactation (not different from NC recorded yield; P ≥ 0.59). In conclusion, using energy intake and milk yield during the non-suckling period underestimated milk production of FC cows during the suckling period. In contrast, estimated milk production of suckled FC cows, based on their calves' estimated milk consumption, did not differ from milk production of NC cows based on recorded machine milk yield. Although calf milk consumption could not be measured directly, the evaluated methods for estimating total milk production of suckled cows and calf milk consumption can be applied in economic and environmental sustainability analyses of cow-calf contact systems.

Long-term calf nursing compared to conventional milking affects milk yield and milk fat content after calf weaning

S. Drendel[1], L. Wieczorreck[1], M. Gurny[1,2], U. Knierim[2], L. Gygax[1], E. Hillmann[1]
[1] Humboldt Universität zu Berlin, Animal Husbandry and Ethology, Lentzeallee 75, 14195 Berlin, Germany,
[2] University of Kassel, Farm Animal Behaviour and Husbandry, Nordbahnhofstraße 1a, 37216 Witzenhausen, Germany

The separation of cows and calves in dairy production is increasingly criticized due to animal welfare concerns. Alternative systems allowing prolonged cow-calf contact are gaining interest, yet previous studies have yielded inconsistent results regarding milk yield and composition. Since dam-calf contact often leads to milk ejection issues during milking, foster cow systems might serve as a compromise between the animals´ and farmers´ needs. After calf weaning, we investigated the differences in milk yield and milk composition between cows that had nursed 3-4 calves for 9- 16 weeks, and cows that had been separated from their calf within 24 h post partum and milked twice daily afterwards. We expected former foster cows to exhibit milk ejection problems after being introduced to the milking herd on the short-term, but to show a similar milk yield and composition after habituation to being milked. On a large dairy farm, a total of 21 foster and 21 conventionally milked cows were matched according to breed, parity, age, and calving date. Data collection included performance parameters (milk yield, fat content) from the regular monthly milk recordings throughout the milking period after calf weaning until 400 DIM. 10 cows left the herd due to illness during data collection and were not present until the end. After weaning, all cows were housed in cubicle stalls. The effect of cow status (foster or milked), days in milk (DIM), and its square, along with their interactions on milk yield and fat content were analyzed using linear mixed models. The animal identity nested within the pair, was included as random effect. After separation from the calves (DIM 60-134), former foster cows started with a lower milk yield than conventionally milked cows, but the two groups converged over the course of lactation (status × DIM: p=0,001), and we found only slight differences for total yield after calf weaning (foster = 28.3 kg/day, milked = 29.3 kg/day, p=0.24). Former foster cows showed a slight increase in fat content toward the end of lactation. However, this difference could not be statistically supported (status x DIM: p=0.26, status x DIM^2: p=0.13). The lower milk yield in foster cows after separation from the calves was likely attributed to either a lower milk production during the suckling period or to a reduced oxytocin release during milking, resulting in impaired milk ejection. Milk ejection problems may lead to incomplete emptying of the udder, resulting in an increased amount of residual milk. This could increase the risk for mastitis, which needs to be investigated in CCC systems. We had expected fat content to be reduced in foster cows due to impaired milk ejection, but this was not the case. Altogether, cows that had nursed their own and 2-3 foster calves over a period of several weeks were found to show only a temporarily reduced milk yield and no difference in milk fat content in the milking parlour compared to conventionally milked cows on the same farm.

Effect of cow-calf contact on milk yield and milk flow in an automatic milking system before, during and after separation from the calf

S. Almlöf[1], S. Ferneborg[2], S. Agenäs[1]
[1] Swedish University of Agricultural Sciences, Applied Animal Science and Welfare, P. O. Box 7024, 750 07 Uppsala, Sweden, [2] Norwegian University of Life Sciences, Faculty of Biosciences, Christian Magnus Falsensvei 30, 1433 Ås, Norway

Interest in cow-calf contact (CCC) dairy systems is increasing. One of the main challenges is lower yield of saleable milk both during and after separation from the calf. This is particularly problematic for farms that do not sell their milk with added value. It is important to clarify the mechanisms behind the lower milk yield and the aim of this study was to increase the understanding of links between milking characteristics and milk yield. A total of 38 cows (26 Swedish Red, 12 Swedish Holstein) calving in October and November 2023 were blocked according to breed and calving date and assigned to Conventional (CONV) or CCC dairy management in a voluntary milking system (DeLaval VMS, DeLaval International AB, Tumba, Sweden). CONV and CCC cows were housed in the same VMS, but CCC had access to a calf contact area that was unavailable for CONV cows. CCC cows could access the contact area at any time of the day and stay as long as they wanted for the first 85±16 days of the lactation (phase 1). After that a fence-line weaning protocol was applied, that allowed cows and calves to touch each other and also allowed stepwise decreased opportunity to suckle through a gate for two weeks (phase 2), until they were completely separated (phase 3). Udder quarter level data on peak and average milk flow (ml/min) and milk yield per milking and per day was extracted from the DelPro system (DeLaval International AB, Tumba, Sweden) for four days during each phase. Data is shown as mean ± SD or as coefficient of variation (CV) in percent. Daily milk yield in CONV was 41±12, 39±11 and 40±10 l/day in phase 1, 2 and 3. Milk volume extracted when milking the CCC cows was 26±13, 35±12 and 37±12 l/day during the same period, indicating that total milk yield most likely was not higher in CCC cows during the contact time, or that total milk yield decreased when suckling stopped. Difficulties with milk ejection during machine milking have been proposed as a potential reason for lower milk yield post separation in CCC cows, but the data reported here does not support that suggestion. Average quarter level milk flow in CONV cows was 1058±287, 1072±280 and 1072±291 ml/min during phase 1, 2 and 3 while it increased in CCC cows from 1073±378 to 1134±304 and 1215±364 ml/min. Peak flows were 1503±349, 1514±338 and 1520±361 in CONV and 1546±468, 1612±369 and 1697±439 in CCC cows, which indicates higher, and gradually increasing, peak flows in CCC cows. Variation was larger for both peak and average flow in CCC (CV 27 and 31% for peak and average flow) than in CONV cows (CV 23 vs 27% for peak and average flow), particularly in phase 1 (peak flow: 23 vs. 31% and average flow: 27 vs 35% for CONV vs CCC). If the individual variation in milk flow is constant across CCC lactations, it opens up for selective breeding favoring cows that have the ability to eject milk to the milking machine in parallel with interacting with calves in CCC systems.

Evaluation of bioactive core based on plant extracts to support neonatal calves diarrhea

L. Mourlhou[1], M. Rumeau[1], P. Gautier[1], L. Le Corre[1], V. Courtois[1], A. Juanchich[1], E. Coudert[1]
[1] Centre Mondial de l'Innovation Roullier, 18 Avenue Franklin Roosevelt, 35400 Saint-Malo, France

Neonatal calves diarrhea is a major issue in livestock farming, with early-life infections causing long-term impacts on health and growth. During the vulnerability period, when calves shift from colostrum-derived passive immunity to their own active immunity, the gut barrier remains immature, prone to oxidative stress, and highly sensitive to enteropathogenic bacteria (e.g., Escherichia coli, Salmonella spp., Clostridium perfringens). This study focused on early gut health, by investigating the effects of different plant extracts (PE) for inclusion in a milk-dispersible formulation designed to support calves health through their antioxidant properties and their ability to limit the growth of diarrheagenic bacteria. Six PE including ceylan cinnamon (CEY); guava (GUA); clove (CLO); chestnut tannin (CHE); oregano (ORE); and thyme (THY) were included in this project. First step was to test PE in vitro against 6 pathogens involved in calves diarrhea (E. coli, S. typhimurium, S. dublin, Y. enterocolitica, C. jejuni and C. perfringens), using a spot assay, at two different concentrations (1 g/L and 5 g/L). For each pathogen, control (no PE) and copper sulfate negative control were included and all conditions were tested in triplicate. Second step was to evaluate every PE antioxidant capacity using 3 complementary colorimetric methods (ABTS, DPPH and FRAP). Based on those primary results, the most relevant PE were combined. Three associations were developed, and the same protocol of microbiology was performed (the same 6 major pathogens tested) to confirm final in vitro effects. Microbial data were analyzed using two-way ANOVA (PE, concentrations), whereas antioxidant measurements were analyzed using one-way ANOVA after log10 transformation to correct skewness and heteroscedasticity, followed by Tukey's post-hoc test using R software. First spot assay on the 6 PE showed that 4 of them (CEY, CHE, CLO and GUA) had significant inhibition rate on at least 3 pathogens ($p < 0.05$). We observed a complete inhibition of S. typhimurium growth with CEY; CLO and CHE; of Y. enterocolitica with CHE and of C. jejuni with CEY; CLO; GUA and CHE. Across the 3 antioxidant assays, CHE showed antioxidant activity 2 to 10 times greater than all other PE, with all differences being significant ($p < 0.01$). These primary results led to three combinations formulated around one major PE: CHE-based; GUA-based and CEY-based formulas. Antimicrobial properties tested on the three associations showed that at the highest concentration, all of them had significant inhibition effect on the same 3 pathogens (S. typhimurium; C. jejuni; C. perfringens). At the lowest concentration, only CHE-based formulation had significant inhibition activity on 2 pathogens (S. typhimurium and C. jejuni). The in vitro trials showed that the CHE-based combination had significant effect on the antioxidant capacities and antimicrobial properties, which are main risks factor of diarrhea. This promising formula is going to be tested on meat and dairy farms, diluted in whole milk to investigate the in vivo efficiency on diarrhea criteria (occurrence, severity, duration) while maintaining optimal milk consumption and growth performances.

Alterations in milk composition and fatty acid profiles as indicators of subclinical and clinical mastitis in Holstein cows

M. Stolcova[1], L. Barton[1], E. Kasna[2]
[1] Institute of Animal Science, Cattle Breeding, Pratelstvi 815, 104 00 Prague 10 Uhrineves, Czech Republic, [2] Institute of Animal Science, Genetics and Breeding of Farm Animals, Pratelstvi 815, 104 00 Prague 10 Uhrineves, Czech Republic

Mastitis remains one of the most significant challenges for animal welfare, while early detection of subclinical mastitis (SCM) is crucial for minimizing production losses. The inflammatory process leads to the impairment of the blood-milk barrier integrity and a subsequent suppression of the secretory activity of mammary epithelial cells. This study aimed to evaluate changes in lactose, citric acid, and milk fatty acid profiles in Holstein cows in relation to their SCM and clinical mastitis (CM) status. A robust dataset of 11,757 milk performance recordings (4 herds, 5–305 days in milk) was analysed, where SCM was defined as a somatic cell count (SCC) > 200,000 cells/mL of milk and CM was identified based on veterinary diagnosis. Statistical analyses were performed using the SAS package (ver. 9.4). The data were analysed using a generalized linear model to compare least squares means, with the effects of herd, year, season, test-day order, breed, and parity being taken into account. Results showed a prevalence of 22% for SCM and 6% for CM. In comparison with healthy individuals, SCM cows exhibited significantly lower lactose (4.83% vs. 4.95%, respectively; $P < 0.001$) and citric acid levels (6.42 mmol/L vs. 6.53 mmol/L, respectively; $P < 0.01$). A moderate negative relationship was demonstrated between the lactose content and the somatic cell score ($r = -0.40$). The reduction in lactose and citrate levels in SCM cows reflects the impaired secretory activity of lactocytes and increased permeability of paracellular pathways. Regarding the fatty acid profile, SCM resulted in a significant inhibition of de novo synthesis. This was evidenced by the lower proportions of short-chain fatty acids and C14:0 in SCM cows compared to those in healthy cows (12.44 vs. 12.78 g/100 g of milk fat and 10.271 vs. 10.45 g/100 g of milk fat, respectively; $P < 0.001$). Conversely, an increase in preformed fatty acids was observed in SCM cows, particularly C18:1 (28.25 vs. 27.91 g/100 g of milk fat; $P = 0.001$) and C18:0 (8.46 vs. 8.39 g/100 g of milk fat, respectively; $P < 0.001$). These findings support the hypothesis of disrupted lipid metabolism in the early stages of inflammation. Reduced de novo fatty acid synthesis is an indicator of the inflammatory process before clinical signs become apparent. As was the case with SCM cows, lower levels of lactose were found in CM cows compared to healthy cows ($P < 0.001$), while the difference in citrate was not significant. In conclusion, these metabolism-induced shifts in milk represent sensitive biomarkers of impaired udder functional integrity, offering potential for automated on-farm health monitoring systems. The study was funded by the Ministry of Agriculture of the Czech Republic (NAZV QL24020269).

Relationships between feeding behaviour and milk fatty acid profiles in lameness-affected Holstein cows

L. Barton[1], M. Stolcova[1], E. Kasna[2]
[1] Institute of Animal Science, Cattle Breeding, Pratelstvi 815, 104 00 Prague 10 Uhrineves, Czech Republic, [2] Institute of Animal Science, Genetics and Breeding of Farm Animals, Pratelstvi 815, 104 00 Prague 10 Uhrineves, Czech Republic

Lameness is one of the most prevalent health problems on dairy farms, with a significant impact on both animal welfare and farm economics. It is widely acknowledged that early identification of affected animals is essential to minimize production losses. The objective of this study was to quantify alterations in feeding behaviour and detailed milk composition associated with lameness in Holstein cows. The investigation utilised a robust dataset, which comprised 9,134 records. The animals were categorised as either healthy or diseased based on clinical diagnoses made during the month of milk recording. Milk composition and fatty acid profile analysis were performed via mid-infrared (MIR) spectroscopy exclusively on samples collected during afternoon milking. Statistical analyses were performed using the SAS package (ver. 9.4). The data were analysed using a generalized linear model to compare least squares means , with the effects of herd, year, season, test-day order, breed, and parity being taken into account. The results demonstrated that lameness-affected cows exhibited a highly significant deficit in feeding behaviour compared to healthy individuals, characterised by a reduction in daily feeding time of 44 minutes (295 vs. 340 min, respectively; $P < 0.001$). In contrast, the analysis of rumination time showed only a marginal decease of mere 8 minutes (447 vs. 455 min, respectively; $P < 0.05$), indicating that the assessment of time spent at the feeder is a more sensitive indicator of discomfort associated with painful standing. This behavioural shift resulted in a significant drop in afternoon milk yield by 0.7 kg (15.61 vs. 16.32 kg, respectively; $P < 0.001$). Detailed analysis of the milk fatty acid profile revealed a specific metabolic response to reduced nutrient intake and stress. The proportion of preformed fatty acids was found to increase significantly in the diseased compared to healthy cows, particularly C18:1 (28.61 vs. 27.31 g/100 g of milk fat, respectively; $P < 0.001$) and C18:0 (8.83 vs. 8.48 g/100 g of milk fat, respectively; $P < 0.001$), indicating mobilization of body reserves. Conversely, a significant decrease was observed in medium-chain fatty acids, specifically C14:0 (10.05 vs. 10.51 g/100 g of milk fat, respectively; $P < 0.001$) and C16:0 (26.45 vs. 27.26 g/100 g of milk fat, respectively; $P < 0.001$), while the proportion of short-chain fatty acids remained unaffected. The milk lactose content demonstrated notable stability (4.91 vs. 4.92%, respectively; $P = 0.09$), confirming that the observed changes in milk fat composition are a consequence of energy deficit and behavioural adaptation rather than disruption of the mammary secretory epithelium. The integration of sensor-derived behavioural data with MIR-based milk profiling has been identified as a potential tool for precision health management in commercial dairy herds. The study was funded by the Ministry of Agriculture of the Czech Republic (NAZV QL24020269).

Mucin distribution and remodelling along the bovine gut-lung axis during respiratory infection

G. Derolez[1,2,3], M. Criado[4], T. Peyret[1], F. Mompart[1], D. Bars-Cortina[1], M. Silva[5], C. Schnee[4], G. Pot[1], H. Robert[1], M. Monié--Ibanes[1], A. Poujade[1], E. Richard[3], G. Meyer[1], M. Ducatez[1], J. Benavides[5], N. Gaide[1], N. Mach[1]
[1] ENVT, IHAP, 23 chemin des cappelles, 31300 Toulouse, France, [2] Université de Caen, UFR Santé, 2 rue des rochambelles, 14032 Caen, France, [3] LABEO, BIOTARGEN, 1 route de rosel, 14280 Saint-Contest, France, [4] Friedrich-Loeffler-Institute, FLI, Südufer 10, 17493 Greifswald, Germany, [5] Instituto de Ganaderia de Montana (CSIC-ULE), CSIC, Grulleros, 24346 Leon, Spain

Mucins are a critical component of mucosal defence, yet their distribution and responsiveness to respiratory pathogens remain poorly characterized in calves. To address this gap, we examined 28 animals, half experimentally infected with Mycoplasma bovis, influenza D virus, and bovine coronavirus, and monitored them until necropsy at 21 days post-infection. Combined Alcian Blue (AB) and Periodic Acid-Schiff (PAS) staining was used to quantify acidic and neutral mucins along the respiratory and digestive tracts, and to correlate these patterns with pathogen burden and lesion severity. Mucin architecture showed pronounced anatomical segregation: the large intestine displayed a dense, acidic, mucin-rich barrier, whereas respiratory lower tract exhibited uniformly sparse, low mucin coverage. Despite clear evidence of infection and associated pulmonary lesions, lung mucin abundance showed minimal remodelling and did not correlate with pathogen load, except for a modest negative association between neutral mucins and M. bovis in the caudal lobe. In contrast, the histological surface of intestinal neutral mucins increased in parallel with respiratory pathogen burden, revealing divergent, organ-specific mucin–pathogen relationships along the gut–lung axis. Together, these findings suggest that mucins in young calves' function as relatively static structural features in the lungs but as more dynamic components of the intestinal barrier. This histopathological characterization will guide upcoming immunohistochemical and RNA-based analyses targeting specific mucins to clarify their roles in mucosal defence and their potential relevance to bovine respiratory disease.

Impact of postnatal drying management and ambient temperature on microbial colonization in neonatal calves

S. Mochkina[1], T. M. Liegsalz[1], C. S. Ostendorf[1], J. Steinhoff-Wagner[1]
[1] TUM School of Life Sciences, Liesel-Beckmann Str. 2, 85354 Freising-Weihenstephan, Germany

Evaporation of amniotic fluid exposes newborn calves to a cooling effect and may influence calves' lying time after birth, attempts to stand up, colostrum intake and thus affect energy status, passive immune system and first contact with pathogenic microorganisms. Licking by the cow may stimulate the calf´s vitality and accelerate drying. A dry hair coat forms a protective barrier against both cold and pathogens. The aim of this study was to investigate the effects of different drying methods in early separated dairy calves on the microbial colonization of the calf´s hair coat, with particular consideration of the drying process, rectal temperature and climate conditions. Newborn Brown Swiss calves (n = 16) were randomly assigned to one of three drying treatments: one hour maternal licking (ML), rubbing with straw (SR), and covering with a waterproof calf blanket without prior drying (BC). Sampling and data recording were conducted four times: immediately after birth (0h) and at one, four, and twelve hours postpartum. Additionally, at each sampling time, the drying level of different body regions (head, peripheral ear, neck, nape, shoulder, back, belly, foreleg, hind leg, hip, loin, tail) was scored (4: dripping wet; 3: like a wrung out towel; 2: slightly damp; 1: completely dry), and rectal temperature, body surface temperature, relative humidity and ambient temperature in the calving area were recorded. Calf vitality, health status, and the calving conditions were also documented. Microbial surface samples per calf were collected using a standardized sampling technique with a sterile cotton glove, which was transferred to a sterile saline solution. Microbiological analysis was performed by culturing total bacterial count (TBC), Enterobacteriaceae, Coliforms, Lactobacilli, and Staphylococci. All calves dried over time ($p<0.05$). Except for rapidly drying areas, significant differences in drying level were observed between the treatment groups, whereby body regions covered by a blanket remaining wet for longer compared to the same regions of calves dried with straw or by maternal licking. At the belly and hind limb, calves that were licked by the dam were drier than those in SR ($p<0.05$). The temperature humidity index (THI) showed an influence only on the peripheral ear and highly mobile (neck, belly, lateral hindquarter) body regions ($P<0.05$). Rectal temperature as well as body surface temperature did not differ between treatments but were influenced by sampling time, ambient temperature and THI ($P<0.05$). Bacterial colonization at birth was mainly influenced by dystocia and associated human handling of the calf ($P<0.05$). The drying method had hardly any effect on bacterial quantities, however Enterobacteriaceae, coliform bacteria, and lactobacilli changed over time ($p<0.05$). In ML calves, Enterobacteriaceae and Coliforms decreased over time, whereas they remained relatively constant in calves dried with straw or covered with a blanket. TBC and Staphylococci decreased significantly with increasing THI. Waterproof blankets impede the evaporation of amniotic fluid and may lead to prolonged wetness and increased potential for delayed cold stress. Additionally, the hair coat dries in a flattened position, which may impair its insulating function. It seems important to dry calves before applying a calf blanket. Microbial results point to the importance of hygiene during calving.

Breeding broilers against growth-related 'defects' – lessons from the past to the future

A. Cahaner[1]
[1] *Hebrew University, Faculty of Agriculture, Hertzel St., 7610001 Rehovot, Israel*

Since the 1940s, higher growth rate, being essential for efficient meat production, has been the main objective of the commercial broiler breeding programs. Due to its high heritability and ease of phenotyping, breeding for more rapid growth has been very successful, with broilers growing faster every year, continuously reaching higher body weights at earlier ages. Consequently, over the years several growth-related 'defects' have emerged, most notably (1) excessive fat deposition, (2) leg problems, and (3) ascites. Due to their association with elevated growth rate, initially each defect was considered a biological limit to selection for further higher growth rate, and therefore growth-reducing diets had been suggested to mitigate these defects, at the cost of lower overall efficiency of production. However, our experimental-selection studies, conducted since 1980, showed that the tendencies to develop these defects, although quite heritable, have been genetically independent of growth rate. Thus, identification of the genotypes prone to develop each defect facilitated selection against them while continuing successful selection for more rapid growth rate, and for other important traits (meat yield, feed efficiency, etc.). In recent years, new defects, breast muscle myopathies, have emerged: White Striping (WS, in 2007), Wooden Breast (WB, 2011), and Spaghetti Meat (SM, 2015). As with the earlier growth-related defects, the use of growth-reducing management (lower-density diets) and slow-growing breeds have been suggested to reduce the prevalence and severity (P&S) of the breast muscle myopathies, while breeding companies have amended their programs with selection against them. Indeed, WS had gone and WB is currently found only among males reared rapidly to high BW (>3.5 kg). The P&S of SM have not been declining yet, apparently due to later emergence and to different biological nature. Whereas the P&S of WB clearly increase with higher body weight and breast yield and therefore rarely found in females, the P&S of SM are higher in females than in males, and within-sex they are lowly associated with BW and breast size. Moreover, the phenotyping of SM is very difficult because this myopathy cannot be measured or assessed on live broilers, and the levels of SM observed in processed carcasses reflect the impacts of the defeathering machines, which vary considerably between days, and even between hours in a day, within each processing plant. The positive side of these effect – it is suggested that aggressive defeathering can be used as a tool to better phenotype the levels of the inherent tendency of broilers to develop SM. These phenotypic values, if heritable, are expected to lead to a successful genetic reduction in the P&S of SM. The continuous genetic elevation in growth rate and BW of broilers has been accompanied also with higher levels of internal heat. Hot ambience hinders the dissipation of this excessive heat, forcing broilers from fast-growing stocks to minimize feed intake and consequently reduce actual growth and efficiency. The susceptibility of broilers to high ambient temperatures, which increases as their daily feed intake and body weight gain increase, is a basic biological phenomenon observed in all broilers of similar growth rate and body weight. Therefore the heat susceptibility should not be considered as a heritable 'defect' independent of growth rate. Currently, the losses due to high ambient temperatures are successfully avoided (or at least reduced) by sophisticated cooling of commercial broiler houses. However, due to the high costs of artificial cooling systems and the energy they use, genetic mitigation by reducing or elimination feather coverage is suggested as sustainable future mitigation.

Genome engineering approaches to address male chick culling and broiler reproductive constraints

E. Ben-Tal Cohen[1], O. Genin[1,3], M. Pfann[1,2], M. Mimon[1], I. Cohen[1,2], T. Kushnir[1], A. Haron[1], D. Shinder[1,3], S. Dharanivasan[1], C. Avitan[1], E. Lamed[3], C. Tepe[3], E. Hershkowitz[3], S. Druyan[1], Y. Cinnamon[1]

Smith Faculty of Agriculture, Food and Environment, Herzel, 7610001 Rehovot, Israel, [3] NextHen, HaYarkon 5a, 5120123 Bnei Brak, Israel

Over decades of intensive genetic selection, poultry breeding has produced two highly specialized systems: layers optimized for egg production and broilers for rapid growth and meat yield. These advances made poultry one of the most efficient animal production systems worldwide, but also created biological, welfare, and economic challenges. In the egg industry, male chicks are no longer suitable for meat production, and approximately 7 billion are culled globally each year. In broiler production, selection for rapid growth has introduced physiological constraints on reproduction, requiring intensive management with welfare and economic consequences. To address these challenges, in collaboration with NextHen, we developed a genetic engineering platform enabling precise manipulation of the chicken genome and generation of transgenic lines. Using this platform, we initiated two projects to provide practical solutions. Despite different challenges, both follow three principles: (1) improved animal welfare, (2) a non-GMO end product identical to current commercial chickens, and (3) clear industry economic benefit. The first solution is the GOLDA chicken breed, developed to eliminate manual sorting and male chick culling while integrating into existing hatchery workflows. The system is based on a sex-linked construct integrated into the maternal Z chromosome. When activated, it halts embryonic development selectively in male embryos while allowing normal development of wild-type females. Activation is controlled by an optogenetic switch triggered by blue light illumination through the eggshell prior to incubation. In validation experiments, fertilized eggs from GOLDA hens were illuminated and hatched. More than 1,000 female chicks were produced with no male offspring observed, demonstrating the potential for 100% accuracy in commercial settings. The resulting females matured normally and produced eggs comparable to commercial layers. The second project, Layers Laying Broilers (LLB), addresses the conflict between rapid growth and reproductive efficiency in broiler breeding systems. The concept relies on the separation between germ cells and somatic tissues. In the LLB design, chickens possess a layer-type body (e.g., Leghorn), while their gametes carry non-GMO broiler genetics and produce broiler offspring. To control this system, a genetic model is currently being developed to eliminate endogenous layer PGCs in LLB chickens. This is based on a binary conditional design in which two breeding lines each carry one component of a sterility system. Individually fertile, their cross produces sterile offspring. Early proof-of-concept experiments demonstrate the feasibility of this approach. The LLB strategy aims to establish layer-type breeding flocks, operated under layer management conditions, that produce WT broiler hatching eggs, while addressing key animal welfare challenges in broiler breeders, including feed restriction, and enabling egg production at rates comparable to layer systems. Together, these approaches demonstrate the potential of precision genome engineering to address key structural challenges in poultry production and improving animal welfare and industry sustainability.

Broiler breeders can be selected in free-mating systems. Analysis of performance, egg quality and welfare in three breeds.

Europe is committed to the progressive abolition of cage systems for farm animals. This shift requires adapting the reproductive methods used in broiler breeder selection, which traditionally ensure parentage control by artificially inseminating animals housed in individual cages. Transitioning to floor-based free mating systems would align with societal expectations, yet raises major questions regarding reproductive efficiency, animal welfare and health status. Scientific data on floor reproduction remain scarce, particularly for males and in fast-growing broiler breeders under feed restriction. This study aims to evaluate the feasibility of free reproduction across three broiler breeds with contrasted growth— pHu+ (≈ 61 g/d), D+ (≈ 36 g/d), X33 (≈ 26 g/d) — by evaluating their performance, health and welfare in this system. Two successive batches were reared from 18 to 33-36 weeks of age. Birds were housed on wood shaving in enriched pens (perches, nests, pecking devices) under feed restriction adapted to their breed. Initially separated by sex, birds were mixed during 3 to 6 weeks for a free mating reproduction period. Production traits included laying rate, egg quality (weight, shape index, shell thickness, shell percentage, rigidity, and breaking strength). Between 200 and 250 eggs per group were incubated to assess fertility. Welfare and health indicators comprised growth trajectory, feather condition (3-level score), and footpad dermatitis (5-level score). Statistical analyses used type II ANOVA for continuous traits and cumulative link models for ordinal scores, to assess the effects of breed, batch, age and sex on performance, health and welfare traits. Egg fertility remained consistently high across breeds (D+: 97.8%, pHu+: 95.4%, X33: 91.2%) and batches, demonstrating that floor mating ensure fertility. Laying dynamics and egg quality differed among breeds. pHu+ hens produced rounder eggs with thicker and heavier shells, and greater rigidity and breaking strength ($p<0.001$), along with better stability of shell characteristics over time compared with D+ and X33 breeds. We observed deviations in growth from theoretical cage-based curved suggesting increased energy expenditure under floor conditions, and highlighting the need to adapt feeding strategies when shifting systems. Footpad health was satisfactory, with no severe lesions recorded; however, the fast-growing breed showed greater susceptibility under higher litter moisture conditions. Feather condition declined with age, likely reflecting mating activity rather than severe aggression, which remained limited under adapted light management. Taken together, these findings demonstrate that floor-based reproduction in broiler breeders is feasible without compromising fertility. Nevertheless, genetic background strongly modulated egg quality and sensitivity to environmental conditions, with the fast-growing breed exhibiting better shell quality but greater vulnerability to footpad dermatitis. These results support the need to develop breed-specific nutritional, environmental, and genetic selection strategies for a successful transition to cage-free reproduction that preserves animal health, welfare, reproductive efficiency, and long-term breeding objectives.

Beyond additivity: SNP matrix transformation and deep learning improve genomic prediction of egg performance and quality traits in laying hens

B. E. Osatohanmwen[1,2], S. Hosseini[3], M. Schmutz[4], T. Beissinger[5], A. R. Sharifi[1]
[1] Division of Animal Breeding and Genetics, Department of Animal Sciences, Albrecht-Thaer-Weg 3, 37075 Goettingen, Germany, [2] Division of Plant Breeding methodology, Department of Crop Sciences, Von-Siebold-Straße 8, 37075 Goettingen, Germany, [3] Bavarian State Research Center for Agriculture, Institute of Animal Breeding, Prof.-Duerrwaechter-Platz 1, 85586 Grub-Poing, Germany, [4] Lohmann Breeders GmbH, Am Seedeich 9–11, 27472 Cuxhaven, Germany, [5] Heritable Ag, Mountain View, 94040 California, United States

Accurate genomic prediction depends not only on genetic effects but also on how genomic information is represented and modeled. The genomic best linear unbiased prediction (GBLUP) partitions additive and dominance effects into separate components, assuming independence between them. This limits its ability to capture complex genomic interactions unless they are explicitly modeled. In this study, we applied two SNP matrix transformations: (i) the 2NP matrix, which concatenates the additive-centered (Z) and dominance-deviation (W) matrices into a unified input, and (ii) a locus-specific dominance-transformed matrix. Both approaches were designed to enhance nonlinear learning of genomic effects using tree-based boosting and deep-learning (DL) methods. We evaluated these transformations in combination with convolutional neural networks (CNN2NP, CNN2NPSTR, and CNNTrans) and Light Gradient Boosting Machine (2NPLGBM and LGBMTrans) using data from a commercial laying hen line. The predictive performance of these models was compared with GBLUP models (GBLUP_ADD and GBLUP_ADDOM) and with standard CNN and LightGBM models for the traits egg production, egg weight, shell strength, and color. Heritability ranged from low for egg production (h^2 = 0.06–0.08) to moderate for shell strength (h^2 = 0.125–0.284) and egg weight (h^2 = 0.33–0.45). Dominance variance was generally small for all traits, but reached a maximum of 11.9% for shell strength. For traits with moderate heritability, models with the 2NP matrix achieved the highest performance. CNN2NP had the strongest predictive ability for egg weight, shell strength, and color, surpassing GBLUP by 6–18% for egg weight and 63% for shell strength, while CNN2NPSTR and CNNTrans showed smaller, inconsistent improvement compared to GBLUP. Notably, 2NPLGBM consistently ranked below CNN2NP, suggesting that convolutional architectures are more effective than tree-based boosting methods at exploiting the additive–dominance representation of the 2NP matrix. GBLUP_ADDOM performed similarly to GBLUP_ADD for most traits, indicating limited benefit from modeling dominance. For egg production traits, GBLUP remained superior, while deep learning and boosting models exhibited unstable or near-zero predictive ability. The higher performance of CNN2NP over GBLUP and other models demonstrated that performance increases arise from the interaction between the matrix transformation and the model architecture, rather than from the matrix transformation alone. Interestingly, the limited improvement observed for egg production traits highlights the reduced effectiveness of complex models for low-heritability traits. Overall, the 2NP matrix provides a way to represent additive and dominance genetic effects based on quantitative genetics principles. When combined with convolutional neural networks, it enables the model to capture complex, higher-order interactions across the genome. In this way, the approach extends classical genomic prediction methods such as GBLUP into a nonlinear method while still maintaining interpretability. Thus, the 2NP matrix offers a practical bridge between quantitative genetics and DL methods for predicting the genetic performance of complex traits.

Tailored interferon receptor knockouts in chickens reveal key regulators of disease resilience

M. Alhussien[1], B. Schusser[1], R. Preisinger[2]
[1] Technical University of Munich, Reproductive Biotechnology, Liesel-Beckmann-Strasse 1, 85354 Freising, Germany, [2] EW Group GmbH, Hogenbögen 1, 49429 Visbek, Germany

The global poultry industry faces increasing demands for high-efficiency production alongside the need to improve disease resilience in sustainable and socially responsible systems. However, breeding for health traits remains challenging due to their complexity, low heritability, and the difficulty of obtaining robust phenotypic data under field conditions. A deeper mechanistic understanding of immune pathways is therefore required to support next-generation breeding strategies. Recent advances in CRISPR/Cas genome editing in poultry have demonstrated the feasibility of introducing disease resistance traits, such as resistance to avian leukosis virus, highlighting the potential of targeting key immune pathways. Here, we generated genetically altered chicken models lacking receptors for type I interferons (IFNAR1) or type III interferons (IFNLR1) to investigate the role of interferon signaling in immune regulation and disease outcome. Loss of interferon signaling resulted in defined modulations in immune cell composition, including reduced circulating B cells and monocytes, and shifts in T-cell subsets. These changes were accompanied by impaired adaptive immune responses, characterized by reduced antigen-specific IgM and IgY production and altered dynamics of B- and T-cell responses following immunization. In infection experiments with avian influenza virus, type I and type III interferons exhibited non-redundant roles in host defense. IFNAR1 deficiency led to rapid disease progression, increased viral replication, dysregulated inflammatory responses, and reduced survival. In contrast, IFNLR1 deficiency showed context-dependent effects, including altered tissue-specific responses and reduced pathology in certain compartments, highlighting distinct functional specializations of both pathways. Together, these findings identify interferon signaling as a central regulator of immune system function and disease outcome in chickens. This work provides a mechanistic framework to understand variation in disease resilience, which is essential for the development of next-generation breeding strategies, although translation into practical applications remains a key challenge.

A systematic review of resilience indicator traits in chickens

M. Van Der Sluis[1], L. Büttgen[1], S. Auerbach[2], A. Collin[3], A. Bulamu Ekiri[4], K. Wimmers[5,6], T. Fernandes Farias[1], H. Bergmann[2], E. D. Ellen[1]

[1] Wageningen University & Research, Animal Breeding and Genomics, P.O. Box 338, 6700 AH Wageningen, Netherlands, [2] Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Institute of Epidemiology, Südufer 10, 17493 Greifswald - Riems Island, Germany, [3] Université de Tours, INRAE, BOA, 37380 Nouzilly, France, [4] School of Veterinary Medicine, University of Surrey, Department of Comparative Biomedical Sciences, Daphne Jackson Rd, GU2 7AL Surrey, United Kingdom, [5] Research Institute for Farm Animal Biology (FBN), Genetics and Genomics, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [6] University Rostock, Faculty of Agriculture, Civil and Environmental Engineering, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany

The resilience of an animal is its ability to cope with short-term disturbances, including those caused by pathogens, through response and rapid recovery to its original state. Resilience is of great relevance in – among other things – the context of a changing climate, especially in extensive production systems. To provide an up-to-date overview of the scientific knowledge on chicken resilience, a systematic literature review was conducted, focusing on 1) identifying indicator traits which have been applied in chickens to quantify or rank the birds' resilience, 2) identifying data processing methods which might be broadly applicable for studying resilience in chickens or even other species, and 3) developing hypotheses for the development of (more) practically applicable or precise resilience indicator traits in chickens. The protocol and review were conducted according to PRISMA guidelines, broken down into the common four key components: Population, Exposure, Comparator, and Outcome (PECO), to answer the question "What resilience measures have been identified in chickens?". Using predefined search criteria, including 'chickens' as the population of interest, a stress exposure description, and the term 'resilience', 760 publications were retrieved for initial screening. The screening of titles and abstracts followed a hierarchical screening process and was assisted by the AI-based tool ASReview (not replacing human verification), followed by full text screening and analysis. Following screening, 33 relevant publications on resilience indicator traits used in chickens were identified, out of 96 publications included in the full text screening. The majority of publications were small or medium scale studies and trials, and only two studies used routinely collected big data. Immune (39%) or thermal challenges (42%), especially heat stress, were most prevalent in the assessed studies. Of the studied resilience indicators, most were production- or performance-related parameters and/or immunity or disease-related parameters. Genetics- or gene expression-related indicators were reported in about half of the assessed studies, while reporting on behavioral indicators of resilience – other than feed intake – was limited (12%). Overall, the systematic review provides a comprehensive overview of published resilience indicators in chickens and highlights gaps for future research. Based on the assessed studies, we advise to additionally study stressors other than immune or temperature challenges, such as failures in water supply or handling by humans, which birds might commonly encounter in practice. This review furthermore reveals a need for improved alignment in the use of terms like resilience, robustness, resistance, tolerance or adaptability, and highlights the relevance of assessing the phase of recovery after a short-term disturbance in the context of resilience. This work was co-funded by the European Union's Horizon Europe Project 101136346 EUPAHW.

Genetic parameters for behavioural plasticity and predictability and their relationship with welfare traits in laying hens

G. Vaccari[1], M. B. Petelle[2], P. Willemsem[3], S. G. Gebhardt-Henrich[2], M. J. Toscano[2], P. Duenk[1]
[1] Wageningen University & Research, Animal Breeding and Genomics, Droevendaalsesteeg 1, 6708PB Wageningen, Netherlands, [2] VPH Institute, University of Bern, Center for Proper Housing: Poultry and Rabbits (ZTHZ), Division of Animal Welfare, Burgerweg 22, 3052 Zollikofen, Switzerland, [3] Institut de Selection Animale B.V., Spoorstraat 69, 5831CK Boxmeer, Netherlands

Animal welfare in modern poultry production is a pressing concern. The introduction of group-housed aviary systems now widely adopted in Europe has allowed new social interactions and spaces for animals to explore, yet the genetic basis of behaviour and its genetic correlation to welfare remains poorly understood. A major constraint has been the difficulty of recording individual-level behavioural phenotypes at scale. Advances in automated tracking technologies, such as Radio Frequency Identification (RFID) systems, have now made it possible to generate continuous, high-resolution behavioural profiles for large numbers of individually identified animals, opening new avenues for genetic analysis. This study takes the concepts of plasticity and predictability as novel traits in poultry, measured on a laying hen population from the HenTrack project. Derived from the longitudinal RFID-based movement records of approximately 2,250 laying hens (white and brown genetic lines), these traits capture two distinct dimensions of individual behavioural variation. Firstly, plasticity describes how an animal's behaviour changes over time as it acclimates to a new environment. Secondly, predictability quantifies how consistently an individual behaves around its own daily average. Both traits are well established in wildlife ecology and behavioural biology but have rarely been examined in a livestock genetics context, representing a meaningful conceptual and methodological novelty for the field. In previous studies, consistent inter-individual differences in plasticity and predictability were observed, and we expect a portion of this variation to be genetically based. Furthermore, predictability had a positive phenotypic correlation with keel bone fracture severity, suggesting that more predictable, less flexible animals may be less able to adapt their behaviour to avoid injury, a finding with direct implications for selection strategies aimed at improving welfare. Here, we will estimate heritability and genetic and phenotypic correlations of plasticity, predictability and keel bone fractures, a key welfare problem in laying hens. Genetic parameters will be estimated using univariate and bivariate genomic animal models (REML, ASReml), with additive genetic effects modelled via a genomic relationship matrix (G-matrix) constructed from a 60K SNP panel. To explore the underlying genetic architecture of these traits, genome-wide association studies (GWAS) will be conducted using a linear mixed-model approach on the 60K panel. Analyses will be performed separately within each genetic line, allowing us to assess whether the two lines differ in their genetic basis for behaviour. We expect these traits to show low to moderate heritability, in line with estimates previously reported for related behavioural phenotypes in this dataset and anticipate detecting genetic correlations that illuminate the relationship between behavioural traits and health outcomes. These results will provide the first genetic parameter estimates for plasticity and predictability in poultry, laying the groundwork for their potential inclusion in breeding programmes targeting welfare improvement.

Field-based phenotyping of egg laying and dual-purpose poultry lines in agroforestry systems: Implications for next-generation breeding for regenerative farm resilience

M. Odintsov Vaintrub[1]
[1] *La Perla Verde, Contrada Specola, 64100 Teramo, Italy*

Future poultry breeding strategies for Agroforestry and outdoor production systems should address a wide range of aspects. In addition to production efficiency important parameters such as resilience to environmental variability, climate stress, and welfare expectations are also key aspects. While genetic selection programs have historically focused on performance traits under controlled housing conditions, heritage breeds were highlighted as potential alternatives despite the lack of commercial availability. Due to the increased interest in alternative and pasture-based production systems, an evaluation was required for available poultry lines under more heterogeneous environmental contexts. This study presents a field-based phenotyping framework applied to commercial laying hens (Highlander) and dual-purpose lines (GAINA & EUREKA) managed within a rotational pastured poultry system integrated into an agroforestry setting in central Italy. The trial evaluated the adaptability and performance in mobile coops with outdoor pasture access. Each flock consisted of approximately 30 hens and one rooster, managed within electric-net enclosures across a mulberry orchard used as a multifunctional grazing environment. Data collection focused on production and resilience indicators relevant to next-generation breeding goals. Parameters included egg production (quantity and quality), feed intake, labour requirements, behavioural adaptation to pasture, and mortality events under seasonal climatic variation. Additional observations included the adaptability of each line to a short chain economic model typical to small scale agroforestry farms. Observations report limited variability in egg quantity per line with 75 – 82% of egg lying per day across all three. However, substantial variability occurred in the GAINA line, with significant variability in egg size and shell quality. Feed consumption was similar for GAINA and Highlander lines, but was 20% higher in EUREKA. The Highlander line registered higher exploratory behaviour and pasture utilization, while others showed reduced environmental engagement. Accordingly, yolk colour density (measured on 1-15 scale) and indicator for metabolic capacity for beta carotene absorption from grass was higher in Highlander (13 vs 11 in the other two). This line also required 30% more workload due to escape events. Overall mortality was minimal, with only two cases registered in GAINA line, with pathological analysis reporting egg retention and cloaca prophylaxis as causes. After completing the growth cycle, dual use lines registered above 3 kg avg weight, with EUREKA hens roughly 300g heavier, Highlander growth was economically insignificant (1.3 avg weight). However, the added value in dual purpose lines became insignificant in comparison to the increased feeding costs across the production cycle. The results underline the importance of expanding phenotyping environments beyond controlled housing conditions to support breeding strategies aligned with diversified poultry production systems. Identification of genetic traits supports the development of next-generation poultry lines suited to evolving production landscapes and regenerative farming systems.

Effects of in ovo stimulation with bioactive substances on epigenetic modifications in broiler chickens

A. Bełdowska[1], M. Barszcz[2], A. Dunisławska[1]
[1] Bydgoszcz University of Science and Technology, Department of Animal Biotechnology and Genetics, Mazowiecka 28, 85-084 Bydgoszcz, Poland, [2] The Kielanowski Institute of Animal Physiology and Nutrition, Polish Academy of Sciences, Department of Animal Nutrition, Instytucka 3, 05-110 Jabłonna, Poland

Early life nutritional and microbial stimulation may induce long term epigenetic effects in poultry. In ovo administration of bioactive substances represents a strategy to modulate intestinal development before hatching. Sodium butyrate (SB), a short-chain fatty acid (SCFA) naturally produced by intestinal microbiota, serves as an energy source for enterocytes and functions as an epigenetic regulator, partly through inhibition of histone deacetylases. Galactooligosaccharides (GOS), a prebiotic that selectively stimulates the growth and activity of intestinal bacteria, along with SB, are both important modulators of intestinal physiology. Due to the close interaction between the gastrointestinal tract and peripheral organs via the gut–liver axis, early exposure to this bioactive substances may influence epigenetic programming in many tissue. The liver plays a central role in metabolic regulation, immune homeostasis and remains in constant functional interaction with the gastrointestinal tract through the gut–liver axis. The aim of the study was to evaluate the effect of in ovo administration of bioactive substances on global DNA methylation levels and histone deacetylase in liver, cecal mucosa and ileum mucosa of broiler chickens. Fertilized eggs of Ross 308 broilers were injected on 12 day of incubation. Four experimental groups were established: non injected control, saline injected control (NaCl), injected by GOS and injected by SB. After hatching, birds were reared under standard production conditions until day 42. All samples were collected postmortem. Global DNA methylation was quantified in the same tissues in which histone deacetylase (HDAC) activity was determined, namely the cecal mucosa, ileal mucosa, and liver. Global DNA methylation levels were expressed as the percentage of 5-methylcytosine (5-mC) in total DNA. HDAC activity was expressed as units per gram of tissue (U/g). The obtained results demonstrated that in ovo stimulation influenced global DNA methylation in a tissue dependent manner. In the liver, a significant decrease in global methylation was observed in the GOS group compared to the NaCl group. In the SB group, methylation levels were slightly reduced compared to NaCl, although the difference was not statistically significant. In the cecum, no significant differences were detected, however, a downward trend in global methylation was noted in both the NaCl and SB groups relative to the non-injected control. In the ileum, global DNA methylation remained relatively stable in all experimental groups. No significant differences in HDAC activity were observed in the liver or ileal mucosa among the experimental groups. In contrast, HDAC activity in the cecal mucosa differed significantly between groups, with the highest value recorded in the sodium butyrate group compared to the control. These results support the hypothesis that bioactive substances applied during embryonic development may influence a long-term epigenetic effects in broiler chickens. The study was financed by grant UMO-2021/43/D/NZ9/01548 financed by the National Science Center in Cracow (Poland). Mobility financially supported by the Minister of Science under the program ”Regional Initiative of Excellence” (RID/SP/0017/2024/01).

Prenatal motor activity in layer embryos: first evidence of sex-linked differences and exploration of strain effects

R. Garant[1], B. Tobalske[2], N. Van Staaveren[1], D. Powers[3], T. Widowski[1], B. Willie[4,5], A. Harlander[1]
[1] University of Guelph, Department of Animal Biosciences, 50 Stone Rd E, N1G 2W1 Guelph, Canada, [2] University of Montana, Division of Biological and Biomedical Sciences, 32 Campus Dr, MT 59812 Missoula, United States, [3] George Fox University, Department of Biological and Molecular Sciences, 414 N Meridian St, OR 97132 Newberg, United States, [4] Utah State University, College of Veterinary Medicine, Old Main Hill, UT 84322 Logan, United States, [5] Shriners Hospital for Children Canada, Research Centre, 1003 Bd Décarie, H4A 0A9 Montréal, Canada

In wild birds, species differ in embryonic movement patterns. For example, brood-parasitic cuckoos exhibit substantially higher embryonic movement than their hosts, a pattern interpreted as pre-hatch "exercise" that strengthens chicks for high-force, early post-hatch tasks such as ejecting host eggs. Because embryonic movement contributes to musculoskeletal development in wild precocial species, it seems plausible that physiological priming of motor and muscle properties prior to hatch may also occur in domestic chickens. We hypothesize that genetic background including sex may influence embryonic movement in domestic strains, particularly given the distinct origins of white-feathered (White Leghorn ancestry) and brown-feathered (Rhode Island Red ancestry) commercial lines. To test this, 408 eggs (200 white-feathered strain, and 208 brown-feathered strain) were placed into a NatureForm I-series incubator (99.5°F and 55% humidity) with an automatic egg turning mechanism (rotating every 60 minutes). On embryonic day 17, eggs were removed from the incubator (1 tray at a time, 30 eggs/tray), placed onto a heated blanket (99-100°F), and covered with a 63L storage container (59.44 x 48.77 x 34.04 cm). Each egg was removed from the egg tray and individually placed into the chamber of a validated Egg Buddy digital egg monitor (Avitronics, UK); a noninvasive device whose sensors detect changes in reflected light caused by internal movement. A GoPro camera positioned 20 cm above the monitor recorded the device's display in real time. The display was recorded for 120 seconds/egg: 60 seconds for chamber habituation, and 60 seconds for movement recording. Videos were later visually scored to determine embryonic movement rate (movements/minute). A total of 330 eggs hatched into 172 females (92 brown, 80 white) and 158 males (73 brown, 85 white). Effects of sex and strain on embryonic movement rate (EMR) were analyzed using a generalized linear mixed model in SAS, including their interaction as a fixed effect. Overall EMR did not differ significantly between white and brown strains ($p=0.3178$), However, males showed higher EMR than females ($p=0.039$), driven by a strain by sex-specific effect: brown males moved more than brown females ($p=0.0316$) , whereas no sex difference was detected within the white strain, despite white males having the highest numerical EMR (107.60 ± 3.48). To our knowledge, these results provide the first documentation of sex-specific EMR in domestic, brown-feathered chickens. The absence of a main effect of strain on EMR at day 17 suggests that baseline prenatal motor activity may be relatively conserved across these two commercial white- and brown-feathered lines at this stage, despite their distinct founder ancestries. One interpretation is that strain-differences in motor phenotypes either emerge earlier or later in incubation or manifests more clearly after hatch under differing motivational and environmental contexts. Ongoing analyses at earlier incubation days and post-hatch behaviour will address these questions (and will be presented at the conference).

Temporal dynamics and sex-specific transcriptomic remodeling of chicken primordial germ cells in extended in vitro culture

S. Altgilbers[1], G. Neufeld[1], C. Klein[1]
[1] Friedrich-Loeffler-Institut, Institut für Nutztiergenetik (ING), Biotechnology, Höltystr. 10, 31535 Neustadt am Rübenberge, Germany

Primordial germ cells (PGCs) are vital for the introduction of genetic modification into the chicken genome and the ex situ conservation of male and female avian biodiversity. While in vitro culture is necessary for these applications, the impact of prolonged cultivation on the PGC transcriptome, particularly regarding sex-specific differences and molecular integrity, remains poorly understood. In this study, we performed single-cell RNA sequencing (10x Genomics) on gonadal PGCs derived from Lohmann LSL-classic embryos (ED 6.5). To evaluate the effects of culture, cells were analyzed at three time points: 3 days (short-term), 4 weeks (mid-term), and 7 weeks (long-term). Using a feeder-free and serum-free culture system, we analyzed 43 biological replicates (19 female, 24 male). This experimental mixture of genotypes was deconvoluted using genetic variants detection by Souporcell (v2.5). Our analysis revealed significant transcriptional shifts over time. The 4-week culture period exhibited the highest overall gene diversity, with a notably high proportion of long non-coding RNAs (~42%). In contrast, the 7-week group showed a marked reduction in total expressed genes, suggesting a 'transcriptional narrowing' during long-term maintenance. Across all time points, PGCs maintained the expression of core pluripotency-associated factors (NANOG, POU5f3, SOX3, SALL4) and canonical germline marker genes (DAZL, DND1, SMC1B, ELAVL4, DDX4). Additionally, we identified a shift in the number of differentially expressed genes (DEGs) between sexes as cultivation progressed, with the most pronounced differences appearing at 4 weeks. While PGCs remain phenotypically stable, our findings reveal significant time-dependent and sex-specific transcriptomic remodeling; identifying these functional roles and the underlying heterogeneity in in vitro cultures is a critical step toward optimizing in vitro conditions for enhanced germline transmission and the preservation of avian genetic resources via PGCs.

Quantitative genetic analysis of growth, carcass and meat traits in Sundheimer chickens

D. Kohnke[1], M. Schmid[4,5], J. Bennewitz[2], M. G. G. Chagunda[3]
[1] University of Hohenheim, Institute for Tropical Agricultural Sciences, Garbenstr. 17, 70599 Stuttgart, Germany, [2] University of Hohenheim, Institute of Animal Science, Garbenstr. 17, 70599 Stuttgart, Germany, [3] University of Edinburgh, The Roslin Institute, EH25, 9RG Ediburgh, United Kingdom, [4] Research Institute for Farm Animal Biology (FBN), Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany, [5] University of Rostock, Faculty of Agricultural, Civil and Environmental Engineering, Justus-von-Liebig-Weg 6b, 18059 Rostock, Germany

The Sundheimer chicken is an endangered, purebred dual-purpose breed from Germany. Genetic improvement of performance traits may encourage wider use of this breed and is therefore seen to reduce its endangered status. Within the dual-purpose concept, focus is on laying traits of hens and on growth, carcass and meat traits of roosters; this ongoing study initially addresses the latter. The study aimed at estimating variance components to get a first impression on the heritable variation for these traits in the Sundheimer breed. To establish a founder population, hatching eggs were collected from 19 breeders. Using these animals, matings were subsequently carried out, based on individual performance and pedigree to avoid inbreeding. The rearing phase was carried out with mixed sexes in mobile houses until sex determination at day 64/65. Thereafter, in the years 2021–2023, the growth performance test was conducted in small groups in a fixed house until slaughter at day 119, and in 2024 in a large group in a mobile house with access to pasture until day 122. Roosters were fed organic feed throughout. Body weight (BW) was recorded at four time points: BW1 (day 24/30), BW2 (day 63–65), BW3 (day 105/107) and BW4 (day 118/121. Average daily gain (ADG) for the rearing (based on BW1 and BW2) and fattening period (based on BW2 and BW4) were derived as measures of growth performance. Carcass weight (24 h pm, CW), dressing percentage (DP), and breast (BP), leg (LP) and wing (WP) proportions were recorded. Phenotypic and genotypic data were available for 418 roosters for growth traits and 258 for carcass traits. Genotyping used the Illumina Chicken 50K BeadChip; after quality control, 37,731 SNPs remained. Raw data were Box–Cox transformed and Z-standardized prior to variance component analysis by means of mixed linear animal models. The test-year–housing-group effect was included as a fixed effect after evaluation by Wald test. The variance and covariance structure of the animal effect was modelled using a genomic relationship matrix. Descriptive analyses of growth traits yielded mean values (± SD) of BW1 293 g (±78), BW2 1,127 g (±160), BW3 2,014 g (±260) and BW4 2,296 g (±290), and ADG in the rearing and fattening phase of 23.0 g (±3.6) and 21.2 g (±4.2). Mean CW was 1,311 g (±221) and DP 58.1% (±2.4). Mean cut proportions were 17.1% (±1.2) for BP, 36.5% (±1.3) for LP and 13.7% (±1.1) for WP. All heritability estimates were significant ($p < 0.001$) and ranged from medium to high values for growth traits, with h^2 (SE) of 0.39 (0.10) for BW1, 0.56 (0.09) for BW2, 0.46 (0.09) for BW3, 0.46 (0.09) for BW4, 0.59 (0.09) for ADG during rearing and 0.41 (0.09), 0.65 (0.13) for CW and 0.41 (0.15) for DP. Heritabilities were comparably lower for BP 0.32 (0.17), LP 0.23 (0.15) and WP 0.34 (0.16). The medium to high heritabilities of the growth traits indicate a potential to breed for these traits, however, given the population makeup and limited sample size the results must be taken with caution. Larger sample sizes and a broader range of testing environments are required to draw inferences regarding genetic gain. In addition, to maintain the dual-purpose type, the genetic correlation between growth traits in roosters and laying traits in hens must be considered.

Genotype and housing systems influence Eimeria prevalence in FUNAAB Alpha and indigenous Nigerian chickens under natural infection conditions

E. Odah[1], W. Mathew[2], T. Micheal[4], I. B.m[3]
[1] Federal Univeritsy Wukari, 1,2Department of Animal Science, Along Katsina-Ala Road, Wukari, P.M.B. 1020 Wukari, Nigeria, [2] Federal University of Agriculture, Abeokuta, Animal Breeding and Genetics, Alabata Road, Abeokuta, Ogun State, P.M.B 111101 Abeokuta, Nigeria, [3] Federal University of Agriculture, Abeokuta, Animal Breeding and Genetics, Alabata Road, Abeokuta, Ogun State, P.M.B 111101 Abeokuta, Nigeria, [4] Federal University of Agriculture, Abeokuta, Veterinary Microbiology and Parasitology, Alabata Road, Abeokuta, Ogun State, P.M.B 111101 Abeokuta, Nigeria

Coccidiosis, caused by protozoan parasites of the genus Eimeria, remains one of the most economically important diseases affecting poultry production worldwide. In Nigeria, both indigenous and improved chicken populations contribute substantially to food security, yet information on how host genetics and management systems influence Eimeria infection dynamics under natural conditions remains limited. The recently developed FUNAAB Alpha chicken was selected for improved productivity and adaptation to tropical environments, but its susceptibility to parasitic infections relative to indigenous chickens has not been evaluated. This study, therefore, investigated the prevalence and species composition of Eimeria infections in FUNAAB Alpha and Nigerian indigenous chickens and assessed the effects of genotype, sex, and housing system on infection patterns under natural exposure conditions. A total of 600 chickens were examined, comprising 300 FUNAAB Alpha and 300 indigenous Nigerian chickens representing three genotypes (normal feather, naked neck, and frizzle feather). Birds were maintained under two housing systems (deep litter and battery cage). Faecal samples were collected over a 20-week period and analysed using flotation and McMaster counting techniques to detect and quantify Eimeria oocysts. Species identification was performed using morphological measurements and shape indices under light microscopy. Oocyst count data were $\log_{10}$-transformed and analysed using generalized linear models (GENMOD procedure, SAS 9.2) to evaluate the effects of genotype, sex, housing system, and their interactions on parasite prevalence. Overall, 47.0% of sampled birds were positive for Eimeria oocysts, indicating substantial infection pressure in the study population. Indigenous chickens exhibited significantly higher prevalence (55.7%) compared with FUNAAB Alpha chickens (38.3%), suggesting population-level differences in susceptibility or exposure. Six Eimeria species were detected across populations. Eimeria tenella was the predominant species in both chicken groups, while species distribution differed between populations. Eimeria necatrix occurred more frequently in FUNAAB Alpha chickens, whereas Eimeria brunetti was detected exclusively in indigenous chickens. Prevalence of E. acervulina and E. maxima did not differ significantly between populations. Host genotype and management factors influenced infection patterns differently across populations. In indigenous chickens, oocyst prevalence did not differ significantly among genotypes, sexes, or housing systems, although slightly higher values were observed in females, frizzle-feathered birds, and deep-litter systems. In contrast, FUNAAB Alpha chickens showed significant genotype and housing effects. Birds reared under deep-litter management had substantially higher infection prevalence than cage-reared birds, and frizzle-feathered chickens showed the highest susceptibility among the three genotypes. No significant sex effects were detected. These findings demonstrate that both genetic background and management conditions shape Eimeria infection dynamics in Nigerian chicken populations.
